Angiokeratoma Corporis Diffusum (Fabry Disease)

See Chapter 86.4.

An inborn error of glycolipid metabolism (α-galactosidase), angiokeratoma corporis diffusum is an X-linked recessive disorder that is fully penetrant in males and is of variable penetrance in carrier females. Angiokeratomas appear before puberty and occur in profusion over the genitalia, hips, buttocks, and thighs and in the umbilical and inguinal regions. They consist of 0.1-3.0 mm red to blue-black papules that may have a hyperkeratotic surface. Telangiectasias are seen in the mucosa and conjunctiva. On light microscopy, these angiokeratomas appear as blood-filled, dilated, endothelium-lined vascular spaces. Granular lipid deposits are demonstrable in dermal macrophages, fibrocytes, and endothelial cells.

Additional clinical manifestations include recurrent episodes of fever and agonizing pain, cyanosis and flushing of the acral limb areas, paresthesias of the hands and feet, corneal opacities detectable on slit-lamp examination, and hypohidrosis. Renal involvement and cardiac involvement are the usual causes of death. The biochemical defect is a deficiency of the lysosomal enzyme α-galactosidase, with accumulation of ceramide trihexoside in tissues, particularly vascular endothelium, and excretion in urine (see Chapter 86.4 for therapy). Similar cutaneous lesions have also been described in another lysosomal enzyme disorder, α-L-fucosidase deficiency, and in sialidosis, a storage disease with neuraminidase deficiency.

Chapter 651

Cutaneous Nevi

Kari L. Martin

Nevus skin lesions are characterized histopathologically by collections of well-differentiated cell types normally found in the skin. Vascular nevi are described in Chapter 650. Melanocytic nevi are subdivided into 2 broad categories: those that appear after birth (acquired nevi) and those that are present at birth (congenital nevi).

ACQUIRED MELANOCYTIC NEVUS

Melanocytic nevus is a benign cluster of melanocytic nevus cells that arises as a result of alteration and proliferation of melanocytes at the epidermal–dermal junction.

Epidemiology

The number of acquired melanocytic nevi increases gradually during childhood and more slowly in early adulthood. The number reaches a plateau in the 3rd or 4th decade and then slowly decreases thereafter. The mean number of melanocytic nevi in an adult varies depending on genetics, skin color, and sun exposure. The greater the number of nevi present, the greater is the risk for development of **melanoma,** though the majority of melanomas arise de novo. Sun exposure during childhood, particularly intermittent, intense exposure of an individual with light skin, and a propensity to burn and freckle rather than tan are important determinants of the number of melanocytic nevi that develop. Red-haired children, despite their light skin and propensity to freckle and sunburn, have fewer nevi than other children. Increased numbers of nevi are also associated with immunosuppression and administration of chemotherapy.

Clinical Manifestations

Nevocellular nevi have a well-defined life history and are classified as **junctional, compound,** or **dermal** in accordance with the location of the nevus cells in the skin. In childhood, >90% of nevi are junctional; melanocyte proliferation occurs at the junction of the epidermis and dermis to form nests of cells. Junctional nevi appear anywhere on the body in various shades of brown; they are relatively small, discrete, flat, and variable in shape. The melanized nevus cells are cuboidal or epithelioid in configuration and occur in nests on the epidermal side of the basement membrane. Although some nevi, particularly those on the palms, soles, and genitalia, remain junctional throughout life, most become compound as melanocytes migrate into the papillary dermis to form nests at both the epidermal–dermal junction and within the dermis. If the junctional melanocytes stop proliferating, nests of melanocytes remain only within the dermis, forming an intradermal nevus. With maturation, compound and intradermal nevi may become raised, dome-shaped, verrucous, or pedunculated. Slightly elevated lesions are usually compound. Distinctly elevated lesions are usually intradermal. With age, the dermal melanocytic nests regress and the nevi gradually disappear.

Prognosis and Treatment

Acquired pigmented nevi are benign, but a very small percentage undergo malignant transformation. Suspicious changes are indications for excision and histopathologic evaluation; they include rapid increase in size; development of satellite lesions; variegation of color, particularly with shades of red, brown, gray, black, and blue; pigmentary incontinence; notching or irregularity of the borders; changes in texture such as scaling, erosion, ulceration, and induration; and regional lymphadenopathy. Most of these changes are from irritation, infection, or maturation; darkening and gradual increase in size and elevation normally occur during adolescence and should not be cause for concern. Two common benign changes are clonal nevi (fried-egg moles) and eclipse nevi. A clonal nevus is light brown with a dark raised center representing a clonal change of a subset of nevus cells within the lesion. Eclipse nevi are flat and light brown with dark brown rims. They are seen primarily in the scalp (Fig. 651-1). Consideration should be given to the presence of risk factors for development of melanoma and the patient's parents' wishes about removal of the nevus. If doubt remains about the benign nature of a nevus, excision is a safe and simple outpatient procedure that may be justified to allay anxiety.

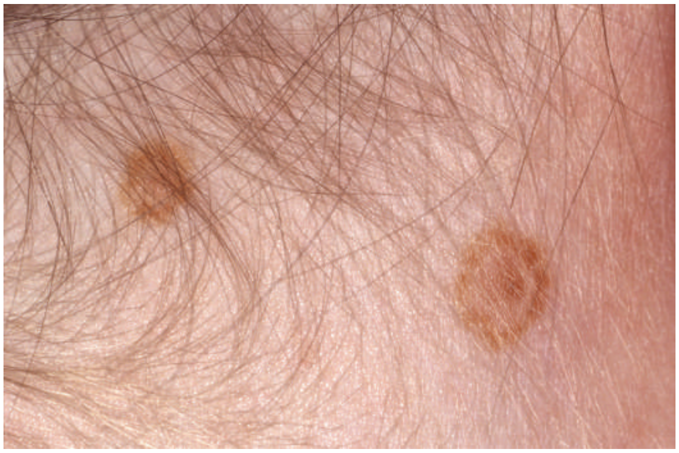

Figure 651-1 Eclipse nevi (rim moles) in the scalp.

ATYPICAL MELANOCYTIC NEVUS

Atypical melanocytic nevi occur both in an **autosomal dominant familial melanoma-prone** setting (familial mole–melanoma syndrome, dysplastic nevus syndrome, BK mole syndrome) and as a sporadic event. Only 2% of all pediatric melanomas occur in individuals with this familial syndrome; melanoma develops before age 20 yr in 10% of individuals with the syndrome. Malignant melanoma has been reported in children with the dysplastic nevus syndrome as young as 10 yr. Risk for development of melanoma is essentially 100% in individuals with dysplastic nevus syndrome who have 2 family members who have had melanomas. The term *atypical mole syndrome* describes lesions in those individuals without an autosomal dominant familial history of melanoma but with more than 50 nevi, some of which are atypical. The lifetime risk of melanoma associated with dysplastic nevi in this context is estimated to be 5-10%.

Atypical nevi tend to be large (5-15 mm) and round to oval. They have irregular margins and variegated color, and portions of them are elevated. These nevi are most common on the posterior trunk, suggesting that intermittent, intense sun exposure has a role in their genesis. They may also occur in sun-protected areas such as the breasts, buttocks, and scalp. Atypical nevi do not usually develop until puberty, although scalp lesions may be present earlier. Atypical nevi demonstrate disordered proliferation of atypical intraepidermal melanocytes, lymphocytic infiltration, fibroplasia, and angiogenesis. It may be helpful to obtain histopathologic documentation of dysplastic change by biopsy to identify these individuals. It is prudent to excise borderline atypical nevi in immunocompromised children or in those treated with irradiation or chemotherapeutic agents. Although chemotherapy is associated with the development of a greater number of melanocytic nevi, it has not been directly linked to increased risk for development of melanoma. The threshold for removal of clinically atypical nevi is also lower at sites that are difficult to observe, such as the scalp. Children with atypical nevi should undergo a complete skin examination every 6-12 mo. In these children, photographic mole mapping serves as a useful adjunct in following nevus change. Parents must be counseled about the importance of sun protection and avoidance and should be instructed to look for early signs of melanoma on a regular basis, approximately every 3-4 mo.

CONGENITAL MELANOCYTIC NEVUS

Congenital melanocytic nevi are present in ≈1% of newborn infants. These nevi have been categorized by size: giant congenital nevi are >20 cm in diameter (adult size) or >5% of the body surface; small congenital nevi are <1.5 cm in diameter, and intermediate nevi are in between these dimensions. Congenital nevi are characterized by the presence of nevus cells in the lower reticular dermis; between collagen bundles; surrounding cutaneous appendages, nerves, and vessels in the lower dermis; and occasionally extending to the subcuticular fat. They often harbor *NRAS* mutations, but not *BRAF* mutations typically seen in regular melanocytic nevi. Identification is often uncertain, however, because they may have the histologic features of ordinary junctional, compound, or intradermal nevi. Some nevi that were not present at birth display histopathologic features of congenital nevi; these should not be considered congenital. Furthermore, congenital nevi may be difficult to distinguish clinically from other types of pigmented lesions, adding to the difficulty that parents may have in identifying nevi that were present at birth. The clinical differential diagnosis includes dermal melanocytosis, café-au-lait macules, and smooth muscle hamartoma.

Sites of predilection for small congenital nevi are the lower trunk, upper back, shoulders, chest, and proximal limbs. The lesions may be flat, elevated, verrucous, or nodular and may be various shades of brown, blue, or black. Given the difficulty in identifying small congenital nevi with certainty, data regarding their malignant potential are controversial and likely overstated. The true incidence of melanoma in congenital nevi, especially small and medium-sized lesions, is unknown. Removal of all small congenital nevi is not warranted because the development of melanoma in a small congenital nevus is an exceedingly rare event before puberty. A number of factors must be weighed in the decision about whether or not to remove a nevus, including its location, the ability to monitor it clinically, the potential for scarring, the presence of other risk factors for melanoma, and the presence of atypical clinical features.

Giant congenital pigmented nevi (<1 in 20,000 births) occur most commonly on the posterior trunk (Fig. 651-2) but may also appear on the head or extremities. These nevi are of special significance because of their association with leptomeningeal melanocytosis (neurocutaneous melanocytosis) and their predisposition for development of malignant melanoma. Leptomeningeal involvement occurs most often when the nevus is located on the head or midline on the trunk, particularly when associated with multiple "satellite" melanocytic nevi (>20 lesions). Nevus cells within the leptomeninges and brain parenchyma may cause increased intracranial pressure, hydrocephalus, seizures, intellectual disability, and motor deficits and may result in melanoma. Malignancy can be identified by careful cytologic examination of the cerebrospinal fluid for melanin-containing cells. MRI demonstrates asymptomatic leptomeningeal melanosis in ≈30% of individuals with giant congenital nevus of the type described above. The overall incidence of malignant melanoma arising in a giant congenital nevus has been estimated to be ≈5-10% but is more likely to be approximately 1-2%. The median age at diagnosis of the melanomas that arise within a giant congenital nevus is 7 yr. The mortality rate approaches 100%. The risk of melanoma is greater in patients in whom the predicted adult size of the nevus is >40 cm, lesions on trunk, and presence of satellite lesions. Management of giant congenital nevi remains controversial and should involve the parents, pediatrician, dermatologist, and plastic surgeon. If the nevus lies over the head or spine, MRI may allow detection of **neural melanosis,** the presence of which makes gross removal of a nevus from the skin a futile effort. In the absence of neural melanosis, early excision and repair aided by tissue expanders or grafting may reduce the burden of nevus cells and thus the potential for development of melanoma, but at the cost of many potentially disfiguring operations. Nevus cells deep within subcutaneous tissues may evade excision. Random biopsies of the nevus are not helpful, but biopsy of newly expanding nodules is indicated. Follow-up every 6 mo for 5 yr and every 12 mo thereafter is recommended. Serial photographs of the nevus may aid in detecting changes.

Figure 651-2 "Bathing suit" large congenital melanocytic nevus.

MELANOMA

Malignant melanoma accounts for 1-3% of all pediatric malignancies, and approximately 2% of all melanomas occur before age 20 yr. The incidence of melanoma continues to increase. Melanoma is 7 times more frequent in the 2nd decade of life than in the 1st decade of life. Melanoma develops primarily in white individuals, on the head and trunk in males, and on the extremities in females. Risk factors for development of melanoma include the presence of the familial atypical mole–melanoma syndrome or xeroderma pigmentosum; an increased number of acquired melanocytic nevi, or atypical nevi; fair complexion; excessive sun exposure, especially intermittent exposure to intense sunlight; a personal or family (1st-degree relative) history of a previous melanoma, giant congenital nevus, and immunosuppression. In previously well children, UV radiation is responsible for most melanomas. Fewer than 5% of childhood melanomas develop within giant congenital nevi or in individuals with the familial atypical mole–melanoma syndrome. Approximately 40-50% of the time, melanoma develops at a site where there was no apparent nevus. The mortality rate from melanoma is related primarily to tumor thickness and the level of invasion into the skin. The overall mortality rate reaches ≈40%, regardless of whether the tumor arises in a child or adult.

Given the lack of effective therapy for melanoma, prevention and early detection are the most effective measures. Emphasis should be given to avoidance of intense midday sun exposure between 10 AM and 3 PM; wearing of protective clothing such as a hat, long sleeves, and pants; and use of sunscreen. Early detection includes frequent clinical and photographic examinations of patients at risk (dysplastic nevus syndrome) and prompt response to rapid changes in nevi (size, shape, color, inflammation, bleeding or crusting, and sensation). The **ABCD rule** (asymmetry, border irregularities, color variability, diameter >6 mm), which is a useful screening tool for adults, may not be as effective for children.

HALO NEVUS

Halo nevi occur primarily in children and young adults, most commonly on the back (Fig. 651-3). Development of the lesion may coincide with puberty or pregnancy. Several pigmented nevi frequently develop halos simultaneously. Subsequent disappearance of the central nevus over several months is the usual outcome, and the depigmented area usually repigments. Excision and histopathologic examination of the lesion is indicated only when the nature of the central lesion is in question. An acquired melanocytic nevus occasionally develops a peripheral zone of depigmentation over a period of days to weeks. There is a dense inflammatory infiltrate of lymphocytes and histiocytes in addition to the nevus cells. The pale halo reflects disappearance of the melanocytes. This phenomenon is associated with congenital nevi,

Figure 651-3 Well-developed halo nevus.

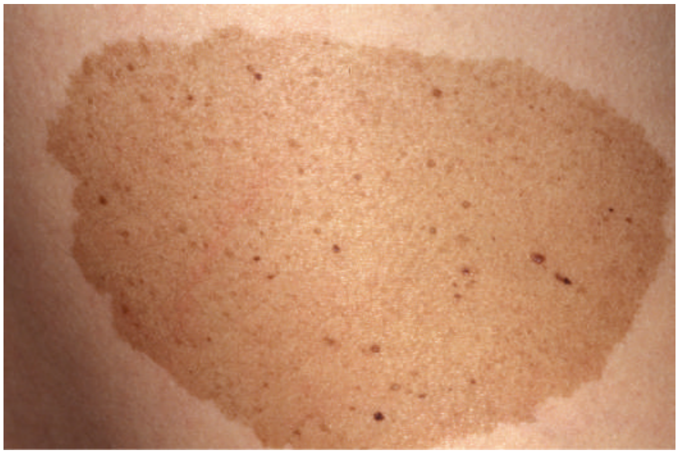

Figure 651-5 Nevus spilus.

Figure 651-4 Dome-shaped red Spitz nevus.

blue nevi, Spitz nevi, dysplastic nevi, neurofibromas, and primary and secondary malignant melanoma, and occasionally with poliosis, Vogt-Koyanagi-Harada syndrome, and pernicious anemia. Patients with vitiligo have an increased incidence of halo nevi. Individuals with halo nevi have circulating antibodies against the cytoplasm of melanocytes and nevus cells.

SPITZ NEVUS (SPINDLE AND EPITHELIOID CELL NEVUS)

Spitz nevus manifests most commonly in the 1st 2 decades of life as a pink to red, smooth, dome-shaped, firm, hairless papule on the face, shoulder, or upper limb (Fig. 651-4). Most are <1 cm in diameter, but they can achieve a size of 3 cm. Rarely, they occur as numerous grouped lesions. Visually similar lesions include pyogenic granuloma, hemangioma, nevocellular nevus, juvenile xanthogranuloma, and basal cell carcinoma, but these entities are histologically distinguishable. Spitz nevus may be difficult to distinguish histopathologically from malignant melanoma because nuclear atypia is a common feature, particularly after local recurrence of the nevus. Difficulty arises in the fact that many other clinical types of melanocytic nevi have a similar histologic appearance. Local recurrence after excision may occur up to 5% of the time. If a nevus arouses clinical suspicion that it may be a melanoma, an excisional biopsy of the entire lesion is recommended. If the margins of excision of a Spitz nevus are positive, reexcision of the site is prudent to avoid difficulties in histopathologic interpretation of the lesion in the future.

ZOSTERIFORM LENTIGINOUS NEVUS (AGMINATED LENTIGINES)

Zosteriform lentiginous nevus is a unilateral, linear, band-like collection of numerous 2-10 mm brown or black macules on the face, trunk, or limbs. The nevus may be present at birth or may develop during childhood. There are higher numbers of melanocytes in elongated rete ridges of the epidermis.

NEVUS SPILUS (SPECKLED LENTIGINOUS NEVUS)

Nevus spilus is a flat brown patch within which are darker flat or raised brown melanocytic elements (Fig. 651-5). It varies considerably in size and can occur anywhere on the body. The color of the macular component may vary from light to dark brown, and the number of darker lesions may be low or high. Nevus spilus is rare at birth and is commonly acquired in late infancy or early childhood. Dark elements within the nevus are usually present initially and tend to increase in number gradually over time. The darker macules represent nevus cells in a junctional or dermal location; the patch has increased numbers of melanocytes in a lentiginous epidermal pattern. The malignant potential of these nevi is uncertain; nevus spilus is found more commonly in individuals with melanoma than in matched control subjects. The nevi need not be excised, unless atypical features or recent clinical changes are noted.

NEVUS OF OTA AND NEVUS OF ITO

Nevus of Ota is more common among females and Asian, and African-American patients. This nevus consists of a permanent patch composed of partially confluent blue, black, and brown macules. Enlargement and darkening may occur with time. Occasionally, some areas of the nevus are raised. The macular nevi resemble the more common dermal melanocytosis of the lower back and buttocks in color and occur unilaterally in the areas supplied by the 1st and 2nd divisions of the trigeminal nerve. Nevus of Ota differs from a more common dermal melanocytosis patch, not only by its distribution but also by having a speckled rather than a uniform appearance. Both are forms of mid-dermal melanocytosis. Nevus of Ota also has a greater concentration of elongated, dendritic dermal melanocytes located in the upper rather than the lower portion of the dermis. This nevus is sometimes present at birth; in other cases, it may arise during the 1st or 2nd decade of life. Patchy involvement of the conjunctiva, hard palate, pharynx, nasal mucosa, buccal mucosa, or tympanic membrane occurs in some patients. Malignant change is exceedingly rare. Laser therapy may effectively decrease the pigmentation but can be unpredictable.

Nevus of Ito is localized to the supraclavicular, scapular, and deltoid regions. This nevus tends to be more diffuse in its distribution and less mottled than nevus of Ota. It is also a form of mid-dermal

melanocytosis. The only available treatments are masking with cosmetics and laser therapy.

BLUE NEVI

The common blue nevus is a solitary, asymptomatic, smooth, dome-shaped, blue to blue-gray papule <10 mm in diameter on the dorsal aspect of the hands and feet. Rarely, common blue nevi form large plaques. Blue nevus is nearly always acquired, often during childhood and more commonly in females. Microscopically, it is characterized by groups of intensely pigmented spindle-shaped melanocytes in the dermis. This nevus is benign.

The cellular blue nevus is typically 1-3 cm in diameter and occurs most frequently on the buttocks and in the sacrococcygeal area. In addition to collections of deeply pigmented dermal dendritic melanocytes, cellular islands composed of large spindle-shaped cells are noted in the dermis and may extend into the subcutaneous fat. A histologic continuum may be seen from blue nevi to cellular blue nevi. A combined nevus is the association of a blue nevus with an overlying melanocytic nevus.

The blue-gray that is characteristic of these nevi is an optical effect caused by dermal melanin. Longer wavelengths of visible light penetrate to the deep dermis and are absorbed there by melanin; shorter-wavelength blue light cannot penetrate deeply but instead is reflected back to the observer.

NEVUS DEPIGMENTOSUS (ACHROMIC NEVUS)

Nevi depigmentosi are usually present at birth; they are localized macular hypopigmented patches or streaks, often with bizarre, irregular borders (Fig. 651-6). They can resemble hypomelanosis of Ito clinically, except that they are more localized and often unilateral. Small lesions may also resemble the ash leaf macules of tuberous sclerosis. Nevi depigmentosi appear to represent a focal defect in transfer of melanosomes to keratinocytes.

Figure 651-6 Large nevus depigmentosus of the abdomen.

EPIDERMAL NEVI

Epidermal nevi may be visible at birth or may develop in the 1st few mo or yr of life. They affect both sexes equally and usually occur sporadically. Epidermal nevi are hamartomatous lesions characterized by hyperplasia of the epidermis and/or adnexal structures in a focal area of the skin.

Epidermal nevi are classified into a number of variants, depending on the morphology and extent of the individual nevus and the predominant epidermal structure. An epidermal nevus may appear initially as a discolored, slightly scaly patch that, with maturation, becomes more linear, thickened, verrucous, and hyperpigmented. *Systematized* refers to a diffuse or extensive distribution of lesions, and *ichthyosis hystrix* indicates that the distribution is extensive and bilateral (Fig. 651-7). Morphologic types include pigmented papillomas, often in a linear distribution; unilateral hyperkeratotic streaks involving a limb and perhaps a portion of the trunk; velvety hyperpigmented plaques; and whorled or marbled hyperkeratotic lesions in localized plaques or over extensive areas of the body along Blaschko lines. An inflammatory linear verrucous variant is markedly pruritic and tends to become erythematous, scaling, and crusted. Many harbor *RAS* mutations.

The histologic pattern evolves as an epidermal nevus matures, but epidermal hyperplasia of some degree is apparent in all stages of development. One or another dermal appendage may predominate in a particular lesion. These nevi must be distinguished from lichen striatus, lymphangioma circumscriptum, shagreen patch of tuberous sclerosis, congenital hairy nevi, linear porokeratosis, linear lichen planus, linear psoriasis, the verrucous stage of incontinentia pigmenti, and nevus sebaceus (Jadassohn). Keratolytic agents such as retinoic acid and salicylic acid may be moderately effective in reducing scaling and controlling pruritus, but definitive treatment requires full-thickness excision; recurrence is usual if more superficial removal is attempted. Alternatively, the nevus may be left intact. Epidermal nevi are occasionally associated with other abnormalities of the skin and soft tissues, eyes, and nervous, cardiovascular, musculoskeletal, and urogenital systems. In these instances, the disorder is referred to as epidermal nevus syndrome. This syndrome, however, is not a distinct clinical entity. The well-established syndromes that involve a type of epidermal nevus and distinct birth defects include the **proteus** and **CHILD** (congenital hemidysplasia with ichthyosiform erythroderma and limb defects) syndromes.

Nevus Sebaceus (Jadassohn)

A relatively small, sharply demarcated, oval or linear, elevated yellow-orange plaque that is usually devoid of hair, nevus sebaceus occurs on the head and neck of infants (Fig. 651-8). Although the lesion is characterized histopathologically by an abundance of sebaceous glands, all

Figure 651-7 Epidermal nevus (ichthyosis hystrix type).

Figure 651-8 Orange-yellow nevus sebaceus of the scalp.

Figure 651-10 Large smooth muscle hamartoma of the buttock.

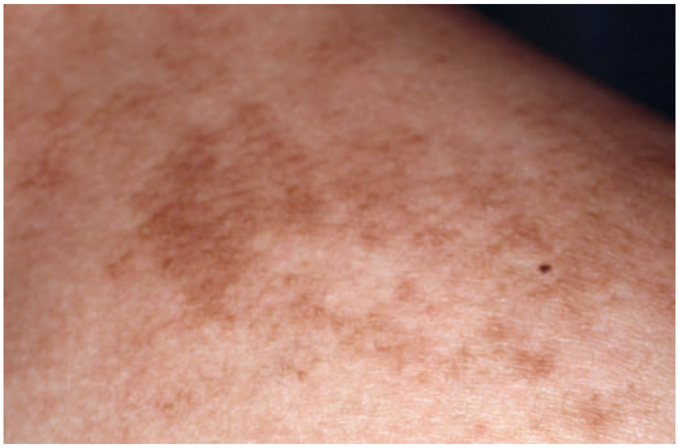

Figure 651-9 Becker nevus on the shoulder of an adolescent male.

elements of the skin are represented. It is frequently flat and inconspicuous in early childhood. With maturity, usually during adolescence, the lesions become verrucous and studded with large rubbery nodules. The changing clinical appearance reflects the histologic pattern, which is characterized by a variable degree of hyperkeratosis, hyperplasia of the epidermis, malformed hair follicles, and often a profusion of sebaceous glands and the presence of ectopic apocrine glands. Sebaceous nevi are caused by somatic mosaic mutations in *HRAS* and *KRAS.* The disruption of these oncogenes helps explain the 14% incidence of these lesions developing tumors throughout a patient's lifetime. Most tumors are benign (trichoblastomas, syringocystadenoma papilliferum, trichilemmomas), but basal cell carcinoma can occur as well. The *treatment of choice* is total excision before adolescence. Sebaceous nevi associated with central nervous system, skeletal, and ocular defects represent a variant of the epidermal nevus syndrome.

Becker Nevus (Becker Melanosis)

Becker nevus develops predominantly in males, during childhood or adolescence, initially as a hyperpigmented patch. The lesion commonly develops hypertrichosis, limited to the area of hyperpigmentation, and evolves into a unilateral, slightly thickened, irregular, hyperpigmented plaque. The most common sites are the upper torso and upper arm (Fig. 651-9). The nevus shows an increased number of basal melanocytes and variable epidermal hyperplasia. Becker melanosis is commonly associated with a smooth muscle hamartoma, which may appear as slight perifollicular papular elevations or slight induration. Stroking of such a lesion may induce smooth muscle contraction and make the hairs stand up (pseudo-Darier sign). The nevus is benign, has no risk for malignant change, and is rarely associated with other anomalies.

NEVUS COMEDONICUS

An uncommon organoid nevus of epithelial origin, nevus comedonicus consists of linear plaques of plugged follicles that simulate comedones; they may be present at birth or may appear during childhood. The horny plugs represent keratinous debris within dilated, malformed pilosebaceous follicles. The lesions are most often unilateral and may develop at any site. Rarely, they are associated with other congenital malformations, including skeletal defects, cerebral anomalies, and cataracts. Although these lesions are often asymptomatic, some affected individuals experience recurrent inflammation, resulting in cyst formation, fistulas, and scarring. There is no effective treatment except full-thickness excision; palliation of larger lesions may be achieved by regular applications of a retinoic acid preparation.

CONNECTIVE TISSUE NEVUS

Connective tissue nevus is a hamartoma of collagen, elastin, and/or glycosaminoglycans of the dermal extracellular matrix. It may occur as a solitary defect or as a manifestation of an associated disorder. These nevi may occur at any site but are most common on the back, buttocks, arms, and thighs. They are skin-colored, ivory, or yellow plaques, 2-15 cm in diameter, composed of many tiny papules or grouped nodules that are frequently difficult to appreciate visually because of the subtle color changes. The plaques have a rubbery or cobblestone consistency on palpation. Biopsy findings are variable and include increased amounts and/or degeneration or fragmentation of dermal collagen, elastic tissue, or ground substance. Similar lesions occurring with tuberous sclerosis are called shagreen patches; however, shagreen patches consist only of excessive amounts of collagen. The association of many small papular connective tissue nevi with osteopoikilosis is called dermatofibrosis lenticularis disseminata **(Buschke-Ollendorf syndrome).**

SMOOTH MUSCLE HAMARTOMA

Smooth muscle hamartoma is a developmental anomaly resulting from hyperplasia of the smooth muscle (arrector pili) associated with hair follicles. It is usually evident at birth or shortly thereafter as a flesh-colored or lightly pigmented plaque with overlying hypertrichosis on the trunk or limbs (Fig. 651-10). Transient elevation or a rippling movement of the lesion, caused by contraction of the muscle bundles, can sometimes be elicited by stroking of the surface (pseudo-Darier sign). Smooth muscle hamartoma can be mistaken for congenital pigmented nevus, but the distinction is important because the former has no risk for malignant melanoma and need not be removed.

Chapter 652

Hyperpigmented Lesions

Anna M. Juern and Beth A. Drolet

DISORDERS OF PIGMENT

Normal pigmentation requires migration of melanoblasts from the neural crest to the dermal–epidermal junction, enzymatic processes to form pigment, structural components to contain the pigment (melanosomes), and transfer of pigment to the surrounding keratinocytes. Increased skin color may be generalized or localized and may result from various defects in any of these requirements. Some of these aberrations are a manifestation of systemic disease, others represent generalized or focal developmental or genetic defects, and still others may be nonspecific and the result of cutaneous inflammation.

EPHELIDES (FRECKLES)

Ephelides are light or dark brown, round, oval or irregularly shaped, well-demarcated, macules usually <3 mm in diameter that occur in sun-exposed areas such as the face, upper back, arms, and hands. They are induced by exposure to sun, particularly during the summer, and may fade or disappear during the winter. They are a result of increased sun-induced melanogenesis and melanosome transport from melanocytes to keratinocytes, and not increased number of melanocytes. They are more common in redheads and fair-haired individuals and first appear in the preschool years. Histologically, they are marked by increased melanin pigment in epidermal basal cells, which have more numerous and larger dendritic processes than the melanocytes of the surrounding paler skin. The lack of melanocytic proliferation or elongation of epidermal rete ridges distinguishes them from lentigines. Freckles have been identified as a marker for increased risk for UV-induced neoplasia and hence melanoma, independent of melanocytic nevi.

LENTIGINES

Lentigines, often mistaken for freckles or junctional nevi, are small (<3 cm), round, dark brown macules that can appear anywhere on the body with an early age of onset. They are more common in darkly pigmented than in lightly pigmented individuals. They are unrelated to sun exposure and remain permanently. Histologically, they have elongated, club-shaped, epidermal rete ridges with increased numbers of melanocytes and dense epidermal deposits of melanin. No nests of melanocytes are found. The lesions are benign and, when few, may be viewed as a normal occurrence and are seen most commonly on the lower lip.

Eruptive/generalized lentiginosis (lentiginosis profusa) involves innumerable small, pigmented macules that are present at birth or appear during childhood. There are no associated abnormalities, and mucous membranes are spared. **Carney complex** is an autosomal dominant syndrome characterized by multiple lentigines and multiple neoplasias, including: myxomas of the skin, heart (atrial) and breast; psammomatous melanotic schwannomas; epithelioid blue nevi of skin and mucosae; growth hormone-producing pituitary adenomas; and testicular Sertoli cell tumors. Components of the Carney complex have been described previously as the NAME (nevi, atrial myxoma, myxoid neurofibroma, ephelides) and LAMB (lentigines, atrial myxoma, mucocutaneous myxoma, blue nevi) syndromes. It is inherited in an autosomal dominant pattern and caused by an inactivating mutation of the *PRKAR1* gene.

The **multiple lentigines syndrome** (formerly LEOPARD) is an autosomal dominant entity consisting of a generalized, symmetric distribution of *l*entigines (Fig. 652-1) in association with *e*lectrocardiogram *a*bnormalities, *o*cular hypertelorism, *p*ulmonary stenosis, *a*bnormal genitals (cryptorchidism, hypogonadism, hypospadias), growth *r*etardation, and sensorineural *d*eafness (type 1, *PTPN11* gene; type 2, *RAF1* gene). Other features include hypertrophic obstructive cardiomyopathy and pectus excavatum or carinatum.

Figure 652-1 Multiple lentigines in LEOPARD (*l*entigines in association with electrocardiogram *a*bnormalities, *o*cular hypertelorism, *p*ulmonary stenosis, *a*bnormal genitals [cryptorchidism, hypogonadism, hypospadias], growth *r*etardation, and sensorineural *d*eafness) syndrome.

The **Peutz-Jeghers syndrome** is characterized by melanotic macules on the lips and mucous membranes and by gastrointestinal (GI) polyposis. It is inherited as an autosomal dominant trait (*STK11* gene). Onset is noted in infancy and early childhood when pigmented macules appear on the lips and buccal mucosa. The macules are usually a few millimeters in size but may be as large as 1-2 cm. Macules also appear occasionally on the palate, gums, tongue, and vaginal mucosa. Cutaneous lesions may develop on the nose, hands, and feet; around the mouth, eyes, and umbilicus; and as longitudinal bands or diffuse hyperpigmentation of the nails. Pigmented macules often fade from the lips and skin during puberty and adulthood but generally do not disappear from mucosal surfaces. Buccal mucosal macules are the most constant feature of the disorder; in some families, occasional members may be affected only with the pigmentary changes. Indistinguishable pigmentary changes beginning in adult life, without intestinal involvement, also occur sporadically in individuals.

Polyposis usually involves the jejunum and ileum but may also occur in the stomach, duodenum, colon, and rectum (see Chapter 345). Episodic abdominal pain, diarrhea, melena, and intussusception are frequent complications. Patients have a significantly increased risk of GI tract and non–GI tract tumors at a young age. GI cancer has been reported in ≈2-3% of patients; the lifetime relative risk for GI malignancy is 13. The relative risk of non–GI tract malignancies, including ovarian, cervical, and testicular tumors, is 9. Peutz-Jeghers syndrome must be differentiated from other syndromes associated with multiple lentigines (Laugier-Hunziker syndrome), from ordinary freckling, from Gardner syndrome, and from Cronkhite-Canada syndrome, a disorder characterized by GI polyposis, alopecia, onychodystrophy, and diffuse pigmentation of the palms, volar aspects of the fingers, and dorsal hands. Treatment of Peutz-Jeghers melanotic macules is not required or indicated, but multiple different lasers have been successful for cosmesis, in some cases.

CAFÉ-AU-LAIT SPOTS

Café-au-lait spots are uniformly hyperpigmented, sharply demarcated macular lesions, the hues of which vary with the normal degree of pigmentation of the individual: They are tan or light brown in white individuals and may be dark brown in black children (Figs. 652-2 and 652-3). Café-au-lait spots vary tremendously in size and may be large, covering a significant portion of the trunk or limb. Generally the borders are smooth, but some have exceedingly irregular borders. The lesions are characterized by increased numbers of melanocytes and

Figure 652-2 Multiple café-au-lait macules on a child with neurofibromatosis type 1. *(From Eichenfield LF, Frieden IJ, Esterly NB:* Textbook of neonatal dermatology, *Philadelphia, 2001, WB Saunders, p. 372.)*

melanin in the epidermis but lack the clubbed rete ridges that typify lentigines. One to 3 café-au-lait spots are common in normal children; ≈10% of normal children have café-au-lait macules. The spots may be present at birth or may develop during childhood.

Large, often asymmetric café-au-lait spots with irregular borders are characteristic of patients with Albright **(McCune-Albright)** syndrome (*GNAS1* gene; see Chapter 562.6). This disorder includes polyostotic fibrous dysplasia of bone, leading to pathologic fractures; precocious puberty; and numerous hyperfunctional endocrinopathies. The macular hyperpigmentation may be present at birth or may develop late in childhood (see Fig. 652-3). Cutaneous pigmentation is typically most extensive on the side showing the most severe bone involvement.

Neurofibromatosis Type 1 (von Recklinghausen Disease)

The café-au-lait spot (macule) is the most familiar cutaneous hallmark of the autosomal dominant neurocutaneous syndrome known as neurofibromatosis type 1 (*NF-1*, neurofibromin gene; see Fig. 652-2 and Chapter 596.1). Included in the criteria for this diagnosis is the presence of 5 or more café-au-lait spots >5 mm in diameter in prepubertal patients or 6 or more café-au-lait spots >15 mm in diameter in postpubertal patients. Multiple café-au-lait macules commonly produce a freckled appearance of non–sun-exposed areas such as the axillae (Crowe sign), the inguinal and inframammary regions, and under the chin. Café-au-lait macules can also be seen in segmental NF-1 which results from somatic mosaicism arising from postzygotic mutations in the *NF-1* gene such that the clinical manifestations of NF-1 are present only in a localized body segment. Another variant of NF-1 is hereditary spinal neurofibromatosis, which is a rare disorder that generally presents with multiple café-au-lait macules and multiple, symmetric spinal root neurofibromas but other stigmata of NF-1 are typically absent. The lesions also occur with certain other disorders, including other types of neurofibromatosis, but in these disorders the café-au-lait spots are not a major feature of the disorder (Table 652-1).

Table 652-1 Other Syndromes Associated with Café-Au-Lait Macules

STRENGTH OF ASSOCIATION	SYNDROME	CLINICAL FEATURES	GENE OR LOCUS
Strong	Neurofibromatosis type 2	Acoustic neuromas, schwannomas, neurofibromas, meningiomas, juvenile posterior subcapsular lenticular opacity; café-au-lait seen but not a criterion for diagnosis	*NF-2*
	Multiple familial café-au-lait	Multiple café-au-lait without other stigmata of NF-1	?
	Legius (NF-1–like) syndrome	Multiple café-au-lait and skinfold freckling without other stigmata of NF-1	*SPRED1*
	McCune-Albright syndrome	Segmental café-au-lait, precocious puberty, other endocrinopathies, polyostotic fibrous dysplasia	*GNAS1*
	Constitutional mismatch repair deficiency syndrome	Multiple café-au-lait, adenomatous colonic polyps, multiple malignancies, including colonic adenocarcinoma, glioblastoma, medulloblastoma, and lymphoma	*MLH1, MSH2, MSH6, PMS2*
	Ring chromosome syndromes	Multiple café-au-lait, microcephaly, mental retardation, short stature, skeletal anomalies	Chromosomes 7, 11, 12, 15, 17
	LEOPARD/multiple lentigines syndrome	Café-au-lait, café-noir, lentigines, cardiac conduction defects, ocular hypertelorism, pulmonary stenosis, genitourinary anomalies, growth retardation, hearing loss	*PTPN11*
	Cowden syndrome (multiple hamartoma syndrome)	Facial trichilemmomas, cobblestoning of the oral mucosa, predisposition to soft tissue tumors (lipomas, neuromas), gastrointestinal polyps, fibrocystic breast disease and breast carcinoma, thyroid adenoma, and thyroid cancer	*PTEN*

Continued

Table 652-1 Syndromes Associated with Café-Au-Lait Macules—cont'd

STRENGTH OF ASSOCIATION	SYNDROME	CLINICAL FEATURES	GENE OR LOCUS
	Bannayan-Riley-Ruvalcaba syndrome	Facial trichilemmomas, oral papillomas, pigmented genital macules, gastrointestinal polyps, macrocephaly, vascular anomalies, mental retardation	*PTEN*
Weak	Ataxia-telangiectasia	Cerebellar ataxia, cutaneous and ocular telangiectasias, immunodeficiency, hypogonadism, predisposition to lymphoreticular malignancy	*ATM*
	Bloom syndrome	Photosensitivity, immunodeficiency, chronic lung disease, cryptorchidism, syndactyly, short stature, susceptibility to malignancy	*RECQL3*
	Fanconi anemia	Bone marrow failure, multiple congenital anomalies, predisposition to malignancy, mental retardation, microcephaly	*FANCA, FANCB* (putative), *FANCC, FANCD* locus on chromosome 3, *FANCE* locus on chromosome 6, *FANCF, FANCG, FANCH* (putative)
	Russell-Silver syndrome	Short stature, craniofacial and body asymmetry, low birthweight, microcephaly, triangular facies, fifth finger clinodactyly, congenital cardiac defects	?
	Tuberous sclerosis	Facial angiofibromas, cutaneous collagenomas, seizures, mental retardation, hypomelanotic macules, periungual fibromas, subependymal nodules, subependymal giant cell astrocytoma, cardiac rhabdomyoma, pulmonary lymphangiomyomatosis renal angiomyolipoma, retinal hamartomas	*TSC1, TSC2*
	Turner syndrome	Short stature, lymphedema, congenital heart disease, valgus deformity	X-chromosomal anomalies (XO karyotype or Xp deletion)
	Noonan syndrome	Facial dysmorphism, pulmonary valve stenosis, webbed neck, pectus excavatum, mental retardation, short stature, cryptorchidism, hematologic malignancies	*PTPN11, SOS1, RAF1, KRAS*
	Multiple mucosal neuroma (MEN) syndrome 1	Parathyroid adenoma, pituitary adenoma, pancreatic islet adenoma, lipoma, gingival papules, facial angiofibromas, collagenomas	*MENIN*
	MEN syndrome 2B	Mucosal neuromas, pheochromocytoma, medullary thyroid carcinoma, parathyroid adenoma, marfanoid habitus	*RET*
	Johanson-Blizzard syndrome	Short stature, failure to thrive, microcephaly, sensorineural hearing loss, dental anomalies, congenital heart disease, exocrine pancreatic insufficiency, imperforate anus, genitourinary anomalies, mental retardation, hypothyroidism	*UBR1*
	Microcephalic osteodysplastic primordial dwarfism, type II	Short stature, microcephaly, intrauterine growth retardation, dysmorphic facies, skeletal anomalies, developmental delay, premature puberty	*PCNT2*
	Nijmegen breakage syndrome	Short stature, growth retardation, microcephaly, cleft lip/palate, dysmorphic facies, bronchiectasis, sinusitis, dysgammaglobulinemia with recurrent urinary tract and gastrointestinal infections, mental retardation, spontaneous chromosomal instability, predisposition to malignancy	*NBS1*
	Rubinstein-Taybi syndrome	Short stature, microcephaly, dysmorphic facies, congenital cardiac disease, sternal anomalies, skeletal anomalies, mental retardation	*CREBBP, EP300*
	Kabuki syndrome	Postnatal growth retardation, microcephaly, dysmorphic facies, congenital cardiac defects, malabsorption, anal stenosis, genitourinary anomalies, congenital hip dysplasia, hirsutism, mental retardation	?

INCONTINENTIA PIGMENTI (BLOCH-SULZBERGER DISEASE)

See Chapter 596.7.

POSTINFLAMMATORY PIGMENTARY CHANGES

Either hyperpigmentation or hypopigmentation can occur as a result of cutaneous inflammation. Alteration in pigmentation usually follows a severe inflammatory reaction but may result from mild dermatitis. Dark-skinned children are more likely to show these changes than fair-skinned ones. Although altered pigmentation may persist for weeks to months, patients can be reassured that these lesions are usually temporary.

Chapter 653

Hypopigmented Lesions

Sheila S. Galbraith

ALBINISM

Several types of congenital oculocutaneous albinism (OCA) consist of partial or complete failure of melanin production in the skin, hair, and eyes despite the presence of normal number, structure, and distribution of melanocytes. They may be divided into 2 major classes: those with abnormal protein function involved in the formation and transfer of melanin, and those with defects in melanosomes (Table 653-1).

Table 653-1 Genes Associated with Hypopigmentation

DISORDER	GENE DEFECT
OCULOCUTANEOUS ALBINISM	
OCA1	Tyrosinase
OCA2	P protein
OCA3	*TRP-1*
OCA4	*MATP*
HERMANSKY-PUDLAK	
Type 1	HPS-1 Mouse (pale ear)
Type 2	HPS-2 b3A subunit of AP3
Type 3	HPS-3 Mouse (cocoa)
Type 4	HPS-4 Mouse (light ear)
Type 5	HPS-5 KIAA107
Type 6	HPS-6 Mouse (ruby eye)
Type 7	HPS-7 DTNBP1
Type 8	HPS-8 Bloc153
CHÉDIAK-HIGASHI	*CHS1/LYST*
PIEBALDISM	C-KIT receptor Heterozygous SLUG
WAARDENBURG	
Type 1	Heterozygous PAX-3
Type 2a	*MITF*
Type 2b	Chromosome 1p
Type 2c	Chromosome 8p23
Type 2d	*SNAIL*
Type 2e	*SOX10*
Type 3	Homozygous PAX-3
Type 4	*SOX10* Endothelin 3 Endothelin B receptor

Tyrosinase is the copper-containing enzyme that catalyzes at multiple steps in melanin biosynthesis (see Chapter 85.2). Tyrosinase-positive variants are characterized by darkening of the hair bulb on incubation with tyrosine.

Oculocutaneous albinism type 1 (OCA1) is characterized by great reduction in or absence of tyrosinase activity. OCA1A, the most severe form, is characterized by a lack of visible pigment in hair, skin, and eyes (Fig. 653-1). This manifests as photophobia, nystagmus, defective visual acuity, white hair, and white skin. The irises are blue-gray in oblique light and prominent pink in reflected light. OCA1B, or yellow mutant albinism, manifests at birth as white hair, pink skin, and gray eyes. This type is particularly prevalent in Amish communities. Progressively the hair becomes yellow-red, the skin tans lightly on exposure to the sun, and the irises may accumulate some brown pigment, with a resultant improvement in visual acuity. Photophobia and nystagmus are present but mild. OCATS is a temperature-sensitive type of albinism. The abnormal tyrosinase has decreased activity at 35-37°C (95-98.6°F). Therefore, cooler regions of the body such as the limbs and head pigment to some degree, whereas other areas remain depigmented.

OCA2 ranges from nearly normal to closely resembling type 1 albinism. This is the most common form of albinism seen worldwide. Little or no melanin is present at birth, but pigment, particularly red-yellow pigment, may accumulate during childhood to produce straw-colored or light brown skin in white individuals. Pigmented nevi may develop. Progressive improvement in visual acuity and nystagmus occurs with aging. Black individuals may have yellow-brown skin, dark-brown freckles in sun-exposed areas, and brown coloration of the irises. **Brown OCA** is an allelic variant of OCA2. Prader-Willi and Angelman syndromes, which include hypopigmentation, have deletions that include the gene involved in OCA2.

OCA3 (rufous albinism) is seen predominantly in patients of African descent. It is characterized by red hair, reddish brown skin, pigmented nevi, freckles, reddish brown to brown eyes, nystagmus, photophobia, and decreased visual acuity.

Figure 653-1 White hair and skin in oculocutaneous albinism type 1 (OCA1).

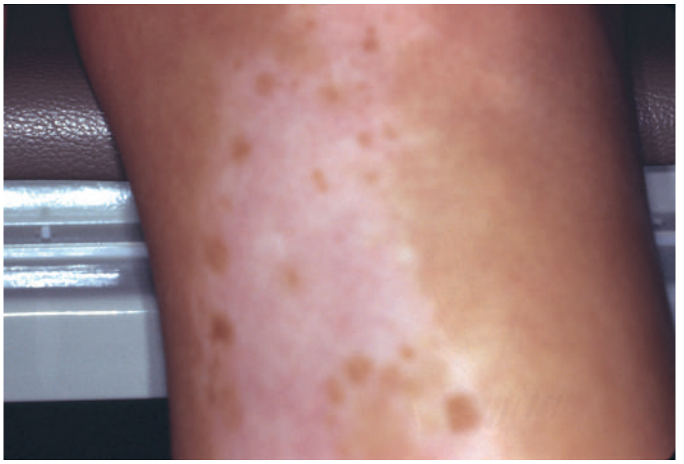

Figure 653-2 Depigmented macule with islands of hyperpigmentation in piebaldism.

OCA4 is a rare OCA with clinical findings similar to those in OCA2.

The **Cross-McKusick-Breen syndrome** consists of tyrosinase-positive albinism with ocular abnormalities, cognitive impairment, spasticity, and athetosis. The genetic defect is unidentified.

Because of the absence of normal protection by adequate amounts of epidermal melanin, persons with albinism are predisposed to development of actinic keratoses and cutaneous carcinoma secondary to skin damage by ultraviolet light. Protective clothing and a broad-spectrum sunscreen (see Chapter 656) should be worn during exposure to sunlight.

Oculocutaneous Albinism with Melanosomal Abnormalities

See Table 653-1.

Hermansky-Pudlak syndrome is a collection of autosomal recessive genetic disorders characterized by OCA, ceroid accumulation in lysosomes, and prolonged bleeding time. In mice, 16 distinct genetic loci that produce coat color mutant phenotypes associated with platelet deficiencies are recognized; eight have been identified in humans.

Chédiak-Higashi syndrome (see Chapter 130) is another genetic abnormality associated with dysfunction of lysosome-related organelles. Patients with Chédiak-Higashi syndrome have hypopigmentation of the skin, eyes, and hair; prolonged bleeding times and easy bruising; recurrent infections; abnormal natural killer cell function; and peripheral neuropathy. Chédiak-Higashi syndrome is caused by mutations in the *CHS1/LYST* gene, which is a lysosomal trafficking regulatory gene.

MELANOBLAST MIGRATION ABNORMALITIES

See Table 653-1.

Piebaldism

A congenital autosomal dominant disorder, piebaldism is characterized by sharply demarcated amelanotic patches that occur most frequently on the forehead, anterior scalp (producing a white forelock), ventral trunk, elbows, and knees. Islands of normal or darker-than-normal pigmentation may be present within the amelanotic areas (Fig. 653-2). The plaques are a result of a permanent localized absence of melanocytes as a result of a defect in the *KIT* protooncogene, which encodes the cell surface receptor transmembrane tyrosine kinase. The pattern of depigmentation arises from defective melanoblast migration from the neural crest during development. The reason that piebaldism is a localized and not a generalized process remains unknown. Piebaldism must be differentiated from vitiligo, which may be progressive and is not usually congenital, nevus depigmentosus, and Waardenburg syndrome.

Waardenburg Syndrome

Waardenburg syndrome also manifests at birth as localized areas of depigmented skin and hair. There are 4 types of Waardenburg syndrome. The hallmark of Waardenburg type 1 is the white forelock, which is seen in 20-60% of patients. Only 15% of patients have areas of depigmented skin. Deafness occurs in 9-37%, heterochromia irides in 20%, and unibrow (synophrys) in 17-69% of those affected. Dystopia canthorum (i.e., telecanthus) is seen in all patients with Waardenburg type 1. Waardenburg type 2 is similar to type 1, except that patients with type 2 lack dystopia canthorum, but they also have a higher incidence of deafness. Waardenburg type 3 is similar to Waardenburg type 1, except that patients also have limb abnormalities. It is also called the Klein-Waardenburg syndrome. Waardenburg type 4 is also called the Shah-Waardenburg syndrome. Patients with this type all have Hirschsprung disease. Dystopia canthorum is seldom seen in these patients.

Tuberous Sclerosis Complex (*TSC1, TSC2* Genes)

See Chapter 596.2 for a discussion of this complex.

Hypomelanosis of Ito

Hypomelanosis of Ito is a rare congenital skin disorder affecting children of both sexes that can have associated defects in several organ systems. There is no evidence for genetic transmission; chromosomal mosaicism and chromosomal translocations have been reported. Hypomelanosis of Ito is currently a descriptive rather than definitive diagnosis. Blaschkoid or mosaic hypomelanosis is a better descriptive term.

The skin lesions of hypomelanosis of Ito are generally present at birth but may be acquired in the 1st 2 yr of life. The lesions are similar to a negative image of those present in incontinentia pigmenti, consisting of bizarre, patterned, hypopigmented macules arranged over the body surface in sharply demarcated whorls, streaks, and patches that follow the lines of Blaschko (Fig. 653-3). The palms, soles, and mucous

Figure 653-3 Marbled hypopigmented streaks on the abdomen in hypomelanosis of Ito.

Figure 653-4 Sharply demarcated, symmetric, depigmented areas of vitiligo.

membranes are spared. The hypopigmentation remains unchanged throughout childhood but fades during adulthood. The degree of depigmentation varies from hypopigmented to achromic. Neither inflammatory nor vesicular lesions precede the development of the pigmentary changes as in incontinentia pigmenti. The hypopigmented areas demonstrate fewer and smaller melanocytes and a decreased number of melanin granules in the basal cell layer than normal. Inflammatory cells and pigment incontinence are lacking.

The majority of patients with mosaic hypomelanosis have no associated abnormalities, but involvement of other organs systems can rarely occur. The most commonly associated abnormalities involve the nervous system, including intellectual disability (70%), seizures (40%), microcephaly (25%), and muscular hypotonia (15%). The musculoskeletal system is the second most frequently involved system, affected by scoliosis and thoracic and limb deformities. Minor ophthalmologic defects (strabismus, nystagmus) are present in 25% of patients, and 10% have cardiac defects. These frequencies are likely to be overestimated because patients with isolated skin disease often do not seek further evaluation. The differential diagnosis includes systematized nevus depigmentosus, which is a stable leukoderma not associated with systemic manifestations. Differentiation from incontinentia pigmenti, particularly the hypopigmented fourth stage, is critical for genetic counseling because incontinentia pigmenti, unlike hypomelanosis of Ito, is inherited.

Vitiligo

Epidemiology and Etiology

Vitiligo is macular depigmentation associated with the destruction of melanocytes. The disorder represents a clinical end-point resulting from a complex interaction of environmental, genetic, and immunologic factors. Autoimmune, genetic, autocytotoxic, and neural theories have been postulated. The prevalence is 0.5% of most populations.

There is definitely an **autoimmune** component to vitiligo. Eighty percent of patients with active disease have an antibody to a surface antigen on pigmented melanocytes. These antibodies appear to be cytotoxic for melanocytes. There is also a correlation between disease activity and the titer of serum antimelanocyte antibody. Melanocyte-specific CD8+ T lymphocytes are also involved in the pathogenesis of vitiligo. These antibodies and T cells recognize a variety of melanocyte enzymatic and structural proteins.

The genetic epidemiology of vitiligo is part of a broader genetically determined autoimmune and autoinflammatory diathesis. Fifteen to 20% of patients with generalized vitiligo have 1 or more affected 1st-degree relatives. In these families the genetic pattern is suggestive of polygenic, multifactorial inheritance. In the other patients, the disease occurs sporadically.

Many authorities believe that the cause of melanocyte destruction in vitiligo is an endogenous cellular abnormality. It has been suggested that melanocytes are destroyed because of the accumulation of a toxic melanin synthesis intermediate and/or lack of protection from hydrogen peroxide and other oxygen radicals. There is in vitro evidence that some of these metabolites may be lethal to melanocytes. Others believe that neurochemical factors damage melanocytes and cause depigmentation. This possibility would explain the pattern of involvement in segmental vitiligo that runs roughly along the course of a dermatome.

Table 653-2 Typical Features of Segmental and Nonsegmental Vitiligo

SEGMENTAL VITILIGO	NONSEGMENTAL VITILIGO
Often begins in childhood	Can begin in childhood, but later onset is more common
Has rapid onset and stabilizes	Is progressive, with flare-ups
Involves hair compartment soon after onset	Involves hair compartment in later stages
Is usually not accompanied by other autoimmune diseases	Is often associated with personal or family history of autoimmunity
Often occurs in the face	Commonly occurs at sites sensitive to pressure and friction and prone to trauma
Is usually responsive to autologous grafting, with stable repigmentation	Frequently relapses in situ after autologous grafting
Can be difficult to distinguish from nevus depigmentosus, especially in cases with early onset	

From Taïeb A, Picardo M: Vitiligo, N Engl J Med *360:160–168, 2009.*

Clinical Manifestations

There are 2 subtypes of vitiligo, generalized (nonsegmental) and segmental, which probably are distinctly different diseases (Table 653-2). Generalized vitiligo (85-90% of cases) may be divided into widespread (type A) and localized (type B). Approximately 50% of all patients with vitiligo have onset before 18 yr of age, and 25% demonstrate depigmentation before age 8 yr. Most children have the generalized form, but the segmental type is more common among children than among adults. Patients with the generalized form usually present with a remarkably symmetric pattern of white macules and patches (Fig. 653-4); the margins may be somewhat hyperpigmented. The

patches tend to be acral and/or periorificial. Occasionally, almost the entire skin surface becomes depigmented.

There are several varieties of localized vitiligo. A form of localized vitiligo is the halo nevus phenomenon, whereby benign moles develop depigmented rings at the periphery. Premature graying of scalp hair (canities) has also been considered a form of localized vitiligo. In segmental vitiligo, depigmented areas are limited to a quasidermatomal distribution. This type of vitiligo has a rapid onset and progression in a localized area without the development of depigmentation in other areas.

A number of **autoimmune diseases** occur in patients with vitiligo, including Addison disease, Hashimoto thyroiditis, pernicious anemia, diabetes mellitus, hypoparathyroidism, and polyglandular autoimmune syndrome with selective immunoglobulin A deficiency. In addition, other diseases with possible immune defects, such as alopecia areata and morphea, have been seen in patients with vitiligo.

Vogt-Koyanagi-Harada syndrome is vitiligo associated with uveitis, dysacusia, meningoencephalitis, and depigmentation of the skin, scalp hair, eyebrows, and eyelashes. In the **Alezzandrini syndrome**, vitiligo is associated with tapetoretinal degeneration and deafness.

Light microscopic examination of early lesions shows mild inflammatory change. Over time, degenerative changes occur in melanocytes, leading to their complete disappearance.

The differential diagnosis of vitiligo includes other causes of widespread acquired leukoderma. The two most common problem diagnoses are tinea versicolor and postinflammatory hypopigmentation.

Treatment

Localized areas of vitiligo may respond to potent topical steroid, topical tacrolimus, or topical pimecrolimus. In patients with more extensive involvement, narrow-band ultraviolet light B (UVB) [UVB311] is the treatment of choice. In all forms of vitiligo, response to therapy is slow, taking many months to years. For those not interested in treatment, cover-up cosmetics may be used. All areas of vitiligo are susceptible to sun damage, and care should be taken to minimize sun exposure of affected areas. Spontaneous remission may be seen in a small percentage of cases.

Chapter 654

Vesiculobullous Disorders

Joel C. Joyce

Many diseases are characterized by vesiculobullous lesions; they vary considerably in cause, age of onset, and pattern. The morphology and distribution of the blister often provides a visual clue to the location of the lesion within the skin. Blisters localized to the **epidermal layers** are thin-walled, relatively flaccid, and easily ruptured. **Subepidermal blisters** are tense, thick-walled, and more durable. Biopsies of blisters can be diagnostic because the level of cleavage within the skin and associated findings, such as the nature of the inflammatory infiltrate, are characteristic for a particular disorder. Other diagnostic procedures, such as immunofluorescence and electron microscopy, can often help distinguish vesiculobullous disorders that have nearly identical histopathologic findings (Table 654-1).

Table 654-1 Sites of Blister Formation and Diagnostic Studies for the Vesiculobullous Disorders

654.1 Erythema Multiforme

Joel C. Joyce

ETIOLOGY

Among the numerous factors implicated in the etiology of erythema multiforme (EM), infection with herpes simplex virus (HSV) is the most common. Infection with *Mycoplasma pneumoniae* is implicated, particularly in children and young adults, but differentiation from Stevens-Johnson syndrome and the so-called *M. pneumoniae*-associated mucositis (see below) can be confusing. HSV labialis and, less commonly, HSV genitalis are implicated in 60-70% of episodes of EM and are believed to trigger nearly all episodes of recurrent EM, frequently in association with sun exposure. HSV antigens and DNA are present in skin lesions of EM but are absent in nonlesional skin. The presence of the human leukocyte antigens A33, B62, B35, DQw3 (DQB1*0301 split), and DR53 is associated with an increased risk of HSV-induced EM, particularly the recurrent form. Most patients experience a single self-limited episode of EM. Lesions of HSV-induced recurrent EM typically develop 10-14 days after onset of recurrent HSV eruptions, have a similar appearance from episode to episode, but may vary in frequency and duration in a given patient. Not all episodes of recurrent HSV evolve into EM in susceptible patients.

Drug-related EM is less common (<10% of patients) and may be associated with nonsteroidal antiinflammatory agents, including acetaminophen, sulfonamides, and other antibiotics. The differential diagnosis in drug-related EM should include toxic epidermal necrolysis and drug hypersensitivity syndrome.

CLINICAL MANIFESTATIONS

EM has numerous morphologic manifestations on the skin, varying from erythematous macules, papules, vesicles, bullae, or urticaria-appearing plaques to patches of confluent erythema. The eruption appears most commonly in patients between the ages of 10 and 40 yr (with highest incidence in males in the 2nd decade) and usually is asymptomatic, although a burning sensation or pruritus may be present. The diagnosis of EM is established by finding the classic lesion: doughnut-shaped, target-like (iris or bull's-eye) papules with an erythematous outer border, an inner pale ring, and a dusky purple to necrotic center (which sometimes blisters and erodes; Figs. 654-1 and 654-2).

Figure 654-1 Early fixed papules with a central dusky zone on the dorsum of the hand of a child with erythema multiforme caused by herpes simplex virus. *(From Weston WL, Lane AT, Morelli J:* Color textbook of pediatric dermatology, *ed 3, St. Louis, 2002, Mosby, p. 156.)*

EM is characterized by an abrupt, symmetric cutaneous eruption, most commonly on the extensor upper extremities; lesions are relatively sparse on the face, trunk, and legs. Lesions can be seen on the palms and soles. The eruption often appears initially as red macules or urticarial plaques that expand centrifugally to form lesions up to 2 cm in diameter with a dusky to necrotic center. Lesions of a particular episode typically appear within 72 hr and remain fixed in place (average duration: 7 days). Oral lesions may occur with a predilection for the vermilion border of the lips and the buccal mucosa, but other mucosal surfaces are spared. EM may manifest initially as urticarial-like lesions, but in distinction to urticaria, a given lesion of EM does not fade within 24 hr. Prodromal symptoms are generally absent. Prognosis is favorable with limited long-term morbidity. Lesions typically resolve without sequelae in approximately 2 wk, but in darker pigmented individuals, pigmentary alterations at the site of lesions can be longstanding. Progression to Stevens-Johnson syndrome does not occur. Many authors distinguish between EM minor (mainly cutaneous typical or atypical targetoid lesions affecting less than 10% body surface area plus no or limited mucosal involvement, often limited to 1 site,

Figure 654-2 "Target" or "iris" lesions with characteristic central dusky zone on palms of a child with erythema multiforme caused by herpes simplex virus. *(From Weston WL, Lane AT, Morelli J: Color* textbook of pediatric dermatology, *ed 3, St. Louis, 2002, Mosby, p. 156.)*

such as the mouth) from EM major (same cutaneous involvement pattern as EM minor plus 2 or more mucosal sites with more-severe oral involvement). EM major and Stevens-Johnson syndrome are accepted to be separate entities.

Pathogenesis

The pathogenesis of EM is unclear, but it may be a host-specific, cell-mediated immune response to an antigenic stimulus, resulting in damage to keratinocytes. HSV *Pol1* gene expressed in HSV-induced recurrent EM lesions upregulates/activates the transcription factor SP1 and inflammatory cytokines. These cytokines, released by activated mononuclear cells and keratinocytes, may contribute to epidermal cell death and constitutional symptoms.

Pathology

Microscopic findings in EM are variable but may aid in diagnosis. Early lesions typically show slight intercellular edema, rare dyskeratotic keratinocytes, and basal vacuolation in the epidermis and a perivascular lymphohistiocytic infiltrate with edema in the upper dermis. More mature lesions show an accentuation of these characteristics and the development of lymphocytic exocytosis and an intense, perivascular, and interstitial mononuclear infiltrate in the upper third of the dermis. In severe cases, the entire epidermis becomes necrotic.

Differential Diagnosis

The **differential diagnosis** of EM also includes bullous pemphigoid, pemphigus, linear immunoglobulin (Ig) A dermatosis, graft-versus-host disease, fixed-drug eruption, bullous-drug eruption, urticaria, viral infections such as HSV, reactive arthritis syndromes, Kawasaki disease, Sweet syndrome, Behçet disease, allergic vasculitis, erythema annulare centrifugum, polymorphous-drug eruption, and periarteritis nodosa. EM that primarily involves the oral mucosa may be confused with Stevens-Johnson syndrome, bullous pemphigoid, pemphigus vulgaris, vesiculobullous or erosive lichen planus, Behçet syndrome, recurrent aphthous stomatitis, and primary herpetic gingivostomatitis. Serum sickness–like reaction to cefaclor (or other antibiotics) may also manifest as EM-like lesions; the lesions may develop a dusky to purple center, but in most cases, the eruption of cefaclor-induced serum sickness–like reaction is pruritic, transient, and migratory and is probably urticarial rather than true EM.

Treatment

Treatment of EM is supportive. Topical emollients, systemic antihistamines, and nonsteroidal antiinflammatory agents do not alter the course of the disease but may provide symptomatic relief. For individuals with severe mucosal disease, opioids can be used to control pain and diligent oral hygiene is essential. No controlled, prospective studies support the use of corticosteroids in the management of EM. Prophylactic oral acyclovir given for 6 mo may be effective in controlling *recurrent episodes of HSV-associated EM*. On discontinuation of acyclovir, both HSV and EM may recur, although episodes may be less frequent and milder. For recurrent cases not responsive to antiviral therapy, steroid-sparing agents used to decrease frequency of recurrence include azathioprine, mycophenolate mofetil, and dapsone. Appropriate laboratory monitoring is recommended.

Bibliography is available at Expert Consult.

654.2 Stevens-Johnson Syndrome

Joel C. Joyce

ETIOLOGY

Drugs, particularly sulfonamides, nonsteroidal antiinflammatory agents, antibiotics, and anticonvulsants, are the most common precipitants of Stevens-Johnson syndrome and toxic epidermal necrolysis. Stevens-Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN; see below) exist along a spectrum: SJS is defined as affected body surface area <10%, SJS-TEN overlap syndrome is affected body surface area between 10% and 30%, and TEN is affected body surface area >30%. **TEN** is the most-severe disorder in the clinical spectrum of the disease, involving considerable constitutional toxicity and extensive necrolysis of the mucous membranes and >30% of the body surface area. Human leukocyte antigen (HLA)-B*1502 and HLA-B*5801 are implicated in the development of these 2 disorders in Han Chinese patients receiving carbamazepine and in Japanese patients receiving allopurinol, respectively.

Infections, particularly in children, also are associated with SJS, although current thinking defines most cases of classic SJS as secondary to medications. Terms such as "***M. pneumoniae*-associated mucositis**" or "**atypical SJS**" have caused difficulty with diagnosis and classification. Individuals, typically children or young adults, often with upper respiratory symptoms from *M. pneumoniae* infection, suffer from variable degrees of mucosal ulceration and erosion (typically mouth but including other mucosae) but lack other cutaneous involvement (unlike traditional SJS-TEN) and are found to have evidence of infection with *M. pneumoniae*, typically by polymerase chain reaction evaluation. In addition to supportive treatment below, affected individuals benefit from antimicrobial treatment for *M. pneumoniae*. Morbidity is typically less severe than for SJS-TEN spectrum disease.

Clinical Manifestations

Cutaneous lesions in SJS generally consist initially of erythematous macules that rapidly and variably develop central necrosis to form vesicles, bullae, and areas of denudation on the face, trunk, and extremities. The skin lesions are typically more widespread than in EM and are accompanied by involvement of **2 or more mucosal surfaces,** namely the eyes, oral cavity, upper airway or esophagus, gastrointestinal tract, or anogenital mucosa (Fig. 654-3). A burning sensation, edema, and erythema of the lips and buccal mucosa are often the presenting signs, followed by development of bullae, ulceration, and hemorrhagic crusting. Lesions may be preceded by a flu-like upper respiratory illness. Pain from mucosal ulceration is often severe, but skin tenderness is minimal to absent in SJS, in contrast to pain in TEN. Corneal ulceration, anterior uveitis, panophthalmitis, bronchitis, pneumonitis, myocarditis, hepatitis, enterocolitis, polyarthritis, hematuria, and acute tubular necrosis leading to renal failure may occur. Disseminated cutaneous bullae and erosions may result in increased insensible fluid loss and a high risk of bacterial superinfection and sepsis. New lesions occur in crops, and complete healing may take 4-6 wk; ocular scarring, visual impairment, and strictures of the

esophagus, bronchi, vagina, urethra, or anus may remain. Nonspecific laboratory abnormalities in SJS include leukocytosis, elevated erythrocyte sedimentation rate, and, occasionally, increased liver transaminase levels and decreased serum albumin values.

Pathogenesis

Pathogenesis is related to drug-specific CD8+ cytotoxic T cells, with perforin/granzyme B and granulysin triggering keratinocyte apoptosis. This process is followed by expanded enactment of apoptosis involving the interaction of soluble Fas ligand with Fas receptor. Recently, consideration has been given to the role that macrophages/monocytes play in development of SJS/TEN via tumor necrosis factor-α, tumor necrosis factor–related apoptosis-inducing ligand (TRAIL), and tumor necrosis factor–inducer of apoptosis weak (TWEAK) signaling pathways. It is likely that many affected individuals have yet unrecognized underlying genetic predispositions.

Differential Diagnosis

The differential diagnosis of SJS includes TEN, urticaria, *M. pneumoniae*–associated mucositis, DRESS (drug rash [or reaction] with eosinophilia and systemic symptoms) syndrome (see Chapter 645.2) and other drug eruptions and viral exanthems, including Kawasaki disease. SJS has rarely been reported in patients with systemic lupus erythematosus.

Treatment

Management of SJS is supportive and symptomatic. Potentially offending drugs must be discontinued as soon as possible. Ophthalmologic consultation is mandatory because ocular sequelae such as corneal scarring can lead to vision loss. Application of cryopreserved amniotic membrane to the ocular surface during the acute phase of the disease limits the destructive and long-term sequelae. Early topical steroid treatment may also reduce ocular sequelae. Oral lesions should be managed with mouthwashes and glycerin swabs. Vaginal lesions should be observed closely and treated to prevent vaginal stricture or fusion. Topical anesthetics (diphenhydramine, dyclonine, viscous lidocaine) may provide relief from pain, particularly when applied before eating. Denuded skin lesions can be cleansed with saline or Burrow solution compresses. Antibiotic therapy is appropriate for documented secondary bacterial infection. Treatment may require admission to an intensive care unit; IV fluids; nutritional support; sheepskin or air–fluid bedding; daily saline or Burrow solution compresses; paraffin gauze or colloidal gel (Hydrogel) dressing of denuded areas; saline compresses on the eyelids, lips, or nose; analgesics; and urinary catheterization (when needed). A daily examination for infection and ocular lesions, which constitute the major cause of long-term morbidity, is essential. Systemic antibiotics are indicated for documented urinary or cutaneous infections and for suspected bacteremia (*Staphylococcus aureus* or *Pseudomonas aeruginosa*) because infection is the leading cause of death. Prophylactic systemic antibiotics are not necessary. Although corticosteroids are sometimes advocated in early, severe cases of SJS, no prospective double-blind studies evaluating their efficacy have been reported. Most authorities discourage their use because of reports of increased morbidity and mortality (sepsis) with their administration, although definitive trials in children are lacking. IV immunoglobulin (IVIG; 1.5-2.0 g/kg/day × 3 days) should be considered in early disease. Total dose greater than 2 g/kg has shown improved but not statistically significant outcomes in children compared to adults. Other immunosuppressive treatment regimens have not demonstrated clear benefit or repeated success in multiple controlled studies.

Bibliography is available at Expert Consult.

654.3 Toxic Epidermal Necrolysis

Joel C. Joyce

EPIDEMIOLOGY AND ETIOLOGY

The pathogenesis of TEN is not proved but may involve a hypersensitivity phenomenon that results in damage primarily to the basal cell layer of the epidermis. Epidermal damage appears to result from keratinocyte apoptosis (see Chapter 654.2). This condition is triggered by many of the same factors that are thought to be responsible for SJS, principally drugs such as the sulfonamides, amoxicillin, phenobarbital, hydantoin, and allopurinol. TEN is defined by (1) widespread blister formation and morbilliform or confluent erythema, associated with skin tenderness; (2) absence of target lesions; (3) sudden onset and generalization within 24-48 hr; (4) histologic findings of full-thickness epidermal necrosis and a minimal-to-absent dermal infiltrate. These criteria categorize TEN as a separate entity from EM.

CLINICAL MANIFESTATIONS

The prodrome consists of fever, malaise, localized skin tenderness, and diffuse erythema. Inflammation of the eyelids, conjunctivae, mouth, and genitals may precede skin lesions. Flaccid bullae may develop,

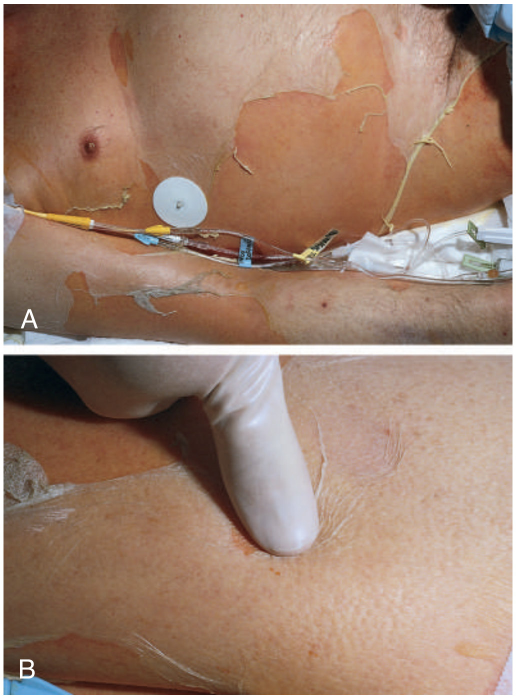

Figure 654-4 **A,** Large sheets of full-thickness epidermis are shed. **B,** Toxic epidermal necrolysis begins with diffuse, hot erythema. In hours the skin becomes painful, and with slight thumb pressure, the skin wrinkles, slides laterally, and separates from the dermis (Nikolsky sign). *(From Habif TP, editor:* Clinical dermatology*, ed 4, Philadelphia, 2004, Mosby, p. 633.)*

although this is not a prominent feature. Characteristically, full-thickness epidermis is lost in large sheets (Fig. 654-4). The **Nikolsky sign** (denudation of the skin with gentle tangential pressure) is present but only in the areas of erythema (Fig. 654-4). Healing takes place over 14 or more days. Scarring, particularly of the eyes, may result in corneal opacity. The course may be relentlessly progressive, complicated by severe dehydration, electrolyte imbalance, shock, and secondary localized infection and septicemia. Loss of nails and hair may also occur. Long-term morbidity includes alterations in skin pigmentation, eye problems (lack of tears, conjunctival scarring, loss of lashes), and strictures of mucosal surfaces. The **differential diagnosis** includes staphylococcal scalded skin syndrome, in which the blister cleavage plane is intraepidermal; graft-versus-host disease; chemical burns; drug eruptions; toxic shock syndrome; and pemphigus. The use of skin histopathology to differentiate SJS-TEN from other similar blistering disorders can be difficult, but early full-thickness epidermal necrosis tends to portend a worse clinical prognosis.

Anticonvulsant hypersensitivity syndrome (DRESS syndrome; see Chapter 645.2) is a multisystem reaction that appears approximately 3 wk to 3 mo after the start of therapy with the offending agent. The skin eruption is red-pink morbilliform eruption often associated with facial swelling, lymphadenopathy, fever, hepatic, renal and pulmonary disease, eosinophilia, atypical lymphocytosis, and leukocytosis.

TREATMENT

Appreciation of the specific etiologic factor is crucial. As most cases are drug-induced, cessation of the offending agent is critical as soon as possible. Management is similar to that for severe burns and may be best accomplished in a burn unit (see Chapter 75). It may include strict reverse isolation, meticulous fluid and electrolyte therapy, use of an air–fluid bed, and daily cultures. Systemic antibiotic therapy is indicated when secondary infection is evident or suspected. Skin care consists of cleansing with isotonic saline or Burrow solution. Biologic or colloid gel (Hydrogel) dressings alleviate pain and reduce fluid loss. Narcotics are often required for pain relief. Mouth and eye care, as for EM major and SJS, may be necessary. Because of an immune mechanism, systemic glucocorticosteroids and IVIG have been used with apparent success. Nonetheless, this treatment remains controversial although trends toward decreased morbidity and mortality in children receiving high-dose IVIG have been demonstrated (see Chapter 654.2).

Bibliography is available at Expert Consult.

654.4 Mechanobullous Disorders

Joel C. Joyce

EPIDERMOLYSIS BULLOSA

Diseases categorized under the general term epidermolysis bullosa (EB) are a heterogeneous group of congenital, genetic blistering disorders. They differ in severity and prognosis, clinical and histologic features, and inheritance patterns but are all characterized by induction of blisters by trauma and exacerbation of blistering in warm weather. The disorders can be categorized under 3 major headings with multiple subgroupings: epidermolysis bullosa simplex (EBS), junctional epidermolysis bullosa (JEB), and dystrophic epidermolysis bullosa (DEB) (Table 654-2). **Kindler syndrome**, which includes poikiloderma and photosensitivity as well as easy blistering, is also considered a separate form of EB. Epidermolysis bullosa acquisita is an autoimmune disorder producing antibodies to the α chain of type VII collagen. Affected mothers may pass the autoantibody to the fetus resulting in similar but transient lesions in the newborn.

EPIDERMOLYSIS BULLOSA SIMPLEX

EBS is a nonscarring, autosomal dominant disorder. The defect in most common types of EBS is in keratin 5 or 14, which makes up intermediate filaments of the basal keratinocytes. The intraepidermal bullae result from cytolysis of the basal cells. There are multiple other rare variants with defects that also result in intraepidermal blistering.

In **EBS–generalized other (formerly Koebner)**, blisters are usually present at birth or during the neonatal period. Sites of predilection are the hands, feet, elbows, knees, legs, and scalp. Intraoral lesions are minimal, nails rarely become dystrophic and usually regrow even when they are shed, and dentition is normal. Bullae heal with minimal to no scar or milia formation. Secondary infection is the primary complication. The propensity to blister decreases with age, and the long-term prognosis is good. Blisters should be drained by puncturing, but the blister top should be left intact to protect the underlying skin. Erosions may be covered with a semipermeable dressing.

EBS–localized (**formerly Weber-Cockayne**) predominantly affects the hands and feet and often manifests when a child begins to walk; onset may be delayed until puberty or early adulthood, when heavy shoes are worn or the feet are subjected to increased trauma. Bullae are usually restricted to the hands and feet (Fig. 654-5); rarely, they occur elsewhere, such as the dorsal aspect of the arms and the shins. The disorder ranges from mildly incapacitating to crippling at times of severe exacerbations.

EBS–Dowling-Meara (herpetiformis) is characterized by grouped blisters resembling those of herpes simplex (Fig. 654-6). During infancy, blistering may be severe and extensive, may involve mucous membranes, and may result in shedding of nails, formation of milia, and mild pigmentary changes, without scarring. After the 1st few mo of life, warm temperatures do not appear to exacerbate blistering. Hyperkeratosis and hyperhidrosis of the palms and soles may develop, but generally, the condition improves with age.

JUNCTIONAL EPIDERMOLYSIS BULLOSA

JEB–Herlitz is an autosomal recessive condition that is life-threatening. Blisters appear at birth or develop during the neonatal period, particularly on the perioral area, scalp, legs, diaper area, and thorax. Nails eventually become dystrophic and then often permanently lost.

Table 654-2 Clinical Presentation and Diagnosis of Selected Epidermolysis Bullosa Subtypes in the Neonatal Period

EB SUBTYPE (USUAL INHERITANCE)	CLINICAL FEATURES		DIAGNOSIS
	Cutaneous	Extracutaneous	
EB simplex–generalized (AD)	Mild to moderate blistering, often generalized Rare scarring, milia	Occasional mucosal blistering	EM: Intrabasal layer split IF: BPAG1 (BP230), BP-180 (BPAG2, collagen XVII), $\alpha_6\beta_4$ integrin, laminin 1, laminin 332, type IV collagen, type VII collagen (EBA antigen) at base of blister
EB simplex–localized (AD)	Mild blistering, often localized, sometimes in 1st 24 mo, but often not until later infancy or childhood Rare scarring, milia	Rare mucosal involvement	EM: Intrastratum basale split IF: Same as for EB simplex—generalized
EB simplex–Dowling-Meara (AD)	Moderate to severe blistering, which starts generalized, then is grouped (herpetiform); milia; nail dystrophy, shedding	Mild mucosal blistering	EM: Intrastratum basale split; clumped keratin filaments IF: Same as for EB simplex—generalized
Junctional EB–non-Herlitz (AR)	Moderate blistering; atrophic scars; nail dystrophy	Mild mucosal blistering; enamel hypoplasia	EM: Intralamina lucida cleavage; variable reduction in hemidesmosomes IF: Absence of staining with 19-DEJ-1 (uncein); variable staining with GB3 and other laminin 332 antibodies, including 46 and K140; BPAG1 (BP230) BP180 (BPAG2, type XVII collagen), $\alpha_6\beta_4$ integrin in blister roof; laminin 1, type IV collagen, type VII collagen (EBA antigen) at base of blister
Junctional EB–Herlitz (AR)	Severe generalized blistering that heals poorly; granulation tissue; scarring; nail dystrophy	Severe mucosal blistering; GI involvement common; laryngeal involvement with airway obstruction; urologic involvement	EM: Cleavage intralamina lucida; markedly reduced or no hemidesmosomes; absence of sub-basal dense plates IF: Absence of staining with 19-DEJ-1 (uncein) and GB3 (laminin 332) and of staining with other laminin 332 antibodies, including 46 and K140; BPAG1 (BP230) and BP180 (BPAG2, type XVII collagen) in blister roof; laminin-1, type IV collagen, and type VII collagen at base of blister
Junctional EB–pyloric atresia (AR)	Severe blistering	Polyhydramnios; pyloric atresia; urologic involvement: uretovesicular obstruction, hydronephrosis	EM: Cleavage intralamina lucida and intraplasma membrane; small hemidesmosomes IF: BPAG1 (BP230) and BP180 (BPAG2, type XVII collagen) in blister roof; laminin-1, type IV collagen, and type VII collagen at base of blister; Absence of 19-DEJ-1(uncein), $\alpha_6\beta_4$ integrin absent or reduced
Dominant dystrophic EB (AD)	Mild to moderate blistering (but may be more severe in newborn period) Milia, scarring Nail dystrophy	Mild mucosal blistering	EM: Cleavage sublamina densa; variable reduction in anchoring fibrils IF: BPAG1 (BP230), BPAG2 (BP180, type XVII collagen), $\alpha_6\beta_4$ integrin, laminin 1, type IV collagen at top of blister Staining for type VII collagen (EBA antigen) is normal, variable, or absent
Recessive dystrophic EB–Hallopeau-Siemens (AR)	Severe blistering Milia, scarring	Severe mucosal blistering; GI involvement common; urologic involvement	EM: Cleavage sublamina densa; absence of anchoring fibrils IF: BPAG1 (BP230), BP-180 (BPAG2, type XVII collagen), $\alpha_6\beta_4$ integrin, laminin 1, type IV collagen at top of blister Variability or absence of staining for type VII collagen (EBA antigen)

AD, autosomal dominant; AR, autosomal recessive; EB, epidermolysis bullosa; EBA, epidermolysis bullosa acquisita; EM, electron microscopy; GI, gastrointestinal; IF, immunohistochemical and immunofluorescence antigen mapping findings.

Modified from Eichenfield LF, Frieden IJ, Esterly NB: Textbook of neonatal dermatology, *Philadelphia, 2001, WB Saunders, p. 159.*

Figure 654-5 Bullae of the feet in epidermolysis bullosa simplex–localized (Weber-Cockayne).

Figure 654-7 Nonhealing granulation tissue in junctional epidermolysis bullosa.

Figure 654-6 Grouped vesicle on an erythematous base in epidermolysis bullosa simplex–Dowling-Meara.

Figure 654-8 Scarring with milia formation over the knee in dominant dystrophic epidermolysis bullosa.

Mucous membrane involvement may be severe, and ulceration of the respiratory, gastrointestinal, and genitourinary epithelium has been documented in many affected children, although less frequently than in severe recessive dystrophic epidermolysis bullosa. Healing is delayed, and vegetating granulomas may persist for a long time. Large, moist, erosive plaques (Fig. 654-7) may provide a portal of entry for bacteria, and septicemia is a frequent cause of death. Mild atrophy may be seen in areas of recurrent blistering. Defective dentition with early loss of teeth as a result of rampant caries is characteristic. Growth retardation and recalcitrant anemia are almost invariable. In addition to infection, cachexia and circulatory failure are common causes of death. Most patients die within the 1st 3 yr of life.

JEB–non-Herlitz is a heterogeneous group of disorders. Blistering may be severe in the neonatal period, making differentiation from the Herlitz type difficult. All conditions associated with the Herlitz type may be seen but are usually milder. **JEB–non-Herlitz generalized (formerly generalized atrophic benign EB)** is included as a variant of non-Herlitz JEB. Another variant of non-Herlitz JEB is associated with **pyloric atresia**.

In all types of JEB, a subepidermal blister is found on light microscopic examination, and electron microscopy demonstrates a cleavage plane in the lamina lucida, between the plasma membranes of the basal cells and the basal lamina. Absence or a great reduction of hemidesmosomes is seen on electron micrographs in **JEB–Herlitz** and some cases of **JEB–non-Herlitz**. The defect is in laminin 332 (formerly laminin 5 or epiligrin), a glycoprotein associated with anchoring filaments beneath the hemidesmosomes. In JEB–non-Herlitz, defects have also been described in other hemidesmosomal components, such as type XVII collagen (BP180). In **JEB–pyloric atresia**, the defect is in the $\alpha_6\beta_4$ integrin.

Treatment for JEB is supportive. The diet should provide adequate calories and supplemental iron. Infections should be treated promptly. Transfusions of packed red blood cells may be required if the patient shows no response to iron and erythropoietin therapy. Strict adherence to wound care regimens is essential. Tissue-engineered skin grafts (artificial skin derived from human keratinocytes and fibroblasts) may be beneficial.

DYSTROPHIC EPIDERMOLYSIS BULLOSA

All forms of DEB result from mutations in collagen VII, a major component of anchoring fibrils that tether the basement membrane and overlying epidermis to its dermal foundation. The blister is subepidermal in all types of DEB. The type and location of the mutation dictate the severity of the phenotype.

Dominant DEB is the most common type of DEB. The spectrum of dominant DEB is varied. Blisters may be manifest at birth and are often limited and characteristically form over acral bony prominences. The lesions heal promptly, with the formation of soft, wrinkled scars, milia, and alterations in pigmentation (Fig. 654-8). Abnormal nails and nail loss are common. In many cases, the blistering process is mild, causing little restriction of activity and not impairing growth and development. Mucous membrane involvement tends to be minimal.

Figure 654-9 Severe scarring of the hands and knees in recessive dystrophic epidermolysis bullosa.

Figure 654-10 Mitten-hand deformity of recessive dystrophic epidermolysis bullosa.

Recessive DEB–severe generalized (formerly recessive DEB–Hallopeau-Siemens) is the most incapacitating form of EB, although the clinical spectrum is wide. Some patients have blisters, scarring, and milia formation primarily on the hands, feet, elbows, and knees (Fig. 654-9). Others have extensive erosions and blister formation at birth that seriously impede their care and feeding. Mucous membrane lesions are common and may cause severe nutritional deprivation, even in older children, whose growth may be retarded. During childhood, esophageal erosions and strictures, scarring of the buccal mucosa, flexion contractures of joints secondary to scarring of the integument, development of cutaneous squamous cell carcinomas, and the development of digital fusion may significantly limit the quality of life (Fig. 654-10). Squamous cell carcinomas and infection are major causes of morbidity and mortality.

Although the skin becomes less sensitive to trauma with aging in patients with recessive DEB, the progressive and permanent deformities complicate management, and the overall prognosis is poor. Foods that traumatize the buccal or esophageal mucosa should be avoided. If esophageal scarring develops, a semiliquid diet and esophageal dilatations may be required. Stricture excision or colonic interposition may be needed to relieve esophageal obstruction. In infants, severe oropharyngeal involvement may necessitate the use of special feeding devices such as a gastrostomy tube. Iron therapy for anemia, intermittent antibiotic therapy for secondary infections, and periodic surgery for release of digits may reduce morbidity. Newer generation wound care dressings, including non-stick dressings made from silicone, are a mainstay of treatment and the daily maintenance of the skin barrier to reduce new skin trauma and promote healing. Tissue-engineered skin grafts containing keratinocytes and fibroblasts are of some benefit. Transdermal gene therapy with allogeneic fibroblasts and the delivery of functional collagens is being pursued. Allogeneic bone marrow transplantation may also be beneficial as may the induction of pluripotent stem cells.

KINDLER SYNDROME

Kindler syndrome, often considered a distant subtype of EB, contains features of both EB such as congenital blistering, and features of the congenital poikilodermas, such as Rothmund-Thomson syndrome and Bloom syndrome (see Chapter 656), which include photosensitivity, congenital poikiloderma, and progressive cutaneous atrophy. Blisters tend to appear on acral sites in infancy or early childhood and are provoked by trauma. Photosensitivity can appear as increased susceptibility to sunburn. Both blistering and photosensitivity can improve greatly with advancing age, but poikilodermatous changes can be progressive. Sclerodermoid-like changes and nail abnormalities of the hands and feet as well as dental abnormalities have been reported.

Kindler syndrome is an autosomal recessive disorder caused by mutations in *KIND1* (also known as *FERMT1*), which encodes kindlin-1, a protein thought to regulate interactions between the extracellular matrix and actin filaments. Blister formation has been shown to occur within the epidermis, within the basement membrane zone, and below the basement membrane. As Kindler syndrome is often confused with EB, at least initially, it can be confirmed by electron microscopy, immunostaining for anti-kindlin-1 antibodies within the skin, or by mutation analysis of the *KIND1* gene.

Treatment is similar to that for EB above, with efforts to reduce trauma to the skin, meticulous wound care, and treatment of skin infections. In addition, sun avoidance measures are beneficial as they can slow the rate of the development of poikiloderma.

654.5 Pemphigus

Joel C. Joyce

PEMPHIGUS VULGARIS

Etiology/Pathogenesis

Pemphigus vulgaris (PV) is a rare autoimmune blistering disorder caused by circulating antibodies to desmoglein III that result in suprabasal cleaving with consequent blister formation. Desmoglein III is a 30-kDa glycoprotein that is complexed with plakoglobin, a plaque protein of desmosomes. The desmogleins are a subfamily of the cadherin family of cell adhesion molecules.

Clinical Manifestations

PV usually first appears as painful oral ulcers, which may be the only evidence of the disease for weeks or months. Subsequently, large, flaccid bullae emerge on nonerythematous skin, most commonly on the face, trunk, pressure points, groin, and axillae. The **Nikolsky sign**

is present. The lesions rupture and enlarge peripherally, producing painful, raw, denuded areas that have little tendency to heal. When healing occurs, it is without scarring, but hyperpigmentation is common. Malodorous, verrucous, and granulomatous lesions may develop at sites of ruptured bullae, particularly in the skinfolds; as this pattern becomes more pronounced, the condition may be more properly referred to as *pemphigus vegetans*. Because the course may rapidly lead to debility, malnutrition, and death, prompt diagnosis is essential. **Neonatal PV** develops in utero as a result of placental transfer of maternal antidesmoglein antibodies from women who have active PV, although it may occur when the mother is in remission. High antepartum maternal titers of PV antibodies and increased maternal disease activity correlate with a poor fetal outcome, including demise.

Pathology

Biopsy of a fresh small blister reveals a suprabasal (intraepidermal) blister containing loose, acantholytic epidermal cells that have lost their intercellular bridges and thus their contact with one another. Immunofluorescence staining with an IgG antibody produces a characteristic pattern ("chicken wire") on direct immunofluorescence preparations of both involved and uninvolved skin of essentially all patients. Serum IgG antibody titers to desmoglein correlate with the clinical course in many patients; thus, serial determinations may have predictive value.

Differential Diagnosis

PV must be differentiated from EM, bullous pemphigoid, SJS, and TEN.

Treatment

The disease is best treated initially with systemic methylprednisolone 1-2 mg/kg/day. Azathioprine, cyclophosphamide, and methotrexate therapy all have been useful in maintenance regimens. IVIG given in cycles may be beneficial to patients whose disease does not respond to steroids. Rituximab with IVIG replacement has been effective in the management of severe pemphigus. Excellent control of the disease may be obtained, but relapse is common. It has been successfully used in children.

PEMPHIGUS FOLIACEUS

Etiology/Pathogenesis

Pemphigus foliaceus is caused by circulating antibodies to a 50-kDa portion of the 160-kDa desmosomal glycoprotein desmoglein I, which result in subcorneal cleavage leading to superficial erosions. This extremely rare disorder is characterized by subcorneal blistering; the site of cleavage is high in the epidermis rather than suprabasal as in PV.

Clinical Manifestations

The superficial blisters rupture quickly, leaving erosions surrounded by erythema that heal with crusting and scaling (Fig. 654-11). The **Nikolsky sign** is present. Focal lesions are usually localized to the scalp, face, neck, and upper trunk. Mucous membrane lesions are minimal or absent. Pruritus, pain, and a burning sensation are frequent complaints. The clinical course varies but is generally more benign than that of PV. **Fogo selvagem (endemic pemphigus foliaceus),** which is endemic in certain areas of Brazil, is identical clinically, histopathologically, and immunologically to pemphigus foliaceus. Recently, it was shown that anti–desmoglein-1 antibodies in individuals with fogo selvagem crossreact with sand fly (*Lutzomyia* sp.) salivary proteins, suggesting an environmental trigger for this autoimmune disease.

Pathology

An intraepidermal acantholytic bulla high in the epidermis is diagnostic. It is imperative to select an early lesion for biopsy. Immunofluorescent staining with an IgG antibody reveals a characteristic intercellular staining pattern similar to that of PV but higher in the epidermis.

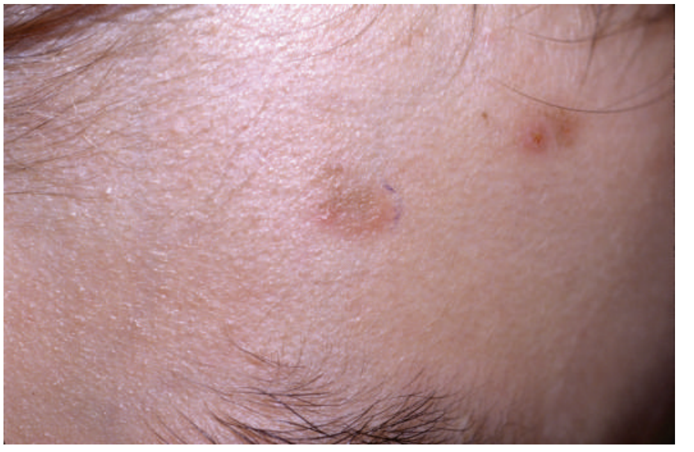

Figure 654-11 Superficial erosions in pemphigus foliaceus.

Differential Diagnosis

When generalized, the eruption may resemble exfoliative dermatitis or any of the chronic blistering disorders; localized erythematous plaques simulate seborrheic dermatitis, psoriasis, impetigo, eczema, and systemic lupus erythematosus.

For localized disease, superpotent topical corticosteroids used twice a day may be all that is needed for control until remission. For more generalized disease, long-term remission is usual after suppression of the disease by systemic methylprednisolone (1 mg/kg/day) therapy. Dapsone (25-100 mg/day) also may be used.

BULLOUS PEMPHIGOID

Etiology/Pathogenesis

Bullous pemphigoid (BP) is caused by circulating antigens to either the 180-kDa or 230-kDa BP antigen that result in a subepidermal blister. The 230-kDa protein (BP230) is part of the hemidesmosome, whereas the 180-kDa protein (BP180, now known as type XVII collagen) localizes to both the hemidesmosome and the upper lamina lucida and is a transmembrane collagenous protein.

Clinical Manifestations

The blisters of BP typically arise in crops on a normal, erythematous, eczematous, or urticarial base. Bullae appear predominantly on the flexural aspects of the extremities, in the axillae, and on the groin and central abdomen. Infants have involvement of the palms, soles, and face more frequently than older children. Individual lesions vary greatly in size, are tense, and are filled with serous fluid that may become hemorrhagic or turbid. Oral lesions occur less frequently and are less severe than in PV. Pruritus, a burning sensation, and subcutaneous edema may accompany the eruption, but constitutional symptoms are not prominent.

Pathology

Biopsy material should be taken from an early bulla arising on an erythematous base. A subepidermal bulla and a dermal inflammatory infiltrate, predominantly of eosinophils, can be identified histopathologically. In sections of a blister or perilesional skin, a band of Ig (usually IgG) and C3 can be demonstrated in the basement membrane zone by direct immunofluorescence. Indirect immunofluorescence studies of serum have positive results in ≈70% of cases for IgG antibodies to the basement membrane zone; the titers, however, do not correlate well with the clinical course.

Diagnosis and Differential Diagnoses

BP rarely occurs in children but must be considered in the differential diagnosis of any chronic blistering disorder. The **differential diagnosis** includes bullous EM, pemphigus, linear IgA dermatosis, bullous drug eruption, dermatitis herpetiformis, herpes simplex infection,

and bullous impetigo, which can be differentiated by histologic examination, immunofluorescence studies, and cultures. The large, tense bullae of BP can generally be distinguished from the smaller, flaccid bullae of PV.

Treatment

Localized bullous pemphigoid can be successfully suppressed with superpotent topical corticosteroids twice a day. Generalized disease usually requires systemic methylprednisolone (1 mg/kg/day) therapy. Rarely are other immunosuppressive treatments necessary, such as azathioprine or mycophenolate mofetil. Refractory cases have been treated with rituximab, but the condition usually remits within a year in most children.

Bibliography is available at Expert Consult.

654.6 Dermatitis Herpetiformis

Joel C. Joyce

ETIOLOGY/PATHOGENESIS

In dermatitis herpetiformis (DH), IgA antibodies are directed at epidermal transglutaminase (transglutaminase 3). **Gluten-sensitive enteropathy (celiac disease)** is found in all patients with DH, although the majority are asymptomatic or have minimal gastrointestinal symptoms (see Chapter 338.2). The severity of the skin disease and the responsiveness to gluten restriction do not correlate with the severity of the intestinal inflammation. An antibody to smooth muscle endomysium is found in 70-90% of patients with DH. Ninety percent of patients with the disease express HLA-DQ2. HLA-DQ2–negative patients with DH usually express HLA-DQ8.

CLINICAL MANIFESTATIONS

DH is characterized by symmetric, grouped, small, tense, erythematous, stinging, intensely pruritic papules and vesicles. The eruption is pleomorphic, including erythematous, urticarial, papular, vesicular, and bullous lesions. Sites of predilection are the knees, elbows, shoulders, buttocks, forehead, and scalp; mucous membranes are usually spared. Hemorrhagic lesions may develop on the palms and soles. When pruritus is severe, excoriations may be the only visible sign (Fig. 654-12).

PATHOLOGY

Subepidermal blisters composed predominantly of neutrophils are found in dermal papillae. The presence of granular IgA on direct immunofluorescence in the dermal papillary tips is diagnostic.

Figure 654-12 Multiple excoriations around the elbows in dermatitis herpetiformis.

DIFFERENTIAL DIAGNOSIS

DH may mimic other chronic blistering diseases and may also resemble scabies, papular urticaria, insect bites, contact dermatitis, and papular eczema.

TREATMENT

Patients with DH show response within weeks to months to a gluten-free diet. Oral administration of dapsone (0.5-2.0 mg/kg/day divided qd or bid) provides immediate relief from the intense pruritus but must be used with caution because of possible serious side effects (methemoglobinemia, hemolysis, and hypersensitivity syndrome [sulfone syndrome]). Dapsone alone may not relieve the intestinal inflammation of celiac disease. Local antipruritic measures may also be useful. Jejunal biopsy is indicated to diagnose gluten-sensitive enteropathy, because cutaneous manifestations may precede malabsorption. The disease is chronic and either a gluten-free diet or dapsone must be continued indefinitely to prevent relapse.

Bibliography is available at Expert Consult.

654.7 Linear Immunoglobulin A Dermatosis (Chronic Bullous Dermatosis of Childhood)

Joel C. Joyce

ETIOLOGY/PATHOGENESIS

Linear IgA dermatosis is a heterogeneous autoimmune disorder with antibodies targeting multiple antigens. It is caused by circulating IgA antibodies, most commonly to LABD97 and LAD-1, which are degradation proteins of BP180 (type XVII collagen). Linear IgA dermatosis may also be seen as a drug eruption. Most cases of drug-induced linear IgA dermatosis are related to vancomycin, although anticonvulsants, ampicillin, cyclosporine, and captopril are implicated.

CLINICAL MANIFESTATIONS

This rare dermatosis is most common in the 1st decade of life, with a peak incidence during the preschool years. The eruption consists of many large symmetrically located, tense bullae filled with clear or hemorrhagic fluid. The bullae are often clustered together and develop on a normal or erythematous, urticarial base. Areas of predilection are the genitals and buttocks (Fig. 654-13), the perioral region, and the scalp. Sausage-shaped bullae may be arranged in an annular or rosette-like fashion around a central crust (Fig. 654-14). Erythematous plaques with gyrate margins bordered by intact bullae may develop over larger areas. Pruritus may be absent or very intense, and systemic signs or symptoms are absent.

PATHOLOGY

The subepidermal bullae are infiltrated with a mixture of inflammatory cells. Neutrophilic abscesses may be noted in the dermal papillary tips, indistinguishable from those of DH. The infiltrate may also be largely eosinophilic, resembling that in BP. Therefore, direct immunofluorescence studies are required for a definitive diagnosis of linear IgA dermatosis; perilesional skin demonstrates linear deposition of IgA and sometimes IgG and C3 at the dermal–epidermal junction. Immunoelectron microscopy has localized the immunoreactants to the sublamina densa, although a combined sublamina densa and lamina lucida pattern has also been seen.

DIFFERENTIAL DIAGNOSIS

The eruption can be distinguished by histopathologic and immunofluorescence studies from pemphigus, BP, DH, and EM. Gram stain and culture preclude the diagnosis of bullous impetigo.

TREATMENT

Many cases of linear IgA dermatosis respond favorably to oral dapsone (see treatment of DH) or sulfapyridine. Other antibiotics, including erythromycin and dicloxacillin have been used, but the response is often transient. Children who show no response to dapsone may benefit from oral therapy with methylprednisolone (1 mg/kg/day) or a combination of these drugs. The usual course is 2-4 yr, although some children have persistent or recurrent disease; there are typically no long-term sequelae. IgA nephropathy is a rare complication.

Chapter 655
Eczematous Disorders
Brianne Z. Dickey and Yvonne E. Chiu

Eczematous skin disorders are a broad group of cutaneous eruptions characterized by erythema, edema, and pruritus. Acute eczematous lesions demonstrate erythema, weeping, oozing, and the formation of microvesicles within the epidermis. Chronic lesions are generally thickened, dry, and scaly, with coarse skin markings (lichenification) and altered pigmentation. Many types of eczema occur in children; the most common is **atopic dermatitis** (see Chapter 145), although seborrheic dermatitis, allergic and irritant contact dermatitis, nummular eczema, and acute palmoplantar eczema (dyshidrosis) are also relatively common in childhood.

Once the diagnosis of eczema has been established, it is important to classify the eruption more specifically for proper management. Pertinent historical data often provide the clue. In some instances, the subsequent course and character of the eruption permit classification. Histologic changes are relatively nonspecific, but all types of eczematous dermatitis are characterized by intraepidermal edema known as spongiosis.

655.1 Contact Dermatitis
Brianne Z. Dickey and Yvonne E. Chiu

The form of eczema known as contact dermatitis can be subdivided into irritant dermatitis, in which nonspecific injury to the skin causes immediate inflammation, and allergic contact dermatitis, resulting from a delayed hypersensitivity reaction. Irritant dermatitis is more frequent in children, particularly during the early years of life. Allergic reactions increase in frequency upon maturation of the immune system.

IRRITANT CONTACT DERMATITIS
Irritant contact dermatitis can result from prolonged or repetitive contact with physical, chemical, or mechanical irritants, including saliva, urine, feces, fragrance, detergents, dyes, henna, plants, caterpillars, abrasive materials, and chafing.

Irritant contact dermatitis may be difficult to distinguish from atopic dermatitis or allergic contact dermatitis. A detailed history and consideration of the sites of involvement, the age of the child, and contactants usually provide clues to the etiologic agent. The propensity for development of irritant dermatitis varies considerably among children; some may respond to minimal injury, making it difficult to identify the offending agent through history. Children with atopic dermatitis are more prone to irritant contact dermatitis as an exacerbating factor. Irritant contact dermatitis usually clears after removal of the stimulus and temporary treatment with a topical corticosteroid preparation (see Chapter 646). Education of patients and parents about the causes of contact dermatitis is crucial to successful therapy.

Dry skin dermatitis results from repetitive wet-to-dry behaviors such as lip-licking (Fig. 655-1), thumb-sucking, frequent hand washing, or excessive sweating. Involved skin is erythematous and fissured, localized to the area of exposure. Treatment of dry skin dermatitis begins with eliminating the offending wet-to-dry behavior. Moisturizer cream applied twice daily decreases transepidermal water loss and replenishes skin lipids to improve hydration. A topical steroid is usually necessary to treat the inflammation.

Juvenile plantar dermatosis occurs mainly in prepubertal children with hyperhidrosis who wear occlusive synthetic footwear. Weight-bearing surfaces of the foot may be pruritic or painful and

Figure 655-1 Perioral irritant contact dermatitis from lip licking.

Figure 655-2 Red, scaly juvenile plantar dermatosis.

develop a fissured or glazed appearance (Fig. 655-2). Immediate application of a thick emollient when socks and shoes are removed or immediately after swimming usually minimizes juvenile plantar dermatosis. Severe inflammatory cases may require short-term (1-2 wk) application of a medium- to high-potency topical steroid.

DIAPER DERMATITIS

Diaper dermatitis refers to any rash in the diaper region; the most common of these is irritant diaper dermatitis. Elevated pH in the diaper area and synergistic activity of urinary and fecal enzymes lead to inflammation, which disrupts the normal skin barrier and increases susceptibility to other irritants and organisms. Additional factors are occlusion, friction, and use of diaper wipes and topical preparations. Loose or frequent stooling predisposes an infant to diaper dermatitis. Diaper dermatitis presents with erythema and scaling, often with papulovesicular or bullous lesions, fissures, and erosions in a patchy or confluent pattern (Fig. 655-3). The genitocrural folds are often spared because concave areas are relatively protected. Chronic hypertrophic, flat-topped papules and infiltrative nodules may occur. **Candidal infection** typically represents a secondary process. It is characterized by "beefy" red-pink, tender skin that has numerous 1-2 mm pustules and satellite papules and involves both concave and convex areas. Discomfort may be marked because of intense inflammation. Allergic contact dermatitis, seborrheic dermatitis, psoriasis, candidiasis, atopic dermatitis, child abuse, and rare disorders such as Langerhans cell histiocytosis, nutritional deficiencies, and acrodermatitis enteropathica should be considered when the eruption is persistent or is recalcitrant to simple therapeutic measures.

Figure 655-3 Severe, erosive diaper dermatitis.

Diaper dermatitis often responds to simple measures; some infants are predisposed to diaper dermatitis, and management may be difficult. The damaging effects of overhydration of the skin and prolonged contact with feces and urine can be obviated by frequent changing of the diapers and periods of "rest" free of diaper use. Cleansing of affected skin is best accomplished with a soft cloth and lukewarm water, patted dry. Overwashing should be avoided because it leads to chapping and a worsening of the dermatitis. Disposable diapers containing a superabsorbent material may help maintain a relatively dry environment. First-line therapy for diaper dermatitis is application of a protective barrier agent (ointment or paste) containing petroleum or zinc oxide at every diaper change. Topical sucralfate is an effective barrier with some antibacterial activity, useful for recalcitrant cases. Low-potency nonhalogenated topical corticosteroids, such as 2.5% hydrocortisone, may be used for short time periods (3-5 days). Treatment with a topical anticandidal agent is indicated for secondary candidal infection. Topical preparations containing triamcinolone-nystatin and betamethasone dipropionate–clotrimazole are generally inappropriate for diaper dermatitis in infants because of the higher potency of the corticosteroid component. If using multiple topical agents, the protective barrier should be applied last. When diaper dermatitis does not respond to typical prevention and treatment strategies, non–diaper-associated causes must be considered.

ALLERGIC CONTACT DERMATITIS

Allergic contact dermatitis is common in childhood and should be considered in any child with recalcitrant eczema. This is a T-cell–mediated hypersensitivity reaction that is provoked by application of an antigen to the skin surface. The antigen penetrates the skin, where it is conjugated with a cutaneous protein, and the hapten–protein complex is transported to the regional lymph nodes by antigen-presenting Langerhans cells. A primary immunologic response occurs locally in the nodes and becomes generalized, presumably because of dissemination of sensitized T cells. Sensitization requires several days and, when followed by a fresh antigenic challenge, manifests as allergic contact dermatitis. Generalized distribution may also occur if enough antigen finds its way into the circulation, such as by consumption. Once sensitization has occurred, each new antigenic challenge may provoke an inflammatory reaction within 8-12 hr; sensitization to a particular antigen usually persists for many years.

Acute allergic contact dermatitis is an erythematous, intensely pruritic, eczematous dermatitis. Acute cases may be edematous and vesiculobullous. The chronic condition has the features of long-standing eczema: lichenification, scaling, fissuring, and pigmentary change. The distribution of the eruption often provides a clue to the diagnosis. Airborne sensitizers usually affect exposed areas, such as the face and arms. Jewelry, topical agents, shoes, clothing, henna tattoo dyes, plants, and even toilet seats cause dermatitis at points of contact.

Rhus dermatitis (poison ivy, poison sumac, poison oak), a response to the plant allergen urushiol, is the most common allergic contact dermatitis. It is often vesiculobullous and may be distinguished by linear streaks of vesicles where the plant leaves have brushed against the skin (Fig. 655-4). Fluid from ruptured cutaneous vesicles does not spread the eruption; antigen retained on skin, clothing, or under fingernails initiates new plaques of dermatitis if not removed by washing with soap and water. Antigen may also be carried by animals on their fur. "Black spot" poison ivy dermatitis is a rare variant that results from oxidation of concentrated urushiol left on the skin and manifests as small discrete black lacquer–like glossy papules with surrounding erythema and edema. Sensitization to 1 plant produces crossreactions with the others. Spontaneous resolution occurs in 1-3 wk, with the most common complication being secondary bacterial infection with normal skin flora. Exposure avoidance and thorough washing after exposure are the mainstays for prevention. Barrier creams or organoclay compounds such as bentoquatam may be effective if applied prior to expected exposure.

Nickel dermatitis develops from contact with jewelry, metal closures on clothing, or even cell phones. Metal closures on pants frequently cause periumbilical dermatitis (Fig. 655-5). Some children are exquisitely sensitive to nickel, with even the trace amounts found in gold jewelry provoking eruptions. The most frequently involved sites from jewelry are the earlobes from nickel-containing earrings. Early ear piercing increases risk of sensitization, and it is recommended to delay piercing until after 10 yr of age. Patch testing for nickel sensitivity is unreliable in infants and toddlers and should only be performed if there is high clinical suspicion.

Shoe dermatitis typically affects the dorsum or soles of the feet and toes, sparing the interdigital spaces; it is usually symmetric. Other forms of allergic contact dermatitis, in contrast to irritant dermatitis, rarely involve the palms and soles. Common allergens are the antioxidants and accelerators in shoe rubber, adhesives, and the chromium salts in tanned leather or shoe dyes. Excessive sweating often leaches these substances from their source.

Apparel contains a number of sensitizers, including dyes, dye fixative, fabric finishes, fibers, resins, and cleaning solutions. Dye may be poorly fixed to clothing and so may be leached out with sweating, as can partially cured formaldehyde resins. The elastic in garments is a frequent cause of clothing dermatitis, and contact allergy to the ink "tag" of tagless baby clothing has been reported. Exposure to other items with fabric, such as infant car seats, may induce reactions similar to clothing.

Topical medications and cosmetics may be unsuspected as allergens, particularly if a medication is being used for a preexisting dermatitis. The most common offenders are neomycin, topical antihistamines, topical anesthetics, fragrances, topical corticosteroids, oxybenzone and octocrylene in chemical sunscreens, preservatives, dye in temporary tattoos, and ethylenediamine, a stabilizer present in many medications. All types of cosmetics can cause facial dermatitis; involvement of the eyelids is characteristic for nail polish sensitivity.

Neomycin sulfate is present in many nonprescription topical antibiotic preparations, and thus children are frequently exposed at an early age. It is one of the most common causes of allergic contact dermatitis, and use of combination products of neomycin with other antibiotics, antifungals, or corticosteroids may induce co-reactivity with these chemically-unrelated substances.

Diagnosis of allergic contact dermatitis is usually based on history; however, patch testing may be helpful, especially in older children. Identification and avoidance of the offending agent is the mainstay of

Figure 655-4 Linear lesions in poison ivy.

Figure 655-5 Chronic periumbilical nickel dermatitis.

managing allergic contact dermatitis. First-line treatment for acute eruption is with midpotency topical corticosteroid ointment for 2-3 wk, as well as symptom management with wet dressings and sedating antihistamines to allow for sleep. Systemic corticosteroids are used when >10% of skin is involved (0.5-1.0 mg/kg prednisone for 7-10 days, followed by a 7-10 day taper). More chronic allergic contact dermatitis is treated with low- to midpotency topical corticosteroids. Desensitization therapy is rarely indicated. Differential diagnosis of allergic contact dermatitis includes herpes simplex virus, impetigo, cellulitis, atopic dermatitis, irritant contact dermatitis, and dermatophytoses.

Bibliography is available at Expert Consult.

655.2 Nummular Eczema

Brianne Z. Dickey and Yvonne E. Chiu

Nummular eczema is characterized by coin-shaped, severely pruritic, eczematous plaques, commonly involving the extensor surfaces of the extremities (Fig. 655-6), buttocks, and shoulders with facial sparing. The plaques are relatively discrete, boggy, vesicular, slightly scaly, and exudative; when chronic, they often become thickened and lichenified, and may develop central clearing. The etiology remains unclear, although nummular eczema possibly represents an atypical morphology of atopic dermatitis. Flares are generally sporadic but may be precipitated by xerosis, irritants, allergens, or occult staphylococcal infection. Most frequently, these lesions are mistaken for tinea corporis, but plaques of nummular eczema are distinguished by the lack of a raised, sharply circumscribed border, the lack of fungal organisms on a potassium hydroxide (KOH) preparation, and frequent weeping or bleeding when scraped. First-line treatment is with emollients, wet dressings, and potent topical corticosteroids. Steroid-impregnated tapes may simultaneously treat and provide barrier protection to these circumscribed eczematous plaques. An oral antihistamine may be helpful, particularly a sedating antihistamine at night. Antibiotics are indicated for secondary infection.

Bibliography is available at Expert Consult.

655.3 Pityriasis Alba

Brianne Z. Dickey and Yvonne E. Chiu

Pityriasis alba occurs mainly in children and causes lesions that are hypopigmented, ill-defined, round or oval patches (Fig. 655-7). They may be mildly erythematous and finely scaly. Lesions occur on the face, neck, upper trunk, and proximal portions of the arms, and are most pronounced on darker skin tones or after tanning of surrounding skin. Itching is minimal or absent. The cause is unknown, but the eruption appears to be exacerbated by dryness and is often regarded as a mild form of eczema. Pityriasis alba is frequently misdiagnosed as vitiligo, tinea versicolor, or tinea corporis. The lesions wax and wane but eventually disappear, and normal pigmentation often takes months to return. Application of a lubricant or emollient may ameliorate the condition. If pruritus is troublesome, a low-potency topical steroid or calcineurin inhibitor may be used.

Bibliography is available at Expert Consult.

655.4 Lichen Simplex Chronicus

Brianne Z. Dickey and Yvonne E. Chiu

Lichen simplex chronicus is a secondary skin disorder resulting from excessive scratching. It is characterized by a chronic pruritic, eczematous, circumscribed plaque that is usually lichenified and hyperpigmented (Fig. 655-8). All affected areas must be accessible to scratching, with the most common sites being the posterior neck, genitalia, wrists, ankles, and dorsal feet. Although the initiating event may be a transient lesion such as an insect bite, trauma from rubbing and scratching accounts for persistence of the plaque. Pruritus must be controlled to

permit healing, thus a covering to prevent scratching may be necessary. A high potency topical corticosteroid under occlusion is often helpful. Second-line therapy includes adding 6% salicylic acid gel to the topical corticosteroid preparation.

655.5 Acute Palmoplantar Eczema (Dyshidrotic Eczema, Dyshidrosis, Pompholyx)

Brianne Z. Dickey and Yvonne E. Chiu

A recurrent, sometimes seasonal, blistering disorder of the hands and feet, acute palmoplantar eczema occurs in all age groups but is uncommon in infancy. The pathogenesis is unknown, although possible predisposing factors include a history of atopy, exposure to contact allergens or irritants, or IV immunoglobulin therapy. The disease is characterized by recurrent crops of small, deep-seated "tapioca-like" vesicles, which are intensely pruritic and may coalesce into tense bullae (Fig. 655-9). Sites of predilection are the palms, soles, and lateral aspects of the fingers and toes. Primary lesions are noninflammatory and are filled with clear fluid, which, unlike sweat, has a physiologic pH and contains protein. Maceration and secondary infection are frequent because of scratching. The chronic phase is characterized by thickened, fissured plaques that may cause considerable discomfort, as well as dystrophic nails. Hyperhidrosis is common in many patients, but the association may be fortuitous. The diagnosis is made clinically. The disorder may be confused with allergic contact dermatitis, which usually affects the dorsal rather than the volar surfaces, and with dermatophytosis, which can be distinguished by a KOH preparation of the roof of a vesicle and by appropriate cultures.

Acute palmoplantar eczema responds to wet dressings, liberal emollient use, and potent topical corticosteroid ointment applied twice daily for 2-4 wk. Weeping skin benefits from twice daily soaking in an astringent solution, such as aluminum subacetate. Second-line treatment is topical tacrolimus 0.1% ointment. Severe disease may require oral corticosteroids with 2 wk taper, or even psoralen UVA therapy. Control of the chronic stage is difficult; lubricants containing mild keratolytic agents in conjunction with a potent topical fluorinated corticosteroid preparation may be indicated. Secondary bacterial infection should be treated systemically with an appropriate antibiotic. Patients should be told to expect recurrence and should protect their hands and feet from the damaging effects of excessive sweating, chemicals, harsh soaps, and adverse weather. Unfortunately, it is impossible to prevent recurrence or to predict its frequency.

Figure 655-9 Vesicular palmar lesions of dyshidrotic eczema with large bullae.

655.6 Seborrheic Dermatitis

Brianne Z. Dickey and Yvonne E. Chiu

ETIOLOGY

Seborrheic dermatitis is a chronic inflammatory disease most common in infancy and adolescence that parallels the distribution, size, and activity of the sebaceous glands. The cause is unknown, as is the role of the sebaceous glands in the disease. *Malassezia furfur* is implicated as a causative agent, although it remains unclear whether dermatitis results from the action of the fungus, its byproducts, or an exaggerated response of the host. In adolescence, seborrheic dermatitis typically occurs after puberty, indicating a possible role for sex hormones.

It is also unknown whether infantile seborrheic dermatitis and adolescent seborrheic dermatitis are the same or different entities. There is no evidence that children with infantile seborrheic dermatitis will experience seborrheic dermatitis as adolescents.

CLINICAL MANIFESTATIONS

The disorder may begin in the 1st mo of life and typically self-resolves by 1 yr. Diffuse or focal scaling and crusting of the scalp, sometimes called cradle cap (Fig. 655-10), may be the initial and at times the only manifestation. A greasy, scaly, erythematous papular dermatitis, which is usually nonpruritic in infants, may involve the face, neck, retroauricular areas, axillae, umbilicus, and diaper area. The dermatitis may be patchy and focal or may spread to involve almost the entire body (Fig. 655-11). Postinflammatory pigmentary changes are common, particularly in black infants. When the scaling becomes pronounced, the condition may resemble psoriasis and, at times, can be distinguished only with difficulty. The possibility of coexistent atopic dermatitis must be considered when there is an acute weeping dermatitis with pruritus, and the two are often clinically inseparable at an early age. An intractable seborrhea-like dermatitis with chronic diarrhea and failure to thrive may reflect systemic dysfunction of the immune system. A chronic seborrhea-like pattern, which responds poorly to treatment, may also result from cutaneous histiocytic infiltrates in infants with Langerhans cell histiocytosis. Seborrheic dermatitis is a common cutaneous manifestation of AIDS in young adults and is characterized by thick, greasy scales on the scalp and large hyperkeratotic erythematous plaques on the face, chest, and genitals.

During adolescence, seborrheic dermatitis is more localized and may be confined to the scalp and intertriginous areas. Also noted may be marginal blepharitis and involvement of the external auditory canal. Scalp changes vary from diffuse, brawny scaling to focal areas of

Figure 655-10 Cradle cap in an infant.

Figure 655-11 Widespread seborrheic dermatitis.

thick, oily, yellow crusts with underlying erythema. Loss of hair is common, and pruritus may be absent to marked. When the dermatitis is severe, erythema and scaling occur at the frontal hairline, the medial aspects of the eyebrows, and in the nasolabial and retroauricular folds. Red, scaly plaques may appear in the axillae, inguinal region, gluteal cleft, and umbilicus. On the extremities, seborrheic plaques may be more eczematous and less erythematous and demarcated. Unlike infantile seborrheic dermatitis, adolescent seborrheic dermatitis generally does not self-resolve and has a chronic relapsing course.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of seborrheic dermatitis includes psoriasis, atopic dermatitis, dermatophytosis, histiocytic disorders, and candidiasis. Secondary bacterial infections and superimposed candidiasis are common.

TREATMENT

Initial management for infantile seborrheic dermatitis is generally conservative given the self-limited nature of this condition. Emollients, baby oil, gentle shampooing with nonmedicated baby shampoo, and gentle use of a soft brush to remove scales are usually effective measures. Persistent lesions may be treated with low-potency topical corticosteroids if inflamed (applied once daily for 1 wk) and a topical antifungal (e.g., ketoconazole 2% cream twice daily). Antifungal shampoos such as ketoconazole 2% shampoo should be used cautiously as they are not tear-free.

First-line therapy for children and adolescents with scalp seborrheic dermatitis is antifungal shampoo used several times weekly to daily (selenium sulfide, ketoconazole, ciclopirox, zinc pyrithione, salicylic acid, or tar). Midpotency topical corticosteroids such as fluocinolone 0.01% shampoo may also be used for inflamed lesions, applied once daily for 2-4 wk. Nonscalp lesions are treated with topical corticosteroid cream (low-potency for facial lesions, midpotency elsewhere), as well as topical antifungals such as ketoconazole 2% cream or ketoconazole 2% shampoo used as a body wash. Second-line therapy for seborrheic dermatitis includes topical calcineurin inhibitors and keratolytic agents such as urea. Severe adult cases improve with oral antifungal agents; however, pediatric studies are lacking. Once acute disease is controlled, antifungal shampoo used on a weekly basis is effective maintenance to reduce risk of relapse.

Chapter 656

Photosensitivity

Brianne Z. Dickey and Yvonne E. Chiu

Photosensitivity denotes a qualitatively or quantitatively abnormal cutaneous reaction to sunlight or artificial light because of UV radiation. The UV light spectrum contains UVA (320-400 nm wavelength), UVB (290-320 nm wavelength), and UVC (100-290 nm wavelength) subtypes. Transmitted radiation <300 nm is largely absorbed in the epidermis, whereas that >300 nm is mostly transmitted to the dermis after variable epidermal melanin absorption. Children vary in susceptibility to UV radiation, depending on their skin type (i.e., its amount of pigment; Table 656-1).

ACUTE SUNBURN REACTION

The most common photosensitive reaction seen in children is acute sunburn. Sunburn is caused mainly by UVB radiation. Sunlight contains many times more UVA than UVB radiation, but UVA must be encountered in much larger quantities than UVB radiation to produce sunburn. Immediate pigment darkening is caused by UVA radiation–induced photooxidative darkening of existing melanin and its transfer from melanocytes to keratinocytes. This effect generally lasts for a few hours and is not photoprotective. UVB-induced effects appear 6-12 hr after initial exposure and reach a peak in 24 hr. Effects include redness, tenderness, edema, and blistering (Fig. 656-1). Severe sunburn induces systemic symptoms of fever, nausea, and headache. Reactive oxidation species generated by UVB induce keratinocyte

Table 656-1 Sun-Reactive Skin Types

FITZPATRICK SKIN TYPE	SUNBURN, TANNING HISTORY
I	Always burns easily, no tanning
II	Usually burns, minimal tanning
III	Sometimes burns, gradual light brown tan
IV	Minimal to no burning, always tans
V	Rarely burns, tans profusely dark brown
VI	Never burns, pigmented black

Figure 656-1 **Sunburn.** Well-demarcated, severe erythema.

membrane damage and are involved in the pathogenesis of sunburn. A portion of the vasodilation seen in UVB-induced erythema is mediated by prostaglandins E_2, E_3, and F_{2A}. Other inflammatory cytokines induced by UVB include interleukins 1, 6, and 8, and tumor necrosis factor-α. Acute sunburn is a self-limited condition that resolves within 1 wk with desquamation and without scarring. Delayed melanogenesis as a result of UVB radiation begins in 2-3 days and lasts several days to a few weeks. Manufacture of new melanin in melanocytes, transfer of melanin from melanocytes to keratinocytes, increase in size and arborization of melanocytes, and activation of quiescent melanocytes produce delayed melanogenesis. This effect reduces skin sensitivity to development of UV-induced erythema. The amount of protection afforded depends on the skin type of the patient. Additional effects and possible complications of sun exposure include increased thickness of the stratum corneum, recurrence or exacerbation of herpes simplex labialis, lupus erythematosus, and many other conditions (Table 656-2).

Acute sunburn should be managed conservatively with cool compresses, aloe vera products, and calamine lotion. Oral analgesics such as ibuprofen and acetaminophen may decrease pain. Topical corticosteroids are only helpful in the acute phase and generally should not be used to treat sunburn once peak erythema has been reached. Topical anesthetics are relatively ineffective and potentially hazardous because of their propensity to cause contact dermatitis. A bland emollient is effective in the desquamative phase.

The long-term sequelae of chronic and intense sun exposure are not often seen in children, but most individuals receive >50% of their lifetime UV dose by age 20 yr; therefore, pediatricians have a pivotal role in educating patients and their parents about the harmful effects, potential malignancy risks, and irreversible skin damage that result from prolonged exposure to the sun and tanning lights. Premature aging, senile elastosis, actinic keratoses, squamous and basal cell carcinomas, and melanomas all occur with greater frequency in sun-damaged skin. In particular, blistering sunburns in childhood and adolescence significantly increase the risk for development of malignant melanoma.

Sun protection is best achieved by sun avoidance, which includes minimizing time in the midday sun (10 AM to 3 PM), staying in the shade, and wearing protective clothing including wide-brimmed hats. Protection is enhanced by a wide variety of sunscreen agents. Physical sunscreens (zinc oxide, titanium dioxide) block UV light, whereas chemical sunscreens (para-aminobenzoic acid [PABA], PABA esters, salicylates, benzophenones, avobenzone, cinnamates, ecamsule) absorb damaging radiation. Most chemical sunscreens are effective for only UVB wavelengths but benzophenones and avobenzone provide protection in both the UVA and UVB ranges; ecamsule is a UVA sunscreen. Stabilizers such as octocrylene and diethyl 2,6-naphthalate increase the time of function of the chemical sunscreens. “Broad-spectrum” sunscreens are combination products that absorb both UVA and UVB, and families should be advised to use products labeled as “broad spectrum” with a sun protective factor (SPF) of at least 30, reapply liberally at least every 2 hr while outdoors, and reapply after swimming. Infants younger than 6 mo of age should not be exposed to direct sunlight but may have SPF 15 physical sunscreens applied to small areas of skin if sunlight avoidance is not possible. SPF is defined as the minimal dose of sunlight required to produce cutaneous erythema after application of a sunscreen, divided by the dose required with no use of sunscreen. SPF applies only to UVB protection; there is no associated rating for UVA protection in the United States aside from the “broad spectrum” designation.

Table 656-2 Cutaneous Reactions to Sunlight

SUNBURN

Photoallergic drug eruptions:
- Systemic drugs include tetracyclines, psoralens, chlorothiazides, sulfonamides, barbiturates, griseofulvin, thiazides, quinidine, phenothiazines
- Topical agents include coal tar derivatives, psoralens, halogenated salicylanilides (soaps), perfume oils (e.g., oil of bergamot), sunscreens (e.g., para-aminobenzoic acid [PABA], cinnamates, benzophenones)

Phototoxic drug eruptions:
- Systemic agents include nalidixic acid, furosemide, nonsteroidal antiinflammatory agents (naproxen, piroxicam), and high doses of agents causing photoallergic eruptions
- Topical agents include 5-fluorouracial, furocoumarins (e.g., lime, lemon, carrot, celery, dill, parsnip, parsley), and high doses of agents causing photoallergic eruptions

Genetic disorders with photosensitivity:
- Xeroderma pigmentosum
- Bloom syndrome
- Cockayne syndrome
- Rothmund-Thomson syndrome
- Trichothiodystrophy
- Smith-Lemli-Opitz syndrome
- Kindler syndrome

Inborn errors of metabolism:
- Porphyrias, protoporphyria
- Hartnup disease and pellagra

Infectious diseases associated with photosensitivity:
- Recurrent herpes simplex infection
- Viral exanthems (accentuated photodistribution; e.g., varicella)

Skin disease exacerbated or precipitated by light:
- Lichen planus
- Darier disease
- Lupus erythematosus including neonatal
- Dermatomyositis
- Psoriasis
- Erythema multiforme
- Atopic dermatitis
- Hailey-Hailey disease

Deficient protection because of a lack of pigment:
- Vitiligo
- Oculocutaneous albinism
- Phenylketonuria
- Chédiak-Higashi syndrome
- Hermansky-Pudlak syndrome
- Waardenburg syndrome

PHOTOSENSITIVE REACTIONS

Photosensitizers in combination with a particular wavelength of light (typically UVA) cause dermatitis that can be classified as phototoxic or photoallergic reactions. Contact of the skin with the photosensitizer may occur externally, internally by enteral or parenteral administration, or through host synthesis of photosensitizers in response to an administered drug.

Photoallergic reactions occur in only a small percentage of persons exposed to photosensitizers and light and require a time interval for sensitization to take place. Thereafter, dermatitis appears within 24 hr of reexposure to the photosensitizer and light. Photoallergic dermatitis is a T-cell–mediated delayed hypersensitivity reaction in which the drug, acting as a hapten, may combine with a skin protein to form the antigenic substance. Photoallergic reactions vary in morphology and may occur on partially covered and on light-exposed skin. Table 656-2 lists some of the important classes of drugs and chemicals responsible for photosensitivity reactions. The most common photoallergens are chemicals present in sunscreens.

Phototoxic reactions occur in all individuals who accumulate adequate amounts of a photosensitizing drug or chemical within the skin. UV radiation excites the agent to a state capable of causing cell or tissue damage through reactive oxygen species formation. Prior sensitization is not required. Dermatitis develops within hours after exposure to radiation in the range of 285-450 nm. The eruption is confined to light-exposed areas and often resembles exaggerated sunburn, but it may be urticarial or bullous. It results in postinflammatory hyperpigmentation. All the drugs that cause photoallergic reactions may also cause a phototoxic dermatitis if given in sufficiently high doses. Several

additional drugs and contactants cause phototoxic reactions (see Table 656-2). Differentiating contact phototoxicity from contact dermatitis caused by poison ivy or poison oak may be difficult, but itching is prominent in contact dermatitis while burning is more prominent in photodermatitis. Postinflammatory hyperpigmentation develops rapidly and can be the presenting sign. Contact with furoucoumarin-containing plants causes a disorder called **phytophotodermatitis**. The most common phytophotodermatitis seen in children is caused by lime juice, which presents as hyperpigmentation in streaky patterns on sun-exposed skin consistent with dripping juice or handprints.

Diagnosis of photosensitive reactions caused by drugs or chemicals relies on a high index of suspicion, an appreciation of the distribution pattern of the eruption, and a history of application or ingestion of a known photosensitizing agent. Phototesting and photopatch testing are also helpful when available. First-line treatment for both photoallergy and phototoxicity consists of discontinuation of the offending agent and good sun protection practices, including avoidance of sun exposure. Photoallergic reactions are treated similarly to contact dermatitis, with a topical corticosteroid to alleviate pruritus when necessary. Severe reactions may necessitate a 2-3 wk course of systemic corticosteroid therapy. Phototoxic reactions are treated similarly to sunburn, with comfort measures such as cool compresses, emollients, and oral analgesics.

PORPHYRIAS

See Chapter 91.

Porphyrias are acquired or inborn disorders due to abnormalities of specific enzyme mutations in the heme biosynthetic pathway. Some have childhood photosensitivity as a consistent feature. The pathogenesis of photosensitivity in porphyria relates to deposition of excess porphyrins in the skin; UV radiation excites these molecules, causing cell and tissue damage via generation of reactive oxygen species. Signs and symptoms may be negligible during the winter, when sun exposure is minimal.

Congenital erythropoietic porphyria (Günther disease) is a rare autosomal recessive disorder affecting the enzyme uroporphyrinogen III synthase. It may cause hydrops fetalis, but more typically manifests in the 1st few mo of life as hemolytic anemia and exquisite sensitivity to light, which may induce repeated severe bullous eruptions that result in mutilating scars (Fig. 656-2). **Hyperpigmentation,** hyperkeratosis, vesiculation, and fragility of skin as well as various nail changes develop in light-exposed areas. Light therapy for an affected neonate presenting with jaundice may inadvertently induce skin manifestations. **Hirsutism** in areas of mild involvement, scarring **alopecia** in severely affected areas, pink to red urine, brown teeth (erythrodontia), splenomegaly, and corneal ulceration are additional characteristic manifestations. Laboratory findings include uroporphyrin I and coproporphyrin I in urine, plasma, and erythrocytes, and coproporphyrin I in feces. Teeth and urine from affected patients fluoresce reddish pink under a Wood lamp as a result of the presence of porphyrins. Skin findings for **hepatoerythropoietic porphyria** closely resemble those seen in congenital erythropoietic porphyria; this extremely rare disorder presents in early childhood and is discussed in greater depth in Chapter 91.

Erythropoietic protoporphyria may be autosomal dominant, autosomal recessive, or X-linked and most commonly involves the enzyme ferrochelatase (FECH). Symptoms develop in early childhood and manifest as intense pain, tingling, or pruritus within 30 minutes of sun exposure, followed by erythema, edema, urticaria, or mild systemic symptoms; these acute manifestations resolve completely within days. The absence of blistering distinguishes erythropoietic protoporphyria from the other cutaneous porphyrias. Nail changes consist of opacification of the nail plate, onycholysis, pain, and tenderness. Recurrent sun exposure produces a subtle chronic eczematous dermatitis with thickened, lichenified skin, especially over the finger joints (Fig. 656-3*A*), as well as mild facial scarring (Fig. 656-3*B*). Pigmentation, hypertrichosis, skin fragility, and mutilation are not seen. Gallstones develop frequently; however, severe liver disease occurs in <5% of patients. Protoporphyrin is detected in plasma, erythrocytes, and feces.

The wavelengths of light mainly responsible for eliciting cutaneous reactions in porphyria are in the region of 400 nm (UVA light). Window glass, including that in automobiles, transmits wavelengths >320 nm and is not protective, and fluorescent indoor lights may be pathogenic. Patients must avoid direct sunlight, wear protective clothing, and use a sunscreen agent that effectively blocks UVA light. Oral beta-carotene also provides some photoprotective benefit. Cutaneous porphyria symptoms are typically constant throughout life, and secondary bacterial infections commonly complicate disease course. Cutaneous porphyrias do not appear to increase risk for skin malignancies. Diagnostic and treatment recommendations for **congenital erythropoietic porphyria** and **erythropoietic protoporphyria** are outlined in Chapter 91.

Figure 656-3 Erythropoietic protoporphyria. **A,** Erythematous thickening over the metacarpal phalangeal joints. **B,** Linear crusts and scarring.

COLLOID MILIUM

Colloid milium is a rare, asymptomatic disorder that occurs on the face (nose, upper lip, upper cheeks) and may extend to the dorsum of the hands and the neck as a profuse eruption of tiny, ivory to yellow, firm, grouped papules. Lesions appear before puberty on otherwise normal skin, unlike the adult variant that develops on sun-damaged skin. Onset may follow an acute sunburn or long-term sun exposure. Most cases reach maximal severity within 3 yr and remain unchanged thereafter, although the condition may remit spontaneously after puberty. Treatment is usually not necessary.

HYDROA VACCINIFORME

Hydroa vacciniforme is a vesiculobullous disorder with unclear etiology, although chronic or latent Epstein-Barr virus infections or lymphoproliferative disorders have been implicated. It begins in early childhood and may remit at puberty, with peak incidence in the spring and summer. Erythematous, pruritic macules develop symmetrically within hours of sun exposure over the ears, nose, lips, cheeks, and dorsal surfaces of the hands and forearms. Lesions progress to stinging tender papules and hemorrhagic vesicles and bullae, resembling chickenpox. They become umbilicated, ulcerated, and crusted, eventually healing with pitted scars and telangiectasias. Associated features are rare but include fever, malaise, hypersensitivity to mosquito bites, conjunctivitis, and other ocular symptoms. This eruption should be distinguished from erythropoietic protoporphyria, which rarely shows vesicles. Typical lesions have been reproduced with repeated doses of UVA or UVB light. First-line treatment includes sun avoidance, broad-spectrum sunscreens, and other sun-protective habits. Other potential therapies include mid-potency topical corticosteroids for inflamed lesions, low-dose courses of narrow-band UVB (NB-UVB) therapy, beta-carotene, hydroxychloroquine, or antiviral agents such as acyclovir.

SOLAR URTICARIA

Solar urticaria is a rare disorder induced by UV or visible irradiation. The disorder is mediated by immunoglobulin E antibodies to either an abnormal photoallergen present only in affected patients (type I) or a normal photoallergen ordinarily present in skin (type II), leading to mast cell degranulation and histamine release. Classic urticarial lesions consisting of erythematous pruritic wheals develop on sun-exposed skin (Fig. 656-4) within 5-10 minutes of sun exposure and fade within 24 hr. Severe reactions involving large areas of skin may lead to systemic symptoms or anaphylaxis. Diagnosis is achieved by history alone or with phototesting. First-line treatment is an oral H_1 antihistamine, plus sun avoidance and protection. Second-line therapy possibilities include oral or topical corticosteroids, photodesensitization using NB-UVB, omalizumab, or intravenous immunoglobulin.

POLYMORPHOUS LIGHT ERUPTION

Polymorphous light eruption (PMLE) is a common photosensitivity reaction that develops most commonly in females. The first eruption typically appears in the spring after the first episode of prolonged sun exposure of the season. Onset of the eruption is delayed by hours to days after sun exposure and lasts for days to sometimes weeks. PMLE usually resolves with increased sun exposure throughout the spring and summer. Areas of involvement tend to be symmetric and are characteristic for a given patient, including some but not all of the exposed or lightly covered skin on the face, neck, upper chest, and distal extremities. Lesions have various morphologies but most commonly are pruritic, 2-5 mm, grouped, erythematous papules or papulovesicles or >5 cm, edematous plaques; lesions are nonscarring. A PMLE variant known as **juvenile spring eruption** characteristically occurs on affected boys' ears each spring, while **pinpoint papular PMLE** is a variant characterized by pinpoint-sized lesions occurring in darker-skinned individuals. Most PMLE cases involve sensitivity to UVA radiation, although some are UVB induced. PMLE most likely results from a delayed-type hypersensitivity reaction to a photo-induced antigen within the skin, with individuals having a genetic predisposition. Provocative phototesting, as well as skin biopsy (showing epidermal spongiosis and superficial and deep lymphocytic infiltrate), aid in diagnosis. Treatment is aimed at prevention with sun avoidance, protective clothing, and broad-spectrum sunscreens. Topical corticosteroids (low-potency for facial lesions, high-potency for lesions elsewhere) can be used for mild eruptions. Second-line approaches include prophylactic NB-UVB phototherapy or hydroxychloroqine in early spring and short course systemic glucocorticoids for severe flares.

ACTINIC PRURIGO

Actinic prurigo, often classified as a variant of PMLE, is a chronic familial photodermatitis inherited as an autosomal dominant trait seen most commonly in Native Americans of North and South America. Human leukocyte antigen (HLA) DRB1*0407 (60-70%) and HLA DRB1*0401 (20%) are strongly associated with actinic prurigo. Most patients are female and are sensitive to UVA radiation. The first episode generally occurs in early childhood, several hr to 2 days after intense sun exposure. The papulonodular lesions are intensely pruritic, erythematous, and crusted. Areas of predilection include the face (Fig. 656-5), lower lip, distal extremities, and, in severe cases, buttocks. Facial lesions may heal with minute pitted or linear scarring. Lesions often become chronic, without periods of total clearing, merging into

Figure 656-4 Urticaria after 5 minutes of exposure to artificial ultraviolet A radiation.

Figure 656-5 Erythematous, excoriated papules in actinic prurigo.

eczematous plaques that become lichenified and occasionally secondarily infected. Associated features that distinguish this disorder from other photoeruptions and atopic dermatitis include cheilitis, conjunctivitis, and traumatic alopecia of the outer half of the eyebrows. Actinic prurigo is a chronic condition that generally persists into adult life, although it may improve spontaneously in the late teenage years. Sun avoidance, protective clothing, and broad-spectrum sunscreens may be helpful in preventing the eruption. Mid- to high-potency topical corticosteroids and antihistamines palliate the pruritus and inflammation. Severe acute eruptions may require oral glucocorticoids. Treatment with NB-UVB beginning in springtime has shown improved tolerance of sunlight during summer months; however, it may induce symptoms in some patients. Thalidomide 50-100 mg/day is very effective, but its use is limited by toxicity, especially severe birth defects when taken by pregnant females.

COCKAYNE SYNDROME

Cockayne syndrome is a rare autosomal recessive disorder. Onset occurs at 1 year of age and is characterized by facial erythema in a butterfly distribution after sun exposure. Later characteristics include loss of adipose tissue and development of thin, atrophic, hyperpigmented skin, particularly over the face. Associated features include dwarfism; microcephaly; mental retardation; progressive dementia; distinct facies (aged look, pinched nose, sunken eyes, large protuberant ears); long limbs; disproportionately large hands and feet; cool and cyanotic extremities; carious teeth; unsteady gait with tremor; limitation of joint mobility; progressive deafness; cataracts; retinal degeneration; optic atrophy; decreased sweating and tearing; and premature graying of the hair. Complications include diabetes and hepatic or renal impairment. Diffuse extensive demyelination of the peripheral and central nervous systems ensues, and patients generally die of atheromatous vascular disease or infections (especially pneumonia) before the 3rd decade. There are 2 types of Cockayne syndrome. Type I (*CSA* gene) is less severe than type II (*CSB* gene). Patients may have xeroderma pigmentosum–Cockayne syndrome overlap, which is phenotypically more like Cockayne syndrome. Photosensitivity in Cockayne syndrome is a result of deficient nucleotide excision repair of UV-induced damage, specifically within actively transcribing regions of DNA (transcription-coupled DNA repair). The etiology of neurologic and other associated features remains unclear; however, evidence points toward a mitochondriopathy. The syndrome is distinguished from progeria (see Chapter 90) by the presence of photosensitivity and ocular abnormalities and from xeroderma pigmentosum by the fact that patients with Cockayne syndrome do not develop skin cancers. Diagnosis is accomplished by genetic testing and performing various tests on cultured fibroblasts. The mainstay of treatment for the photosensitivity of Cockayne syndrome is strict sunlight avoidance and protective measures.

XERODERMA PIGMENTOSUM

Xeroderma pigmentosum is a rare autosomal recessive disorder that results from a defect in nucleotide excision repair. Eight genetic groups have been recognized on the basis of each group's separate defect in ability to repair (xeroderma pigmentosum A through G) or replicate (xeroderma pigmentosum V [variant]) damaged DNA. The wavelength of light that induces the DNA damage ranges from 280-340 nm. Skin changes are first noted during infancy or early childhood in sun-exposed areas though lesions may occur at other sites, including the scalp. The skin lesions consist of erythema, scaling, bullae, crusting, ephelides (freckles), telangiectasia, keratoses (Fig. 656-6), basal and squamous cell carcinomas, and malignant melanomas. Interestingly, although most patients experience exaggerated acute sunburn reactions following minimal UV exposure, up to half of affected patients do not and instead develop progressive freckling. This difference in presentation depends on genetic subtype. Ocular manifestations include photophobia, lacrimation, blepharitis, symblepharon, keratitis, corneal opacities, tumors of the lids, and possible

Figure 656-6 Dyspigmentation and actinic keratoses in child with xeroderma pigmentosum.

Figure 656-7 Poikiloderma on the arm of an infant with Rothmund-Thomson syndrome.

eventual blindness. Neurologic abnormalities such as cognitive deterioration and sensorineural deafness develop in approximately 20% of patients.

This disease is a serious mutilating disorder, and the life span of an affected patient is often brief. Affected families should have genetic counseling. Xeroderma pigmentosum is detectable in cells cultured from amniotic fluid or DNA analysis of chorionic villous samples. Cultured skin fibroblast tests and genetic testing after birth also confirm diagnosis. Affected children should be totally protected from sun exposure; protective clothing, sunglasses, and opaque broad-spectrum sunscreens should be used even for mildly affected children. Light from unshielded fluorescent bulbs and sunlight passing through glass windows (including vehicle windows) are also harmful, thus applied window films are recommended. Early detection and removal of malignancies is mandatory, and oral isotretinoin may be used to prevent nonmelanoma skin cancers. There is crossover between several subtypes of xeroderma pigmentosum and both Cockayne syndrome and trichothiodystrophy.

ROTHMUND-THOMSON SYNDROME

Rothmund-Thomson syndrome is also known as poikiloderma congenitale because of the striking skin changes (Fig. 656-7). It is inherited as an autosomal recessive trait. Mutations in the *RECQL4* gene, which encodes a DNA helicase involved in repair and replication of DNA and

telomeres, are found in approximately 65% of patients. The other mutations causing Rothmund-Thomson syndrome are unknown. Skin changes are noted as early as 3 mo of age and begin on the face. Plaques of erythema and edema appear in a butterfly distribution, as well as on the forehead, ears, neck, dorsal portions of the hands, extensor surfaces of the arms, and buttocks. These are replaced gradually by poikiloderma (reticulated, atrophic, hyperpigmented and hypopigmented telangiectatic patches or plaques). Palmoplantar hyperkeratosis develops in one-third of patients. Light sensitivity is present in many cases, and exposure to the sun may provoke formation of bullae. Areas of involvement, however, are not strictly photodistributed. Short stature; small hands and feet; sparse eyebrows, eyelashes, and pubic and axillary hair, and sparse, fine, prematurely gray scalp hair or alopecia; dystrophic nails; various tooth and skeletal abnormalities; and hypogenitalism are common. Cataracts may also occur at an early age. Most patients have normal mental development. Keratoses and later squamous cell carcinomas may develop on exposed skin. The most worrisome association is that with osteosarcoma, which occurs only in those patients with Rothmund-Thomson syndrome and *RECQL4* mutations. Genetic testing aids diagnosis. Management of dermatologic findings begins with sun avoidance and protection behaviors, and telangiectatic lesions have been shown to respond to pulsed dye laser therapy. In the absence of malignancy, life expectancy is normal.

BLOOM SYNDROME

Bloom syndrome is inherited in an autosomal recessive manner, most commonly in the Ashkenazi Jewish population. It is caused by a mutation in the *BLM/RECQL3* gene, encoding a DNA helicase. Patients are sensitive to UV radiation, with increased rates of chromosomal breaks and sister chromatid exchanges. Erythema and telangiectasia develop during infancy in a butterfly distribution on the face after exposure to sunlight. A bullous eruption on the lips and telangiectatic erythema on the hands and forearms may develop. Café-au-lait spots and hypopigmented macules may be present. Intrauterine growth deficiency developing into short stature and a distinctive facies consisting of a prominent nose and ears and a small, narrow face are generally found. Intellect is average to low average. Immunodeficiency is seen in all patients, manifesting as recurrent ear and pulmonary infections. Gastrointestinal malabsorption, gastroesophageal reflux, and hypogonadism are common. Affected children have an unusual tendency to develop both solid tumors (especially of the skin) and lymphoreticular malignancies, which often result in death during childhood or early adulthood. Sister chromatid exchange analysis is generally performed to confirm diagnosis. The only effective measures to reduce skin disease are sun protection and avoidance.

HARTNUP DISEASE

See Chapter 85.5.

Hartnup disease is a rare inborn error of metabolism with autosomal recessive inheritance. Neutral amino acids, including tryptophan, are not transported across the brush border epithelium of the intestine and kidneys due to mutation of the SLC6A19 gene encoding the transporter. This results in deficiency of nicotinamide synthesis and causes a photo-induced **pellagra-like syndrome.** The urine contains increased amounts of monoamine monocarboxylic amino acids, distinguishing Hartnup disease from dietary pellagra. Cutaneous signs, which precede neurologic manifestations, initially develop during the early months of life. An eczematous, occasionally vesiculobullous, eruption occurs on the face and extremities in a glove-and-stocking photodistribution. Hyperpigmentation and hyperkeratosis may supervene and are intensified by further exposure to sunlight. Episodic flares may be precipitated by febrile illness, sun exposure, emotional stress, and poor nutrition. In most cases, mental development is normal, but some patients display emotional instability and episodic cerebellar ataxia. Neurologic symptoms are fully reversible. Administration of nicotinamide and protection from sunlight results in improvement of both cutaneous and neurologic manifestations.

Chapter 657
Diseases of the Epidermis

657.1 Psoriasis

Brianne Z. Dickey and Yvonne E. Chiu

ETIOLOGY/PATHOGENESIS

Psoriasis is an inflammatory autoimmune-related disease characterized by inflammation and keratinocyte proliferation. Within the dermis, dendritic cells are activated by self-antigens and release cytokines such as interferon-γ, tumor necrosis factor, and interleukin (IL)-12, IL-17, IL-22, and IL-23, which recruit T cells. Once activated, the T cells release cytokines that induce proliferation and abnormal differentiation of epidermal keratinocytes; in turn, more cytokines are produced to perpetuate the cycle. Psoriasis has a complex multifactorial genetic basis. The major psoriasis-susceptibility gene *(PSORS1)* is human leukocyte antigen (HLA)-CW*0602, encoding a class I major histocompatibility complex protein involved in recognition of self-antigens. Numerous other psoriasis susceptibility genes have been identified.

Factors contributing to disease onset/flares in some patients include bacterial and viral infections, trauma, physical or emotional stress, tobacco use/secondhand exposure, and certain medications. There is an association between psoriasis and childhood obesity worldwide.

CLINICAL MANIFESTATIONS

This common, chronic skin disorder is first evident within the 1st 2 decades of life for approximately 30% of affected individuals. **Plaque psoriasis**, the most common (>80%) subtype, is characterized by erythematous papules that coalesce to form plaques with sharply demarcated, irregular borders. If they are unaltered by treatment, a thick silvery or yellow-white scale (resembling mica) develops (Fig. 657-1*A*). Removal of the scale may result in pinpoint bleeding (**Auspitz sign**). The **Koebner phenomenon,** in which new lesions appear at sites of trauma, is a valuable diagnostic feature. Lesions may occur anywhere, but preferred sites are the scalp, knees, elbows, umbilicus, superior intergluteal fold, genitals, and ear canal. Nail involvement, a valuable diagnostic sign, is characterized by pitting of the nail plate, detachment of the plate (onycholysis), yellowish-brown subungual discoloration, and accumulation of subungual debris (Fig. 657-1*B*). Plaques are generally asymptomatic; however, pruritus is more common in children than adults.

Guttate psoriasis, a variant that occurs predominantly in children, is characterized by an acute eruption of many oval or round papules smaller than 1.5 cm that are morphologically identical to the larger plaques of psoriasis (see Fig. 657-1*C*). Sites of predilection are the trunk, face, and proximal portions of the limbs. The onset usually follows a **streptococcal** infection such as pharyngitis; thus, throat culture and serologic titers should be obtained. Guttate psoriasis has also been observed after perianal streptococcal infection, viral infections, sunburn, and withdrawal of systemic corticosteroid therapy or tumor necrosis factor (TNF)-α inhibitors. Clinical course ranges from spontaneous resolution to chronic disease.

Pustular psoriasis is a multisystem autoinflammatory disease characterized by recurrent episodes with the sudden onset of fever, malaise, extracutaneous organ involvement, and a diffuse erythematous-pustular exanthema. It may be associated with plaque psoriasis in some patients; unregulated cytokine production as a result of mutations in the IL-36Ra gene is implicated.

Psoriasis is rare in infants but may be severe and recalcitrant and may pose a diagnostic problem. Psoriatic diaper rash is a common presentation in children younger than 2 yr old. Other rare forms

Figure 657-1 **A,** Chronic psoriatic plaques. **B,** Psoriatic nail dystrophy. **C,** Guttate psoriasis in widespread distribution over the trunk.

include psoriatic erythroderma, localized or generalized pustular psoriasis, linear psoriasis, palmoplantar psoriasis, and inverse psoriasis (occurring in intertriginous areas).

DIFFERENTIAL DIAGNOSIS

Psoriasis is a clinical diagnosis. The differential diagnosis of plaque-type psoriasis includes nummular dermatitis, tinea corporis, seborrheic dermatitis, postinfectious arthritis syndromes, and pityriasis rubra pilaris. Scalp lesions may be confused with seborrheic dermatitis, atopic dermatitis, or tinea capitis. Diaper area psoriasis may mimic seborrheic dermatitis, eczematous diaper dermatitis, perianal streptococcal disease, or candidiasis. Guttate psoriasis can be confused with viral exanthems, secondary syphilis, pityriasis rosea, and pityriasis lichenoides chronica (PLC). Nail psoriasis must be differentiated from onychomycosis, lichen planus, and other causes of onychodystrophy.

PATHOLOGY

When the diagnosis is in doubt, histopathologic examination of an untreated lesion can be helpful. Characteristic changes of psoriasis include parakeratosis, acanthosis, elongated rete ridges, neutrophilic infiltrate in the epidermis sometimes forming microabscesses, dilated dermal blood vessels, and lymphocytic infiltrate in the dermis.

TREATMENT

The therapeutic approach varies with the age of the child, type of psoriasis, sites of involvement, and extent of the disease. Physical and chemical trauma to the skin should be avoided as much as possible to prevent Koebner response lesions. The treatment of psoriasis should be viewed as a 4-tier process.

The **first tier** is **topical therapy.** The first-line topical agents for lesions on the body are emollients, vitamin D analogs (calcipotriene or calcitriol, although calcitriol is less irritating for children), and mid- to high-potency corticosteroids (see Chapter 646). A proprietary formulation containing both calcipotriene and betamethasone dipropionate (a high-potency topical corticosteroid) exists in ointment and solution forms. The preparation that is least potent but effective should be applied twice a day. Second-line topical options for lesions on the body include retinoids (tazarotene), tar preparations, anthralin, and keratolytics (salicylic acid or urea). Facial or intertriginous lesions may be treated with low-potency topical corticosteroids, and/or topical vitamin D analogs or calcineurin inhibitors as corticosteroid-sparing agents. For scalp lesions, applications of a phenol and saline solution (e.g., Baker Cummins P & S liquid) followed by a tar shampoo are effective in the removal of scales. A high- to superpotency corticosteroid in a foam, solution, or lotion base may be applied when the scaling is diminished. Nail lesions are difficult to treat topically; the first-line approach is a high-potency topical corticosteroid to the proximal nail fold.

The **second tier** of therapy is **phototherapy.** Narrow-band UVB (311 nm; NB-UVB) irradiation is the primary form of UVB therapy used in childhood. If available, phototherapy should be used alone or with tar ("Goeckerman treatment") for older children with extensive disease in whom topical therapy alone has failed. Excimer (308 nm) laser UVB irradiation may be used for localized treatment-resistant plaques. Exposure to natural sunlight is often effective for less-severe psoriasis.

The **third tier** is **systemic therapy, required rarely for** children with severe and generalized psoriasis. Methotrexate (0.2-0.7 mg/kg/wk) is the first-line systemic agent for children; other options include oral

retinoids (0.5-1.0 mg/kg/day) and cyclosporine (3-5 mg/kg/day). Oral retinoids may be cautiously combined with phototherapy, although doses may need to be decreased because of the photosensitizing effects of the medication.

The **fourth tier** of therapy is the **biologic response modifiers**, including the TNF-α inhibitors etanercept, infliximab, and adalimumab, and the T-cell function inhibitor alefacept. Ustekinumab is a human monoclonal antibody that prevents interactions between IL-12 and IL-23 and their cell-surface receptors. Anti–IL-17 and anti–IL-17 receptor agents also demonstrate some efficacy. Adult studies with all of these agents show efficacy in treating moderate to severe chronic psoriasis and psoriatic arthritis, although experience in children is limited. Novel small molecules that inhibit the inflammatory response are being tested; these include A3 adenosine receptor agonists, Janus kinase inhibitors, and phosphodiesterase 4 inhibitors.

PROGNOSIS

Prognosis is best for children with limited disease. Psoriasis is a lifelong disease characterized by remissions and exacerbations. Arthritis or various eye diseases may be extracutaneous complications. Metabolic and cardiovascular disorders also occur with increased frequency in patients with psoriasis. For example, increasing degree of obesity and the associated metabolic syndrome (hyperglycemia, hyperlipidemia, hypertension) correlates with psoriasis severity. Patients with psoriasis also have increased rates of stroke, myocardial infarction, and other vascular diseases later in adult life. A proposed mechanism involves the systemic proinflammatory state induced by both psoriasis and these associated conditions, although the direction of causality remains unclear.

Bibliography is available at Expert Consult.

657.2 Pityriasis Lichenoides

Brianne Z. Dickey and Yvonne E. Chiu

Pityriasis lichenoides encompasses a disease spectrum ranging from pityriasis lichenoides chronica (PLC) to pityriasis lichenoides et varioliformis acuta (PLEVA; Mucha-Habermann disease). The designation of pityriasis lichenoides as acute or chronic refers to the morphologic appearance of the lesions rather than to the duration of the disease. No correlation is found between the type of lesion at the onset of the eruption and the duration of the disease. Many patients have both acute and chronic lesions simultaneously, and transition of lesions from 1 form into another occurs occasionally. Febrile ulceronecrotic Mucha-Habermann disease (FUMHD) is a rare subtype of PLEVA that is more severe and potentially life-threatening.

ETIOLOGY/PATHOGENESIS

Two main theories exist for the etiology of pityriasis lichenoides. The first is that it arises in a genetically susceptible individual as a hypersensitivity reaction to an infection. The second is that it represents a monoclonal T-cell lymphocytic proliferation on the pathway to cutaneous T-cell dyscrasia.

CLINICAL MANIFESTATIONS

Pityriasis lichenoides most commonly manifests in the 2nd and 3rd decades of life; 30% of cases manifest before age 20 yr. The overall eruption persists for months to years with a tendency to eventually remit.

PLC manifests gradually as generalized, multiple, 3-5 mm, brown-red papules that are covered by a fine grayish scale (Fig. 657-2). Lesions may be asymptomatic or may cause minimal pruritus and occasionally become vesicular, hemorrhagic, crusted, or superinfected. Individual papules become flat and brownish in 2-6 wk, ultimately leaving a hyperpigmented or hypopigmented macule. Scarring is unusual. Various stages of lesions are present most commonly on the trunk and extremities and generally spare the face, palmoplantar surfaces, scalp, and mucous membranes.

Figure 657-2 Widespread plaques with fine scale in pityriasis lichenoides chronica.

Figure 657-3 Necrotic lesion with erythematous halo in pityriasis lichenoides et varioliformis acuta.

PLEVA manifests as an abrupt eruption of numerous papules that have a vesiculopustular and then a purpuric center, are covered by a dark adherent hemorrhagic or necrotic crust, and are surrounded by an erythematous halo (Fig. 657-3). Constitutional symptoms, such as fever, malaise, headache, and arthralgias, may be present for 2-3 days after the initial outbreak. Lesions are distributed diffusely on the trunk and extremities, as in PLC. Individual lesions heal within a few weeks, sometimes leaving a varioliform scar, and successive crops of papules produce the characteristic polymorphous appearance of the eruption, with lesions in various stages of evolution.

FUMHD manifests as fever and ulceronecrotic nodules up to a few centimeters in diameter, which are most common on the anterior trunk and flexor surfaces of the proximal upper extremities. Hemorrhagic bullae, mucosal ulcers, arthritis, cardiomyopathy, vasculitis, abdominal complaints, and superinfection of cutaneous lesions with *Staphylococcus aureus* may also develop. The ulceronecrotic lesions heal with hypopigmented scarring in a few weeks.

PATHOLOGY

PLC histologically shows a parakeratotic, thickened corneal layer; epidermal spongiosis; a superficial perivascular infiltrate of macrophages and predominantly CD8 lymphocytes that may extend into the epidermis; and small numbers of extravasated erythrocytes in the papillary dermis.

van de Kerkhof PCM: Apremilast: a step forward in the treatment of psoriasis, *Lancet* 380:708–709, 2012.

The histopathologic changes of PLEVA and FUMHD reflect their more-severe nature. Intercellular and intracellular edema in the epidermis may lead to degeneration of keratinocytes. A dense perivascular mononuclear cell infiltrate, endothelial cell swelling, and extravasation of erythrocytes into the epidermis and dermis are additional characteristic features.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of pityriasis lichenoides includes guttate psoriasis, pityriasis rosea, drug eruptions, secondary syphilis, viral exanthems, lymphomatoid papulosis, and lichen planus. The chronicity of pityriasis lichenoides helps preclude pityriasis rosea, viral exanthems, and some drug eruptions. A skin biopsy helps distinguish pityriasis lichenoides from other entities in the differential diagnosis.

TREATMENT

In general, pityriasis lichenoides should be considered a benign condition that does not alter the health of the child. A lubricant to remove excessive scaling may be all that is necessary if the patient is asymptomatic. If treatment is required, first-line agents are oral anti-inflammatory antibiotics such as erythromycin (30-50 mg/kg/day for 2-3 mo). Topical corticosteroids (mid-potency, applied twice daily) and topical calcineurin inhibitors may help the pruritus and inflammation, but do not alter the course of the disease. Phototherapy (NB-UVB) is the second-line treatment option. Methotrexate should be reserved for severely symptomatic cases. The rare FUMHD usually requires inpatient treatment; initially, systemic corticosteroids, methotrexate, intravenous immunoglobulin, or cyclosporine may be necessary, with eventual transition to another form of treatment, as mentioned above, once the disease improves and stabilizes.

Bibliography is available at Expert Consult.

657.3 Keratosis Pilaris

Brianne Z. Dickey and Yvonne E. Chiu

Keratosis pilaris is a common papular eruption resulting from keratin plugging of hair follicles. It displays an autosomal dominant transmission with variable penetrance. Typical areas of involvement include the upper extensor surfaces of the arms and thighs, cheeks, and buttocks. The lesions may resemble gooseflesh; they are noninflammatory, scaly, follicular papules that do not coalesce. They are generally asymptomatic but may be pruritic. Irritation of the follicular plugs occasionally causes erythema surrounding the keratotic papules (Fig. 657-4). A subset of patients have keratosis pilaris associated with facial telangiectasia and ulerythema ophryogenes, a rare cutaneous disorder characterized by inflammatory keratotic facial papules that may result in scars, atrophy, and alopecia. Because the lesions of keratosis pilaris are associated with and accentuated by dry skin, they are often more prominent during the winter. Keratosis pilaris is more frequent in patients with atopic dermatitis and is most common during childhood and early adulthood, tending to subside in the 3rd decade of life. Treatment of keratosis pilaris is optional. Measures to decrease pruritus include moisturization with a bland emollient. Regular applications of a 10-40% urea cream or an α-hydroxy acid preparation such as 12% lactic acid cream or lotion can improve the appearance of keratosis pilaris but may further contribute to pruritus and irritation. Therapy may improve the condition but does not cure it.

Figure 657-4 Keratotic follicular plugs with surrounding erythema in keratosis pilaris.

657.4 Lichen Spinulosus

Brianne Z. Dickey and Yvonne E. Chiu

Lichen spinulosus is an uncommon disorder that occurs principally in children and more frequently in boys. The cause is unknown. The lesions consist of sharply circumscribed irregular plaques of spiny, keratotic, follicular plugs. Plaques may occur anywhere on the body and are often distributed symmetrically on the trunk, elbows, knees, and extensor surfaces of the limbs. Although sometimes erythematous or pruritic, the lesions are usually skin colored and asymptomatic.

Treatment is usually unnecessary. For patients who regard the eruption as a cosmetic defect, urea-containing lubricants (10-40%) are often effective in flattening the projections. The plaques usually disappear spontaneously after several months or years.

657.5 Pityriasis Rosea

Brianne Z. Dickey and Yvonne E. Chiu

ETIOLOGY/PATHOGENESIS

The cause of pityriasis rosea is unknown; a viral agent is suspected, and there is debate over the role of human herpesviruses 6, 7, and 8 in this condition. Supporting evidence for an infectious etiology is the tendency for it to occur in case clusters, although the rash itself is not contagious.

CLINICAL MANIFESTATIONS

This benign, common eruption occurs most frequently in children and young adults. Although a prodrome of fever, malaise, arthralgia, and pharyngitis may precede the eruption, children rarely complain of such symptoms. A **herald patch** classically precedes the generalized eruption and may occur anywhere on the body. Herald patches are generally larger than other lesions and vary from 1-10 cm in diameter; they are annular in configuration and have a raised border with fine, adherent scales. Approximately 5-10 days after the appearance of the herald patch, a widespread, symmetric eruption involving mainly the trunk and proximal limbs becomes evident (Fig. 657-5). In the inverse form of pityriasis rosea, the face, scalp, and distal limbs may be preferentially involved. Lesions may appear in crops for several days. Typical lesions are oval or round, <1 cm in diameter, slightly raised, and pink to brown. The developed lesion is covered by a fine scale, which gives the skin a crinkly appearance. Some lesions clear centrally and produce a collarette of scale that is attached only at the periphery. Papular (more common in black children), vesicular, urticarial, hemorrhagic, large annular, and mucosal lesions are unusual variants. The long axis of each lesion is usually aligned with the cutaneous cleavage lines, a feature that creates the so-called **Christmas tree pattern** on the back. Conformation to skin lines is often more discernible in the anterior and posterior axillary folds and supraclavicular areas. The lesions most commonly are asymptomatic but may be mildly to severely pruritic.

Bibliography

Lam J, Pope E: Pediatric pityriasis lichenoides and cutaneous T-cell lymphoma, *Curr Opin Pediatr* 19:441–445, 2007.

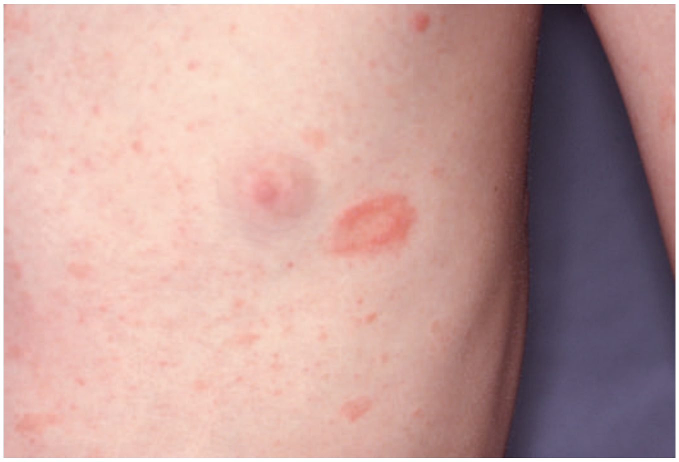

Figure 657-5 Herald patch and surrounding pityriasis rosea.

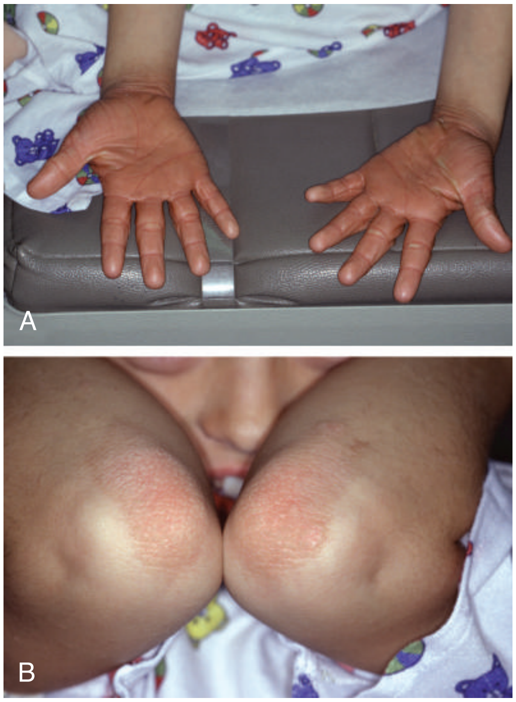

Figure 657-6 Pityriasis rubra pilaris. **A,** Orange palmar hyperkeratosis. **B,** Elbow lesions.

Duration of the eruption varies from 2-12 wk, with self-resolution. After the eruption has resolved, postinflammatory hypopigmentation or hyperpigmentation may be pronounced, particularly in dark-skinned patients. These changes disappear in subsequent weeks to months.

DIFFERENTIAL DIAGNOSIS

The herald patch may be mistaken for tinea corporis, a pitfall that can be avoided if microscopic evaluation of a potassium hydroxide preparation of scrapings of the lesion is performed. The generalized eruption resembles a number of other diseases; secondary syphilis is the most important. Drug eruptions, viral exanthems, guttate psoriasis, PLC, and nummular dermatitis can also be confused with pityriasis rosea.

TREATMENT

Therapy is unnecessary for asymptomatic patients with pityriasis rosea. If scaling is prominent, a bland emollient may suffice. Pruritus may be suppressed by a lubricating lotion containing menthol and camphor or by an oral antihistamine for sedation, particularly at night, when itching may be troublesome. Occasionally, a mid-potency topical corticosteroid preparation may be necessary to alleviate pruritus. Exposure to natural sunlight and NB-UVB phototherapy may reduce disease duration and severity.

Bibliography is available at Expert Consult.

657.6 Pityriasis Rubra Pilaris

Brianne Z. Dickey and Yvonne E. Chiu

ETIOLOGY/PATHOGENESIS

The cause of pityriasis rubra pilaris is unknown. Although genetic forms with autosomal dominant or recessive transmission may account for some cases in childhood, most cases are sporadic. Some studies have indicated a role for TNF-α in disease development, while other hypotheses for causal factors include abnormal vitamin A metabolism, trauma, infections, immunosuppression, and UV light exposure.

CLINICAL MANIFESTATIONS

This rare inflammatory dermatosis is known for its variability in clinical presentation and course of disease. It often has an insidious onset with diffuse scaling and erythema of the scalp, which is indistinguishable from the findings in seborrheic dermatitis, and with thick hyperkeratosis of the palms and soles (Fig. 657-6*A*). Lesions over the elbows and knees are also common (Fig. 657-6*B*), and generalized erythroderma develops in some patients. The characteristic primary lesion is a firm, dome-shaped, tiny, acuminate, pink to red papule, which has a central keratotic plug pierced by a vellus hair. Masses of these papules coalesce to form large, erythematous, sharply demarcated orange-pink plaques with overlying scale, within which islands of normal skin can be distinguished. Typical papules on the dorsum of the proximal phalanges are readily palpated. Gray plaques or papules resembling lichen planus may be found in the oral cavity. Dystrophic changes in the nails may occur and mimic those of psoriasis. Lesions are commonly pruritic. In childhood, the prognosis for eventual resolution is relatively good.

DIFFERENTIAL DIAGNOSIS

Differential diagnosis includes ichthyosis, seborrheic dermatitis, keratoderma of the palms and soles, and psoriasis.

HISTOLOGY

Skin biopsy revealing follicular plugging, epidermal acanthosis, perivascular infiltrate, checkerboard pattern of orthokeratosis and parakeratosis, and an intact granular layer may differentiate this condition from psoriasis and seborrheic dermatitis.

TREATMENT

The numerous therapeutic regimens recommended are difficult to evaluate because pityriasis rubra pilaris has a capricious course with exacerbations and remissions. Moisturization alone is useful in mild cases. Topical agents, such as mid- to high-potency corticosteroids, keratolytics (urea, salicylic acid), vitamin D analogs (calcipotriene), retinoids (tazarotene, tretinoin), and tar, are used in combination with systemic agents for widespread disease and as monotherapy for localized disease. When further treatment is necessary, oral retinoids (isotretinoin 1 mg/kg/day or acitretin 0.5 mg/kg/day) are used as first-line agents, while methotrexate is used as a second-line agent. Third-line treatment options include biologic TNF-α inhibitors, cyclosporine, azathioprine, and NB-UVB phototherapy.

Bibliography is available at Expert Consult.

657.7 Darier Disease (Keratosis Follicularis)

Brianne Z. Dickey and Yvonne E. Chiu

ETIOLOGY/PATHOGENESIS

A rare genetic disorder, Darier disease is inherited as an autosomal dominant trait and is caused by mutations in the *ATP2A2* gene. This gene encodes a cellular calcium pump, and dysfunction results in loss of adhesion between epidermal cells and abnormal keratinization.

CLINICAL MANIFESTATIONS

Onset usually occurs in late childhood. Typical lesions are small, firm, skin-colored, warty papules that are not always follicular in location. The lesions eventually acquire yellow, malodorous, greasy crusts and coalesce to form large, gray-brown, vegetative plaques (Fig. 657-7). The scalp, face, neck, shoulders, chest, back, axillae, limb flexures, and groin are symmetrically involved. Papules, fissures, crusts, and ulcers may appear on the mucous membranes of the lips, tongue, buccal mucosa, pharynx, larynx, and vulva. Hyperkeratosis of the palms and soles and nail dystrophy with subungual hyperkeratosis and longitudinal red and white banding are variable features. Severe pruritus, secondary infection, offensive odor, and pain may occur. Several exacerbating triggers have been identified: sweating, UV light exposure, heat, friction, and infections. Thus, Darier disease has a chronic relapsing course that usually worsens in summertime.

HISTOLOGY

Histologic changes seen in Darier disease are diagnostic. Hyperkeratosis with keratin plugging, intraepidermal separation (acantholysis) with formation of suprabasal clefts, and dyskeratotic epidermal cells are characteristic features.

DIFFERENTIAL DIAGNOSIS

Darier disease is most likely to be confused with seborrheic dermatitis, flat warts, or Hailey-Hailey disease.

TREATMENT

Treatment is nonspecific and begins with emollients and avoidance of triggers. First-line treatment for mild/localized disease is low- to mid-potency corticosteroids; second-line is topical retinoids. Further treatment options include topical keratolytic agents (urea, lactic acid), antiseptic washes (triclosan, chlorhexidine gluconate, or bleach), or calcineurin inhibitors. More severe/generalized disease is treated with oral isotretinoin or acitretin (0.5-1.0 mg/kg/day for 3-4 mo). Secondary infections must be treated appropriately.

Bibliography is available at Expert Consult.

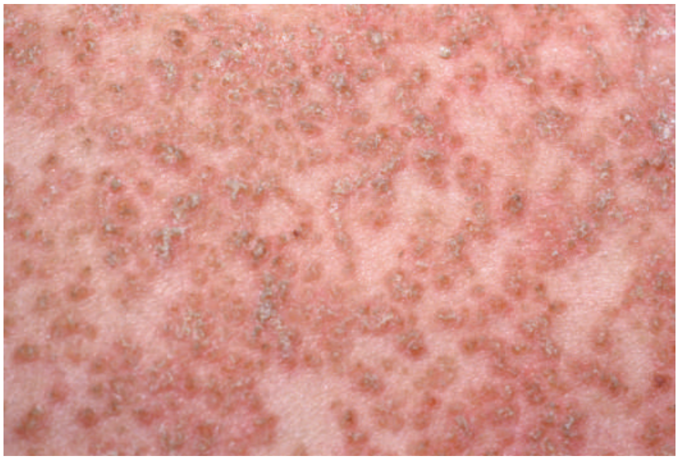

Figure 657-7 Papules coalescing into large plaque on the back of a patient with Darier disease.

657.8 Lichen Nitidus

Brianne Z. Dickey and Yvonne E. Chiu

ETIOLOGY/PATHOGENESIS

The etiology of lichen nitidus is unknown.

CLINICAL MANIFESTATIONS

This chronic, benign, papular eruption is characterized by minute (1-2 mm), flat-topped, shiny, firm papules of uniform size. The papules are most often skin-colored but may be pink or red. In black individuals, they are usually hypopigmented (Fig. 657-8). Sites of predilection are the genitals, abdomen, chest, forearms, wrists, and inner aspects of the thighs. The lesions may be sparse or numerous and may form large plaques; careful examination usually discloses linear papules in a line of scratch (Koebner phenomenon), a valuable clue to the diagnosis because it occurs in only a few diseases. Lichen nitidus occurs in all age groups. The cause is unknown. Patients with lichen nitidus are usually asymptomatic and constitutionally well, although pruritus may be severe. The lesions may be confused with those of lichen planus, and lichen nitidus can rarely occur concurrently with lichen planus.

DIFFERENTIAL DIAGNOSIS

Widespread keratosis pilaris can also be confused with lichen nitidus, but the follicular localization of the papules and the absence of Koebner phenomenon in the former distinguish them. Verruca plana (flat warts), if small and uniform in size, may occasionally resemble lichen nitidus.

HISTOLOGY

Although the diagnosis can be made clinically, a biopsy is occasionally indicated. The lichen nitidus papule consists of sharply circumscribed nests of lymphocytes and histiocytes in the upper dermis enclosed by claw-like epidermal rete ridges.

TREATMENT

The course of lichen nitidus spans months to years, but the lesions eventually involute completely. No treatment is necessary, but mid- to high-potency topical steroids may be used for pruritus.

Bibliography is available at Expert Consult.

657.9 Lichen Striatus

Brianne Z. Dickey and Yvonne E. Chiu

ETIOLOGY/PATHOGENESIS

Lichen striatus is hypothesized to be caused by a combination of genetic predisposition present in a mosaic manner (following the lines of Blaschko) and an infectious trigger.

CLINICAL MANIFESTATIONS

A benign, self-limited eruption, lichen striatus consists of a continuous or discontinuous linear band of papules in a Blaschkoid distribution. The primary lesion is a flat-topped, hypopigmented or pink papule covered with fine scale. Aggregates of these papules form multiple bands or plaques. The papules are gradually replaced by hypopigmented macules, which may be the presenting lesion in some cases. The eruption evolves over a period of days or weeks in an otherwise healthy child, remains stationary for weeks to months, and finally remits without sequelae usually within 2 yr. Symptoms are usually absent, although some children complain of itching. Nail dystrophy may occur when the eruption involves the proximal nail fold and matrix (Fig. 657-9).

DIFFERENTIAL DIAGNOSIS

Lichen striatus is occasionally confused with other disorders. The initial plaque may resemble papular eczema or lichen nitidus until the linear configuration becomes apparent. Linear lichen planus and linear psoriasis are usually associated with typical individual lesions elsewhere on the body. Linear epidermal nevi are permanent lesions that often become more hyperkeratotic and hyperpigmented than those of lichen striatus.

TREATMENT

Treatment is not necessary and generally not very effective. A low-potency topical corticosteroid preparation can be used when pruritus is a problem in a patient with lichen striatus.

Bibliography is available at Expert Consult.

657.10 Lichen Planus

Brianne Z. Dickey and Yvonne E. Chiu

ETIOLOGY/PATHOGENESIS

Lichen planus is the result of an attack on the skin by cytotoxic T cells. The cause is unknown, but granzyme B, perforin, and granulysin are markedly increased in skin involved with lichen planus. A genetic predisposition may exist, and other proposed triggers include metal exposure, certain medications, liver disease, vaccinations (especially hepatitis B vaccination), and infections (especially hepatitis C virus).

CLINICAL MANIFESTATIONS

This is a rare disorder in young children and uncommon in older ones. It is more often seen in children from the Indian subcontinent and of African-American background. The classic form of lichen planus is the most common subtype in children, often exhibiting an acute eruptive onset. The lesions erupt in an explosive fashion, much like a viral exanthem, and spread to involve most of the body surface. The primary lesion is a violaceous, sharply demarcated, polygonal papule with fine white lines (Wickham's striae) or scale on the surface. Papules may coalesce to form large plaques (Fig. 657-10). The papules are intensely pruritic, and additional papules are often induced by scratching (Koebner phenomenon) so that lines of them are detected. Sites of predilection are the flexor surfaces of the wrists, the forearms, the inner aspects of the thighs, and the ankles.

Hypertrophic, linear, bullous, atrophic, annular, follicular, erosive, ulcerative, and actinic forms of lichen planus may also occur in children. Characteristic lesions of mucous membranes consist of pinhead-size white papules that coalesce to form reticulated and lacy patterns on the buccal mucosa. Erosive ulcers are also common in the oral mucosa, and may also involve the gastrointestinal tract. Nail involvement causes nail dystrophy. The disorder may persist for months to years, but the acute eruptive form is most likely to involute permanently. Self-resolution eventually occurs. Intense hyperpigmentation frequently persists for a long time after the resolution of lesions.

HISTOLOGY

The histopathologic findings in lichen planus are specific, consisting of hyperkeratosis, irregular acanthosis, wedge-shaped hypergranulosis, apoptotic keratinocytes in the lower epidermis and upper dermis, and basal cell degeneration with a bandlike lymphocytic infiltrate at the epidermal-dermal junction. Pigment incontinence is frequently seen. Biopsy is indicated if the diagnosis is unclear.

TREATMENT

Treatment is directed at alleviation of the intense pruritus and amelioration of the skin lesions. First-line treatment with a high-potency topical corticosteroid applied twice daily is effective for localized disease on the trunk or extremities; lesions on the face and genitals may be treated with low- to mid-potency corticosteroids. Alternatives to topical steroids include topical calcineurin inhibitors or vitamin D analogs. Thick lesions may require intralesional corticosteroid injection. Oral antihistamines (hydroxyzine) are often added for the

Figure 657-9 Lichen striatus with nail dystrophy.

Bibliography

Tilly JJ, Drolet BA, Esterly NB: Lichenoid eruptions in children, *J Am Acad Dermatol* 51:606–624, 2004.

pruritus. A short course of systemic glucocorticoids or phototherapy (NB-UVB) are used as second-line approaches for rare cases of widespread, intractable lesions. Other medications with efficacy include oral retinoids (acitretin), dapsone, metronidazole, griseofulvin, and methotrexate.

Bibliography is available at Expert Consult.

657.11 Porokeratosis

Brianne Z. Dickey and Yvonne E. Chiu

ETIOLOGY/PATHOGENESIS

Porokeratosis is a disorder of epidermal keratinization. The etiology is unknown except for the disseminated actinic form, which is secondary to chronic sun exposure. Genetic susceptibility, with autosomal dominant transmission, and immunosuppression may also be involved.

CLINICAL MANIFESTATIONS

Porokeratosis is a rare, chronic, progressive disease of keratinization. The prototypical lesion is an atrophic papule or plaque with a surrounding ridge of hyperkeratosis, called cornoid lamella. Several forms have been delineated: solitary plaques, linear porokeratosis, hyperkeratotic lesions of the palms and soles, disseminated eruptive lesions, and superficial actinic porokeratosis. **Classic porokeratosis of Mibelli** begins in childhood and is more common in males. Sites of predilection are the limbs, face, genitals, mucous membranes, palms, and soles. The primary lesion is a small, keratotic papule that slowly enlarges peripherally so that the center becomes depressed, with the edge forming an elevated wall or collar (Fig. 657-11). The configuration of the plaque may be round, oval, or gyrate. The elevated border is split by a thin groove from which minute cornified projections protrude. The central atrophic area is yellow, gray, or tan, and sclerotic, smooth, and dry, whereas the hyperkeratotic border is a darker gray, brown, or black. **Linear porokeratosis** is also more common in childhood and typically follows the lines of Blaschko. The disease is slowly progressive but relatively asymptomatic; some patients experience pruritus or pain. Malignant degeneration to **squamous cell carcinoma** has been reported in long-standing cases.

HISTOLOGY

A skin biopsy is usually unnecessary, but will disclose the characteristic cornoid lamella (plug of stratum corneum cells with retained nuclei), which is responsible for the invariable linear ridge of the lesion. The granular layer is absent beneath the cornoid lamella.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of porokeratosis includes warts, epidermal nevi, lichen planus, granuloma annulare, tinea corporis, nummular eczema, pityriasis rosea, and elastosis perforans serpiginosa.

TREATMENT

No treatment is uniformly successful, thus therapeutic decisions depend largely on lesion size, location, symptoms, and patient preference. Most lesions are asymptomatic and do not require any intervention; however, when treatment is necessary options include pharmacologic management (topical retinoids, topical 5-fluorouracil, topical imiquimod, or oral retinoids [severe cases only]), destructive therapy (liquid nitrogen cryotherapy, electrodessication and curettage, or various lasers), and surgical removal. In general, the less-invasive topical agents should be attempted first. Good sunlight protection should also be encouraged to decrease risk of malignant transformation.

Bibliography is available at Expert Consult.

657.12 Gianotti-Crosti Syndrome (Papular Acrodermatitis)

Brianne Z. Dickey and Yvonne E. Chiu

ETIOLOGY/PATHOGENESIS

The pathogenesis of Gianotti-Crosti syndrome, also known as papular acrodermatitis, is unclear, but an immunologic reaction to viral infections and immunizations has been postulated. Historically, the most common associations are with Epstein-Barr virus, hepatitis B virus (primarily in countries without routine childhood vaccination programs), coxsackievirus A16, and parainfluenza virus, as well as with many childhood immunizations.

CLINICAL MANIFESTATIONS

This distinctive eruption is benign and predominantly occurs in children younger than 5 yr old about 1 wk after a viral illness. Cases are usually sporadic, but epidemics have been recorded. Skin lesions are monomorphic, firm, dusky or coppery red papules ranging in size from 1-10 mm (Fig. 657-12), although there is considerable variation in lesion appearance between patients. The papules often have the appearance of vesicles; when opened, however, no fluid is obtained. The papules sometimes become hemorrhagic. Lines of papules (**Koebner phenomenon**) may be noted on the extremities following minor local

Figure 657-11 Large plaque of porokeratosis of Mibelli with raised border and depressed center.

Figure 657-12 Numerous, flat-topped, red papules in Gianotti-Crosti syndrome.

Bibliography

Bibliography

Sertznig P, von Felbert V, Megahed M: Porokeratosis: present concepts, *J Eur Acad Dermatol Venereol* 26:404–412, 2012.

trauma. The papules occur in crops and may become profuse and coalesce into plaques, forming a symmetric eruption on the face, ears, buttocks, and limbs, including the palms and soles. The trunk is relatively spared, as are the scalp and mucous membranes. The eruption is occasionally associated with malaise and low-grade fever but few other constitutional symptoms. Generalized lymphadenopathy and hepatomegaly (in patients with hepatitis B viremia) constitute the only other abnormal physical findings; jaundice is classically absent despite hepatic enzyme elevation. The eruption resolves spontaneously but may take up to 2 mo. Some residual pigment change may occur but not scarring.

HISTOLOGY

Skin biopsy in Gianotti-Crosti syndrome is not specific, being characterized by a dermal perivascular mononuclear cell infiltrate, capillary endothelial swelling, and epidermal spongiosis and parakeratosis.

DIFFERENTIAL DIAGNOSIS

Gianotti-Crosti syndrome can be confused with other viral exanthems, erythema infectiosum, lichen planus, erythema multiforme, and Henoch-Schönlein purpura.

TREATMENT

The lesions are typically asymptomatic and resolve spontaneously, thus requiring no treatment. If present, pruritus may be relieved by emollients or calamine lotion. Mid-potency topical steroids may relieve pruritus but do not alter disease course. Sedating antihistamines at bedtime are also helpful.

Bibliography is available at Expert Consult.

657.13 Acanthosis Nigricans

Brianne Z. Dickey and Yvonne E. Chiu

See also Chapter 47.

ETIOLOGY/PATHOGENESIS

The skin lesions of acanthosis nigricans may be genetic due to mutations in the fibroblast growth factor receptor gene, or acquired as a manifestation of insulin resistance. In familial cases, acanthosis nigricans is inherited as an autosomal dominant trait and develops in infancy. Insulin resistance with compensatory hyperinsulinism may lead to insulin binding to and activation of insulin-like growth factor receptors, promoting epidermal growth. Common causes of insulin resistance in children are obesity and diabetes mellitus, with acanthosis nigricans seen in >60% of children with a body mass index >98%. In the paraneoplastic form (rare in children), tumor-secreted growth factors induce acanthosis nigricans.

CLINICAL MANIFESTATIONS

Acanthosis nigricans is characterized by symmetric, hyperpigmented, velvety, hyperkeratotic plaques with exaggerated skin lines in intertriginous areas. The most common locations are the posterior neck and axillae (Fig. 657-13), but it is also seen in the inframammary areas, groin, inner thighs, and anogenital region. Prior to plaque development, patients notice a “dirty” appearance of affected skin that does not wash clean. Skin lesions remain asymptomatic unless maceration or secondary infection occurs. Acanthosis nigricans is found more commonly in African-American, Hispanic, and Native American children. The clinical severity and histopathologic features of acanthosis nigricans correlate positively with the degree of hyperinsulinism and with the degree of obesity.

HISTOLOGY

The histologic changes are those of papillomatosis and hyperkeratosis rather than acanthosis or excessive pigment formation. A mild dermal inflammatory infiltrate may be present.

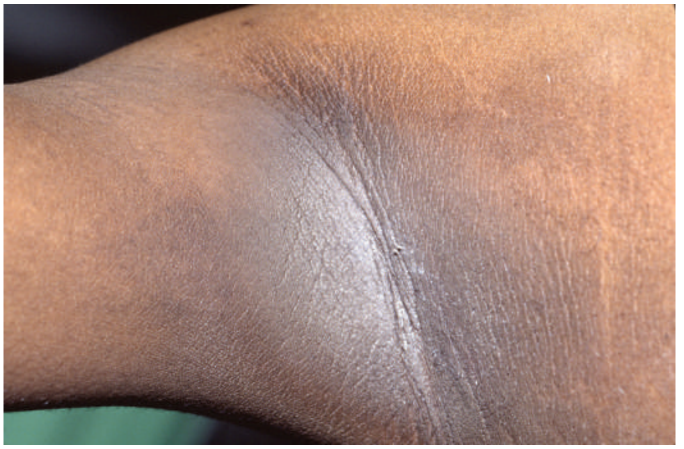

Figure 657-13 Velvety hyperpigmentation of the axilla in acanthosis nigricans.

TREATMENT

Treatment is aimed at palliation of the underlying disorder. Acanthosis nigricans in the obese child is associated with risk factors for glucose homeostasis abnormalities, and counseling families on its causes and consequences may motivate them to make healthy lifestyle changes that can decrease the risk for development of cardiac disease and diabetes mellitus. In children with obesity-related acanthosis nigricans, weight loss should be the primary goal. Appearance of skin lesions responds poorly to local medical management; some patients benefit from topical keratolytic agents (40% urea cream or 12% ammonium lactate cream) and agents that inhibit keratinocyte proliferation (topical vitamin D analogs).

Chapter 658

Disorders of Keratinization

Kari L. Martin

DISORDERS OF CORNIFICATION

Mendelian disorders of cornification (**ichthyoses**) are a primary group of inherited conditions characterized clinically by patterns of scaling and histopathologically by hyperkeratosis. They are usually distinguishable on the basis of inheritance patterns, clinical features, associated defects, and histopathologic changes (Table 658-1). Much work is currently underway to better categorize the genotype-phenotype correlation of these diseases.

COLLODION BABY

Collodion baby is not a single entity but a newborn phenotype that is most often seen in babies who will eventually demonstrate **lamellar ichthyosis** or congenital **ichthyosiform erythroderma**. Less commonly, collodion babies evolve into babies with other forms of ichthyosis or Gaucher disease. A small subset become otherwise healthy babies without chronic skin disease.

Table 658-1 Disorders of Cornification That Usually Manifest in the First Weeks of Life

DISORDER	INHERITANCE	CLINICAL FEATURES	MUTATION	VISUAL METHOD OF DIAGNOSIS
Harlequin ichthyosis	AR	Thick, armor-like scale with fissuring	*ABCA12*	Clinical
Collodion baby	Usually AR	Shiny collodion membrane	Various	Clinical
Recessive X-linked ichthyosis	Recessive X-linked	Collodion membrane May have genital anomalies	Steroid sulfatase	Plasma cholesterol sulfate
Lamellar ichthyosis	Usually AR	Collodion membrane	Transglutaminase I *ABCA12* *CYP4F22*	Clinical
Congenital ichthyosiform erythroderma	AR	Collodion membrane	Transglutaminase 1 *ALOX12B* *ALOXE3*	Clinical
Epidermolytic ichthyosis	AD	Scaling and blistering	Keratins 1, 10, 2e	Clinical and histologic
Ichthyosis hystrix	AD	Plaques of hyperkeratosis	Keratin 1, *GJB2*	Clinical

AD, autosomal dominant; AR, autosomal recessive.; FAD, fatty aldehyde.
From Eichenfield LF, Frieden IJ, Esterly NB: Textbook of neonatal dermatology, *Philadelphia, 2001, WB Saunders, p. 277.*

Collodion babies are covered at birth by a thick, taut membrane resembling oiled parchment or collodion (Fig. 658-1), which is subsequently shed. Affected neonates have ectropion, flattening of the ears and nose, and fixation of the lips in an O-shaped configuration. Hair may be absent or may perforate the abnormal covering. The membrane cracks with initial respiratory efforts and, shortly after birth, begins to desquamate in large sheets. A high-humidity environment and application of nonocclusive lubricants facilitates shedding of the membrane. Complete shedding may take several weeks, and a new membrane may occasionally form in localized areas.

Neonatal morbidity and mortality may be due to cutaneous infection, aspiration pneumonia (squamous material), hypothermia, or hypernatremic dehydration from excessive transcutaneous fluid losses as a result of increased skin permeability. The outcome is uncertain,

Figure 658-1 Typical appearance of a collodion baby.

Figure 658-2 Scale over the shin in ichthyosis vulgaris.

and accurate prognosis depends on identification of the underlying ichthyosis.

COMMON ICHTHYOSES

Ichthyosis Vulgaris

Etiology/Pathogenesis

Autosomal dominant or recessive mutations in the filaggrin gene cause ichthyosis vulgaris (IV). Filaggrin is a filament-aggregating protein that assembles the keratin filament cytoskeleton, causing collapse of the granular cells into classic flattened squamous cell shape. Mutations in filaggrin lead to absence or marked reductions in keratohyalin granules.

Clinical Manifestations

IV is the **most common** of the disorders of keratinization, with an incidence of 1/250 live births. Onset generally occurs in the 1st yr of life. In most cases, it is trivial, consisting only of slight roughening of the skin surface. Scaling is most prominent on the extensor aspects of the extremities, particularly the legs (Fig. 658-2). Flexural surfaces are spared, and the abdomen, neck, and face are relatively uninvolved. **Keratosis pilaris**, particularly on the upper arms and thighs, accentuated markings, and hyperkeratosis on the palms and soles, and atopy are relatively common. Scaling is most pronounced during the winter mo and may abate completely during warm weather. There is no accompanying disorder of hair, teeth, mucosal surfaces, or other organ systems.

Figure 658-3 Sparing of the antecubital fossa in X-linked ichthyosis.

Treatment

Scaling may be diminished by daily applications of an emollient or a lubricant containing urea (10-40%), salicylic acid, or an α-hydroxy acid such as lactic acid (5-12%).

X-Linked Ichthyosis

Etiology/Pathogenesis

X-linked ichthyosis (XLI) involves a deficiency of steroid sulfatase, which hydrolyzes cholesterol sulfate and other sulfated steroids to cholesterol. Cholesterol sulfate accumulates in the stratum corneum and plasma. In the epidermis this accumulation causes malformation of intercellular lipid layers, leading to barrier defects and delay of corneodesmosome degradation, resulting in corneocyte retention.

Clinical Manifestations

Skin peeling may be present at birth but typically begins at 3-6 mo of life. Scaling is most pronounced on the sides of the neck, lower face, preauricular areas, anterior trunk, and the limbs, particularly the legs. The elbow (Fig. 658-3) and knee flexures are generally spared but may be mildly involved. The palms and soles may be slightly thickened but are also usually spared. The condition gradually worsens in severity and extent. Keratosis pilaris is not present, and there is no increased incidence of atopy. Deep corneal opacities that do not interfere with vision develop in late childhood or adolescence and are a useful marker for the disease because they may also be present in carrier females. Some patients have larger deletions on the X chromosome that encompass neighboring genes, generating *contiguous gene deletion syndromes*. These include **Kallmann syndrome** (*KAL1* gene), which consists of hypogonadotrophic hypogonadism and anosmia, **X-linked chondroplasia punctata** (*ARSE* gene), **short stature,** and **ocular albinism**. The rate of testicular cancer may be increased in patients with coexistent Kallmann syndrome. There is also an increased risk of attention deficit hyperactivity disorder and autism owing to a contiguous gene defect in neuroligin 4.

Reduced steroid sulfatase enzyme activity can be detected in fibroblasts, keratinocytes, and leukocytes and, prenatally, in amniocytes or chorionic villus cells. In affected families, an affected male can be detected by restriction enzyme analysis of cultured chorionic villus cell DNA or amniocytes or by in situ hybridization, which identifies steroid sulfatase gene deletions prenatally in chorionic villus cells. A placental steroid sulfatase deficiency in carrier mothers may result in low urinary and serum estriol values, prolonged labor, and insensitivity of the uterus to oxytocin and prostaglandins.

Treatment

Daily application of emollients and a urea-containing lubricant (10-40%) is usually effective. Glycolic or lactic acid (5-12%) in an

emollient base and propylene glycol (40-60%) in water with occlusion overnight are alternative forms of therapy.

AUTOSOMAL RECESSIVE CONGENITAL ICHTHYOSES (ARCI)

Harlequin Ichthyosis

Etiology/Pathogenesis

Harlequin ichthyosis (HI) is caused by mutations in the *ABCA12* gene. Mutation in the gene leads to defective lipid transport and *ABCA12* activity is required for the generation of long-chain ceramides that are essential for the development of the normal skin barrier.

Clinical Manifestations

At birth, markedly thickened, ridged, and cracked skin forms horny plates over the entire body, disfiguring the facial features and constricting the digits. Severe ectropion and chemosis obscure the orbits, the nose and ears are flattened, and the lips are everted and gaping. Nails and hair may be absent. Joint mobility is restricted, and the hands and feet appear fixed and ischemic. Affected neonates have respiratory difficulty, suck poorly, and are subject to severe cutaneous infection. HI used to be uniformly fatal in the neonatal period, but with the use of oral retinoids, more patients survive (~80%) beyond infancy and have severe ichthyosis usually resembling lamellar ichthyosis or nonbullous congenital ichthyosiform erythroderma as adolescents and adults. Those with a compound heterozygous genotype have a better prognosis.

Treatment

Initial treatment includes high fluid intake to avoid dehydration from transepidermal water loss and use of a humidified heated incubator, emulsifying ointments, careful attention to hygiene, and oral retinoids (1 mg/kg/day). Prenatal diagnosis has been accomplished by fetoscopy, fetal skin biopsy, and microscopic examination of cells from amniotic fluid.

Lamellar Ichthyosis and Congenital Ichthyosiform Erythroderma (Nonbullous Congenital Ichthyosiform Erythroderma)

Lamellar ichthyosis (LI) and congenital ichthyosiform erythroderma (CIE; nonbullous congenital ichthyosiform erythroderma; non-HI ARCI) are the most common types of autosomal recessively inherited ichthyosis. Both forms are present at or shortly after birth. Most infants with these forms of ichthyosis present with erythroderma and scaling; but among collodion babies, most turn out to have one of these ichthyosis variants.

Etiology/Pathogenesis

Six genes have been identified that cause non-HI ARCI: *TGM* (the gene encoding transglutaminase), *ABCA12*, *NIPAL4* (also known as *ICHTHYIN*), *CYP4F22*, and the lipoxygenase genes *ALOX12B* and *ALOXE3*. Transglutaminase mutations lead to abnormalities in the cornified envelope, whereas defects in *ABCA12* cause abnormal lipid transport and those in *CYP4F22* produce abnormal lamellar granules. The lipoxygenases are likely to play a role in epidermal barrier formation by affecting lipid metabolism.

Clinical Manifestations

After shedding of the collodion membrane, if present, lamellar ichthyosis evolves into large, quadrilateral, dark scales that are free at the edges and adherent at the center. Scaling is often pronounced and involves the entire body surface, including flexural surfaces (Fig. 658-4). The face is often markedly involved, including ectropion and small, crumpled ears. The palms and soles are generally hyperkeratotic. The hair may be sparse and fine, but the teeth and mucosal surfaces are normal. Unlike in congenital ichthyosiform erythroderma, there is little erythema.

In congenital ichthyosiform erythroderma**,** erythroderma tends to be persistent, and scales, although they are generalized, are finer and whiter than in lamellar ichthyosis (Fig. 658-5). Hyperkeratosis is

Figure 658-4 Generalized scaling of lamellar ichthyosis.

Figure 658-5 Prominent erythema and scale in congenital ichthyosiform erythroderma.

particularly noticeable around the knees, elbows, and ankles. Palms and soles are uniformly hyperkeratotic. Patients have sparse hair, cicatricial alopecia, and nail dystrophy. Neither form includes blistering.

Treatment

Pruritus may be severe and responds minimally to antipruritic therapy. The unattractive appearance of the child and the bad odor from bacterial colonization of macerated scales may create serious psychologic problems. A high-humidity environment in winter and air conditioning in summer reduce discomfort. Generous and frequent applications of emollients and keratolytic agents such as lactic or glycolic acid (5-12%), urea (10-40%), tazarotene (0.1% gel), and retinoic acid (0.1% cream) may lessen the scaling to some extent, although these agents produce stinging if applied to fissured skin. Oral retinoids (1 mg/kg/day) have a beneficial effect in these conditions but do not alter the underlying defect and, therefore, must be administered indefinitely. The long-term risks of these compounds (teratogenic effects and toxicity to bone) may limit their usefulness. Ectropion requires ophthalmologic care and, at times, plastic surgical procedures.

KERATINOPATHIC ICHTHYOSES

Epidermolytic Ichthyosis (Bullous Congenital Ichthyosiform Erythroderma; Epidermolytic Hyperkeratosis)

Etiology/Pathogenesis

Epidermolytic ichthyosis (EI) is an autosomal dominant trait that has been shown to be due to defects in either keratin 1 or keratin 10. These

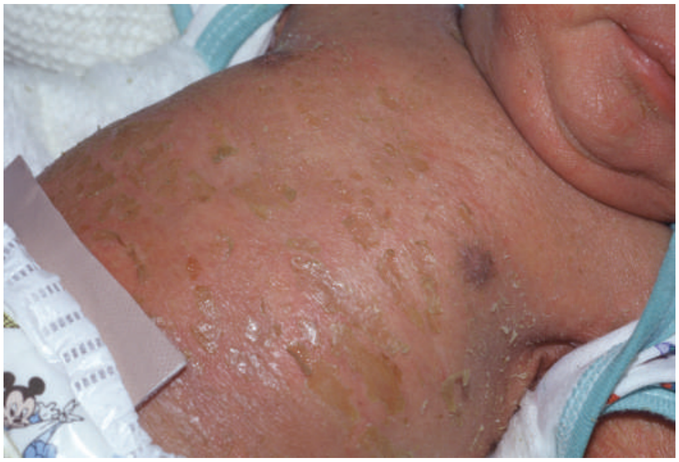

Figure 658-6 Superficial erosions and hyperkeratosis in epidermolytic hyperkeratosis.

keratins are required to form the keratin-intermediate filaments in cells of the suprabasilar layers of the epidermis.

Clinical Manifestations

The clinical manifestations are initially characterized by the onset at birth of widespread blisters and erosions on a background of generalized erythroderma (Fig. 658-6). Recurrent blistering may be widespread in neonates and may cause diagnostic confusion with other blistering disorders. With time, the blister formation ceases, erythema decreases, and generalized hyperkeratosis develops. The scales are small, hard, and verrucous. Distinctive, parallel hyperkeratotic ridges develop over the joint flexures, including the axillary, popliteal, and antecubital fossae, and on the neck and hips. **Palmoplantar keratoderma** is associated with keratin 1 defects. The hair, nails, mucosa, and sweat glands are normal. Malodorous secondary bacterial infection is common and requires appropriate antibiotic therapy.

Histopathology

The histopathology is diagnostic of EI, consisting of hyperkeratosis, degeneration of the epidermal granular layer with an increased number of keratohyalin granules, clear spaces around nuclei, and indistinct cellular boundaries of cells in the upper epidermis. On electron microscopic examination, keratin-intermediate filaments are clumped, and many desmosomes are attached to only one keratinocyte instead of connecting neighboring keratinocytes. Localized forms of the disease may resemble epidermal nevi or keratoderma of the palms and soles but share the distinctive histopathologic changes of EI.

Treatment

Treatment of EI is difficult. Morbidity is increased in the neonatal period as a result of prematurity, sepsis, and fluid and electrolyte imbalance. Bacterial colonization of macerated scales produces a distinctive bad odor that can be controlled somewhat by use of an antibacterial cleanser. Intermittent oral antibiotics are generally necessary. Keratolytic agents are often poorly tolerated. Oral retinoids (1 mg/kg/day) may produce significant improvement. Prenatal diagnosis for affected families is possible by examination of DNA extracts from chorionic villus cells or amniocytes, provided that the specific mutation in the affected parent is known.

OTHER NONSYNDROMIC ICHTHYOSES

Erythrokeratoderma Variabilis

Etiology/Pathogenesis

An autosomal dominant disorder, erythrokeratoderma variabilis (EKV) is caused by mutations in connexins 31 and 30.3. Connexins are proteins that form gap junctions between cells that allow for transport and signaling between neighboring epidermal cells.

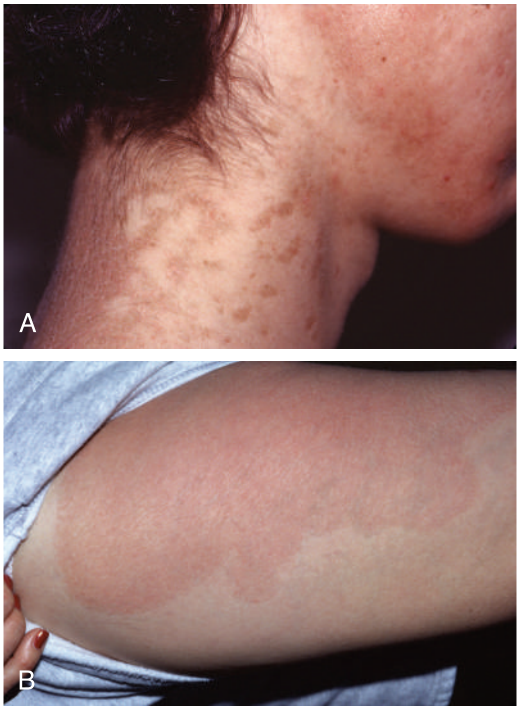

Figure 658-7 Erythrokeratoderma variabilis. **A,** Fixed, hyperkeratotic plaques, **B,** Migratory, erythematous lesion.

Clinical Manifestations

EKV usually manifests in the early mo of life, progresses in childhood, and stabilizes in adolescence. It is characterized by two distinctive manifestations: sharply demarcated, hyperkeratotic plaques (Fig. 658-7*A*) and transient figurate erythema (Fig. 658-7*B*). The distribution is generalized but sparse; sites of predilection are the face, buttocks, axillae, and extensor surfaces of the limbs. The palms and soles may be thickened, but hair, teeth, and nails are normal.

Treatment

There are case reports that topical tazarotene gel 0.1% and oral retinoids (1 mg/kg/day) are effective for treatment of EKV.

Symmetric Progressive Erythrokeratoderma

Etiology/Pathogenesis

Symmetric progressive erythrokeratoderma is an autosomal dominant disorder caused by mutations in the gene encoding loricrin. Loricrin is a major component of the epidermal cornified cell envelope.

Clinical Manifestations

The disorder manifests in childhood as large, fixed, geographic and symmetric, fine, scaling, hyperkeratotic, erythematous plaques primarily on the extremities, buttocks, face, ankles, and wrists. The primary feature distinguishing this disorder from EKV is the lack of variable erythema seen in the latter condition.

Treatment

Symmetric progressive erythrokeratoderma is a very rare disorder, but reports of response to topical and oral retinoids (1 mg/kg/day) exist.

SYNDROMIC ICHTHYOSES

Sjögren-Larsson Syndrome

Etiology/Pathogenesis

The autosomal recessive inborn error of metabolism known as Sjögren-Larsson syndrome is an abnormality of fatty alcohol oxidation that results from a deficiency of fatty aldehyde dehydrogenase (*FALDH3A2*), a component of the fatty alcohol–nicotinamide adenine dinucleotide oxidoreductase enzyme complex.

Clinical Manifestations

The clinical picture of Sjögren-Larsson syndrome consists of ichthyosis, cognitive impairment, and spasticity. The ichthyosis is generalized but is accentuated on the flexures and the lower abdomen and consists of erythroderma, fine scaling, larger platelike scales, and dark hyperkeratosis. The degree of scale varies markedly from patient to patient. Most individuals have **palmoplantar hyperkeratosis**. The skin changes may be identical to the other forms of ichthyosis, and diagnosis is often delayed until the onset of neurologic symptoms. Pruritus is severe and hypohidrosis is common. Glistening dots in the foveal area are a cardinal ophthalmologic sign. About half the patients have primary retinal degeneration. Motor and speech developmental delays are usually noted before 1 yr of age, and spastic diplegia or tetraplegia, epilepsy, and intellectual disability generally become evident in the 1st 3 yr of life. Some patients may walk with the aid of braces, but most are confined to wheelchairs. This deficiency can be demonstrated in cultured skin fibroblasts of affected patients and carriers and, prenatally, in cultured chorionic villus cells and amniocytes from affected fetuses. Elevation of urinary leukotriene B4 (LTB4) may provide an easier approach to diagnosis.

Treatment

Treatment is similar to that for the other forms of ichthyosis; 5-lipoxygenase inhibitors have been used to decrease pruritus.

Netherton Syndrome

Etiology/Pathogenesis

A rare autosomal recessive disorder, Netherton syndrome is caused by mutations in the *SPINK 5* gene, which encodes a serine protease inhibitor (*LEKT1*).

Clinical Manifestations

Netherton syndrome is characterized by ichthyosis (usually ichthyosis linearis circumflexa but occasionally the lamellar or congenital types of ichthyosiform erythroderma), trichorrhexis invaginata and other hair shaft anomalies, and atopic diathesis. The disorder manifests at birth or in the 1st few mo of life as generalized erythema and scaling. The trunk and limbs have diffuse erythema and superimposed migratory, polycyclic, and serpiginous hyperkeratotic lesions (Fig. 658-8), some with a distinctive double-edged margin of scale. Lichenification or hyperkeratosis tends to persist in the antecubital and popliteal fossae. The face and scalp may remain erythematous and scaling. Many hair shaft deformities, most notably, trichorrhexis invaginata, have been described in most patients with Netherton syndrome.

The ichthyosis is present in the 1st 10 days of life and may be especially marked around the eyes, mouth, and perineal area. The erythroderma is often intensified after infection. Infants may suffer from failure to thrive, recurrent bacterial and candidal infections, elevated serum immunoglobulin IgE values, and marked hypernatremic dehydration. The most frequent allergic manifestations are urticaria, angioedema, atopic dermatitis, and asthma. Scalp hair is sparse and short and fractures easily (Fig. 658-9); eyebrows, eyelashes, and body hair are also abnormal. The characteristic hair abnormality can be identified with light microscopy; in the newborn, it may best be identified in eyebrow hair.

Treatment

Owing to the inflammatory nature of the skin disease, oral antihistamines and topical steroids, as used in the treatment of atopic dermatitis, are helpful for Netherton syndrome.

Refsum Syndrome

See Chapters 86.2 and 613.5.

Etiology/Pathogenesis

There are 2 types of Refsum syndrome. The classic form is autosomal recessive and caused by mutations in the *PAHX* gene that result in an increase in phytanic acid. The infantile forms of Refsum syndrome are also autosomal recessive and caused by mutations in the *PEX1*, *PEX2*, or *PEX26* genes. These are peroxisomal abnormalities that lead to an increase in very long chain fatty acids, di- and tri-hydroxycholestanoic acid, and pipecolic acid as well as phytanic acid.

Clinical Manifestations

Refsum syndrome is a multisystem disorder that becomes symptomatic in the 2nd or 3rd decade of life. The ichthyosis may be generalized, is relatively mild, and resembles ichthyosis vulgaris. The ichthyosis may also be localized to the palms and soles. Chronic polyneuritis with progressive paralysis and ataxia, retinitis pigmentosa, anosmia, deafness, bony abnormalities, and electrocardiographic changes are the most characteristic features. The condition is diagnosed through lipid analysis of the blood or skin, which shows elevated phytanic acid values.

The infantile form begins, as suggested by the name, early in life, and in addition to the changes seen in the classic form, affected patients have hepatomegaly, abnormal bile acid profiles, developmental delay, and cognitive impairment.

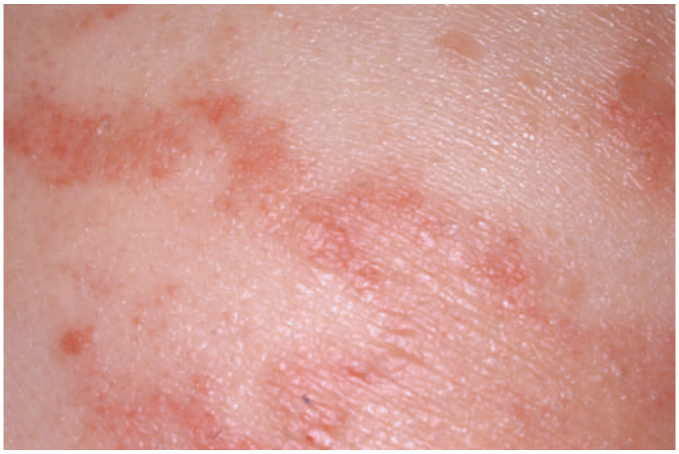

Figure 658-8 Serpiginous, erythematous, hyperkeratotic lesions of ichthyosis linearis circumflexa.

Figure 658-9 Very short scalp hair and thick scale in Netherton syndrome.

Treatment

Phytanic acid is exclusively derived from dietary chlorophyll. Lifelong dietary avoidance of phytanic acid–containing produces clinical improvement in classic Refsum syndrome.

Chondrodysplasia Punctata

See Chapter 86.2.

Etiology/Pathogenesis

Chondrodysplasia punctata (CPD) is a clinically and genetically heterogeneous condition. X-linked dominant CPD, also known as **Conradi-Hünermann syndrome**, is the best-characterized form. There is also an X-linked recessive form caused by mutation in the *ARSE* gene. Rhizomelic chondrodysplasia punctata type 1 is an autosomal recessive disorder caused by mutations in the *PEX7* gene, which encodes the peroxisomal type 2 targeting signal (*PTS2*) receptor. CPD can also be caused by maternal vitamin K deficiency or warfarin teratogenicity.

Clinical Manifestations

These heterogeneous disorders are marked by ichthyosis and bone changes. Nearly all patients with the X-linked dominant form and approximately 25% of those with the recessive type have cutaneous lesions, ranging from severe, generalized erythema and scaling to mild hyperkeratosis. **Rhizomelic chondrodysplasia punctata** is associated with cataracts, hypertelorism, optic nerve atrophy, disproportionate shortening of the proximal extremities, psychomotor retardation, failure to thrive, and spasticity; most affected patients die in infancy. Patients with the X-linked dominant form have asymmetric, variable shortening of the limbs and a distinctive ichthyosiform eruption at birth. Thick, yellow, tightly adherent, keratinized plaques are distributed in a whorled pattern over the entire body. The eruption typically resolves in infancy and may be superseded by a follicular atrophoderma and patchy alopecia.

Additional features in all variants include cataracts and abnormal facies with saddle nose and frontal bossing. The pathognomonic defect, termed **chondrodysplasia punctata**, is stippled epiphyses in the cartilaginous skeleton. This defect, which is seen in various settings and inherited disorders, often in association with peroxisomal deficiency and disturbance of cholesterol biosynthesis, disappears by 3-4 yr of age.

OTHER SYNDROMES WITH ICHTHYOSIS

A number of other rare syndromes with ichthyosis as a consistent feature include the following: keratitis with ichthyosis and deafness (**KID syndrome**, connexin 26 gene), ichthyosis with defective hair having a banded pattern under polarized light and a low sulfur content (**trichothiodystrophy**), multiple sulfatase deficiency, neutral lipid storage disease with ichthyosis (**Chanarin-Dorfman syndrome;** *CGI58* gene), and **CHILD syndrome** (Fig. 658-10; congenital hemidysplasia with ichthyosiform erythroderma and limb defects; *NSDHL* gene).

Figure 658-10 Limb dysplasia and ichthyosiform eruption in CHILD (congenital hemidysplasia with ichthyosiform erythroderma and limb defects) syndrome.

Palmoplantar Keratodermas

Excessive hyperkeratosis of the palms and soles may occur as a manifestation of a focal or generalized congenital hereditary skin disorder or may result from such chronic skin diseases as psoriasis, eczema, pityriasis rubra pilaris, lupus erythematosus, or postinfectious arthritis syndrome.

Diffuse Hyperkeratosis of Palms and Soles (Unna-Thost, Vorner)

Unna-Thost and Vorner type palmoplantar keratodermas (PPKs), although clinically inseparable, were thought to be separate entities. They were separated histologically by the presence (Vorner) or absence (Unna-Thost) of epidermolytic hyperkeratosis. They represent the clinical spectrum of the same disease caused by mutations in keratin (*KRT1* and *KRT9* genes). This autosomal dominant disorder manifests in the 1st few mo of life as erythema that gradually progresses to sharply demarcated, hyperkeratotic, scaling plaques over the palms (Fig. 658-11) and soles. The margins of the plaques often remain red; plaques may extend along the lateral aspects of the hands and feet and onto the volar wrists and the heels. Hyperhidrosis is usually present, but hair, teeth, and nails are usually normal. Striate (*DSG1*, *DSP*, *KRT1* genes) and punctate forms of palmar and plantar hyperkeratosis represent distinct entities.

Figure 658-11 Palmar keratoderma with epidermolytic changes seen on biopsy.

Mal De Meleda (*SLURP-1* Gene)

A rare, progressive autosomal recessive condition, mal de Meleda is characterized by erythema and thick scales on the palms, fingers, soles, and flexor aspects of the wrists, knees, and elbows. Hyperhidrosis, nail thickening or koilonychia, and eczema may also occur.

Vohwinkel Palmoplantar Keratoderma (Mutilating Keratoderma)

Vohwinkel PPK is a progressive autosomal dominant disease consisting of honeycombed hyperkeratosis of palms and soles, sparing the arches; starfish-like and linear keratoses on the dorsum of the hands, fingers, feet, and knees; and ainhum-like constriction of the digits that sometimes leads to autoamputation. Varying degrees of alopecia may be seen. Two forms have been identified. Vohwinkel PPK with ichthyosis is caused by mutations in the loricrin gene, and Vohwinkel PPK with deafness by mutations in connexin 26.

Papillon-Lefèvre Syndrome (Cathepsin C Gene)

An autosomal recessive erythematous hyperkeratosis of the palms and soles, Papillon-Lefèvre syndrome sometimes extends to the dorsal

hands and feet, elbows, and knees later in childhood. The PPK may be either diffuse, striate, or punctuate. This syndrome is characterized by periodontal inflammation, leading to loss of teeth by age 4-5 yr if untreated.

Other Syndromes

Keratoderma of palms and soles also occurs as a feature of some forms of ichthyosis and ectodermal dysplasia. **Richner-Hanhart syndrome** is an autosomal recessive focal palmoplantar keratoderma with corneal ulcers, progressive mental impairment, and a deficiency of tyrosine aminotransferase, which leads to tyrosinemia. **Pachyonychia congenita** is transmitted as an autosomal dominant trait with variable expressivity. The classic type I form **(Jadassohn-Lewandowski syndrome)** is due to mutations in the gene for keratin 16. Major features of the syndrome are onychogryposis; palmoplantar keratoderma; follicular hyperkeratosis, especially of the elbows and knees; and oral leukokeratosis. The nail dystrophy is the most striking feature and may be present at birth or develop early in life. The nails are thickened and tubular, projecting upward at the free edge to form a conical roof over a mass of subungual keratotic debris. Repeated paronychial inflammation may result in shedding of the nails. The feature seen most consistently among patients with this condition is keratoderma of the palms and soles. Additional associated features include hyperhidrosis of the palms and soles, and bullae and erosions on the palms and soles. Some patients have shown a selective cell-mediated defect in recognition and processing of *Candida*. Surgical removal of the nails and excision of the nail matrix have been helpful in some patients.

Treatment

Treatment for PPK is the same no matter what its cause. In mild cases, emollient therapy may suffice. Keratolytic agents such as salicylic acid, lactic acid, and urea creams may be required. Oral retinoids are the treatment of choice for severe cases unresponsive to topical therapy.

Chapter 659
Diseases of the Dermis

Sheila S. Galbraith

KELOID

Etiology and Pathogenesis

Keloids are usually induced by trauma and commonly follow ear piercing, burns, scalds, and surgical procedures. The resulting keloid is larger than the initial area of trauma to the skin. Certain individuals are predisposed to keloid formation; a familial tendency (recessive or dominant inheritance) or the presence of foreign material in the wound may have a pathogenic role. *Keloids are a rare feature of Ehlers-Danlos syndrome, Rubinstein-Taybi syndrome*, and pachydermoperiostosis. Keloids result from an abnormal fibrous wound healing response in which tissue repair and regeneration–regulation control mechanisms are lost. Collagen production is 20 times that seen in normal scars and the type I : type III collagen ratio is abnormally high. In keloids, tissue values of tumor growth factor-β and platelet-derived growth factor are elevated; fibroblasts are more sensitive to their effects, and their degradation rate is decreased.

Figure 659-1 Keloid of earlobe after piercing.

Clinical Manifestations

A *keloid* is a sharply demarcated, benign, dense growth of connective tissue that forms in the dermis after trauma. The lesions are firm, raised, pink to hyperpigmented, and rubbery; they may be tender or pruritic. Sites of predilection are the face, earlobes (Fig. 659-1), neck, shoulders, upper trunk, sternum, and lower legs. In both keloids and hypertrophic scars, new collagen forms over a much longer period than in wounds that heal normally.

Histology

A keloid consists of whorled and interlaced hyalinized collagen fibers.

Differential Diagnosis

Keloids should be differentiated from *hypertrophic scars*, which remain confined to the site of injury and gradually involute over time.

Treatment

Young keloids may diminish in size if injected intralesionally at 4 wk intervals with triamcinolone suspension (10-40 mg/mL). At times, a more concentrated suspension is required. Large or old keloids may require surgical excision followed by intralesional injections of corticosteroid. The risk of recurrence at the same site argues against surgical excision alone, although earlobe keloids respond well to surgical excision, pressure dressings, and intralesional steroids. Placement of topical silicone gel sheeting over the keloid for several hours per day for several weeks may help in some patients.

STRIAE CUTIS DISTENSAE (STRETCH MARKS)

Etiology and Pathogenesis

Striae formation is common in adolescence. The most frequent causes are rapid growth, pregnancy, obesity, Cushing disease, and prolonged corticosteroid therapy. The pathogenesis is unknown, but the occurrence of alterations in elastic fibers is thought to be the primary process.

Clinical Manifestations

These thinned, depressed, erythematous bands of atrophic skin eventually become silvery, opalescent, and smooth. They occur most frequently in areas that have been subject to distention, such as the lower back (Fig. 659-2), buttocks, thighs, breasts, abdomen, and shoulders.

Differential Diagnosis

Striae distensae resemble atrophic scars.

Treatment

Controlled trials of treatments for striae are lacking; however, striae tend to spontaneously become less conspicuous as the color fades with time.

Figure 659-2 Striae on the back of an adolescent.

Figure 659-3 Annular lesion with a raised papular border and depressed center, characteristic of granuloma annulare.

CORTICOSTEROID-INDUCED ATROPHY

Etiology and Pathogenesis

Both topical and systemic corticosteroid treatment can result in cutaneous atrophy. This is particularly common when a potent or superpotent topical corticosteroid is applied under occlusion or to an intertriginous area for a prolonged period. Keratinocyte growth is decreased, but epidermal maturation is accelerated, resulting in a thinning of the epidermis and stratum corneum. Fibroblast growth and function are also decreased, leading to the dermal changes. The mechanism involves inhibition of synthesis of collagen type I, noncollagenous proteins, and total protein content of the skin, along with progressive reduction of dermal proteoglycans and glycosaminoglycans.

Clinical Manifestations

Affected skin is thin, fragile, smooth, and semitransparent, with telangiectasias, prominent veins, and loss of normal skin markings.

Histology

Histopathologically, one sees thinning of the epidermis. Spaces between dermal collagen and elastic fibers are small, producing a more compact but thin dermis.

Treatment

Optimal treatment is prevention by proper use of topical steroids to avoid side effects.

GRANULOMA ANNULARE

Etiology and Pathogenesis

The cause of granuloma annulare is unknown. Some cases of granuloma annulare, particularly the generalized form, may be associated with diabetes mellitus or with anterior uveitis. However, most cases are seen in healthy children.

Clinical Manifestations

This common dermatosis occurs predominantly in children and young adults. Affected children are usually healthy. Typical lesions begin as firm, smooth, erythematous papules. They gradually enlarge to form annular plaques with a papular border and a normal, slightly atrophic or discolored central area up to several centimeters in size. Lesions may occur anywhere on the body, but mucous membranes are spared. Favored sites include the dorsum of the hands (Fig. 659-3) and feet. The disseminated papular form is rare in children. Subcutaneous granuloma annulare tends to develop on the scalp and limbs, particularly in the pretibial area. These lesions are firm, usually nontender, skin-colored nodules. Perforating granuloma annulare is characterized by the development of a yellowish center in some of the superficial papular lesions as a result of transepidermal elimination of altered collagen.

Differential Diagnosis

Annular lesions are often mistaken for tinea corporis because of the elevated advancing border. They differ in that they are not scaly. Papular lesions, another variant, may simulate rheumatoid nodules, particularly when grouped on the fingers and elbows.

Histology

The lesion of granuloma annulare consists of a granuloma with a central area of necrotic collagen; mucin deposition; and a peripheral palisading infiltrate of lymphocytes, histiocytes, and foreign body giant cells. The pattern resembles that of necrobiosis lipoidica and rheumatoid nodule, but subtle histologic differences usually permit differentiation.

Treatment

The eruption persists for months to years, but spontaneous resolution without residual change is usual; 50% of lesions clear within 2 yr. Application of a potent or superpotent topical corticosteroid preparation or intralesional injections (5-10 mg/mL) of corticosteroid may hasten involution, but nonintervention is usual.

NECROBIOSIS LIPOIDICA

Etiology and Pathogenesis

The cause of necrobiosis lipoidica is unknown, but 50-75% of patients have **diabetes mellitus**; necrobiosis lipoidica occurs in 0.3% of all diabetic patients.

Clinical Manifestations

This disorder manifests as erythematous papules that evolve into irregularly shaped, sharply demarcated, yellow, sclerotic plaques with central telangiectasia and a violaceous border. Scaling, crusting, and ulceration are frequent. Lesions develop most commonly on the shins (Fig. 659-4). Slow extension of a given lesion over the years is usual, but long periods of quiescence or complete healing with scarring may occur.

Histology

Poorly defined areas of necrobiotic collagen are seen throughout, but primarily low in the dermis, associated with mucin deposition. Surrounding the necrobiotic, disordered areas of collagen is a palisading lymphohistiocytic granulomatous infiltrate. Some lesions are more characteristically granulomatous, with limited necrobiosis of collagen.

Differential Diagnosis

Necrobiosis lipoidica must be differentiated clinically from xanthomas, morphea, granuloma annulare, erythema nodosum, and pretibial myxedema.

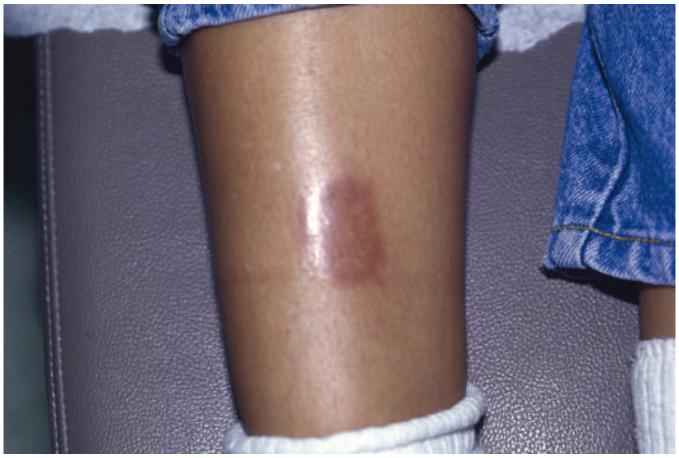

Figure 659-4 Yellow sclerotic plaque of necrobiosis lipoidica on the shin.

Figure 659-5 Ivory-colored perivaginal plaque with hemorrhage.

Treatment

The lesions persist despite good control of the diabetes but may improve minimally after applications of high-potency topical steroids or local injection of a corticosteroid. Pentoxifylline has also been used.

LICHEN SCLEROSUS

Etiology and Pathogenesis

The cause of lichen sclerosis is unknown. Several studies have identified the presence of autoantibodies to the glycoprotein extracellular matrix protein 1 (ECM-1). The exact role of these antibodies are currently under investigation, however.

Clinical Manifestations

Lichen sclerosus manifests initially as shiny, indurated, ivory-colored papules, often with a violaceous halo. The surface shows prominent dilated pilosebaceous or sweat duct orifices that often contain yellow or brown plugs. The papules coalesce to form irregular plaques of variable size, which may develop hemorrhagic bullae in their margins. In the later stages, atrophy results in a depressed plaque with a wrinkled surface. This disorder occurs more commonly in girls than in boys. Sites of predilection in girls are the vulvar (Fig. 659-5), perianal, and perineal skin. Extensive involvement may produce a sclerotic, atrophic plaque of hourglass configuration; shrinkage of the labia and stenosis of the introitus may result. Vaginal discharge precedes vulvar lesions in approximately 20% of patients. In boys, the prepuce and glans penis are often involved, usually in association with phimosis; most boys with the disorder were not circumcised early in life. Sites elsewhere on the body that are most commonly involved include the upper trunk, the neck, the axillae, the flexor surfaces of wrists, and the areas around the umbilicus and the eyes. Pruritus may be severe.

Figure 659-6 Erythematous, hyperpigmented plaque of early morphea.

Differential Diagnosis

In children, lichen sclerosus is most frequently confused with focal morphea (see Chapter 160), with which it may coexist. In the genital area, it may be mistakenly attributed to sexual abuse.

Histology

Biopsy is diagnostic, revealing hyperkeratosis with follicular plugging, hydropic degeneration of basal cells, a bandlike dermal lymphocytic infiltrate, homogenized collagen, and thinned elastic fibers in the upper dermis.

Treatment

Vulvar lichen sclerosus in childhood usually improves with puberty but does not always resolve completely, and symptoms can recur throughout life. Long-term observation for the development of squamous cell carcinoma is necessary. Superpotent topical corticosteroids provide relief from pruritus and produce clearing of lesions, including those in the genital area. Topical tacrolimus and pimecrolimus have also been used. It is not known how response to treatment affects long-term cancer risk.

MORPHEA

Etiology and Pathogenesis

Morphea is a sclerosing condition of the dermis and subcutaneous tissue of unknown etiology.

Clinical Manifestations

Morphea is characterized by solitary, multiple, or linear circumscribed areas of erythema that evolve into indurated, sclerotic, atrophic plaques (Fig. 659-6), later healing, or "burning out" with pigment change. It is seen more commonly in females. The most common types of morphea are plaque and linear. Morphea can affect any area of skin. When confined to the frontal scalp, forehead, and midface in a linear band, it is referred to as **en coup de sabre**. When located on one side of the face, it is called **progressive hemifacial atrophy**. These forms of morphea carry a poorer prognosis because of the associated underlying central nervous system involvement or musculoskeletal atrophy that can be cosmetically disfiguring. Linear morphea over a joint may lead to restriction of mobility (Fig. 659-7). Pansclerotic morphea is a rare, severe, disabling variant.

Differential Diagnosis

The differential diagnosis of morphea includes granuloma annulare, necrobiosis lipoidica, lichen sclerosis, and late-stage Lyme disease (acrodermatitis chronica atrophicans).

Figure 659-7 Linear morphea with involvement over the ankle.

Histology

Thickening or sclerosis of the dermis with collagen degeneration is seen in morphea.

Treatment

Morphea tends to persist, with gradual outward expansion on the skin for 3-5 yr until spontaneous cessation of the inflammatory phase occurs. Topical calcipotriene alone or in combination with high- to superpotency topical steroids or topical tacrolimus have been used for less-severe disease. For the various forms of linear morphea and for severe plaque morphea, ultraviolet A-1 (UVA-1) phototherapy, or methotrexate with or without pulsed intravenous or oral glucocorticosteroids may halt progression and help shorten the disease course. There are no good comparison studies to suggest which therapy is optimal. Physical therapy is needed in linear morphea over a joint to maintain mobility. Significant postinflammatory pigment alteration may persist for years.

SCLEREDEMA (SCLEREDEMA ADULTORUM, SCLEREDEMA OF BUSCHKE)

Etiology and Pathogenesis

The cause of scleredema is unknown. There are 3 types. Type 1 (55% of cases) is preceded by a febrile illness, often related to an upper or lower respiratory infection (streptococcal most commonly). Type 2 (25%) is associated with paraproteinemias, including multiple myeloma. Type 3 (20%) is seen in diabetes mellitus.

Clinical Manifestations

Fifty percent of patients with scleredema are younger than 20 yr old and almost always have type 1. Onset of type 1 is sudden, with brawny edema of the face and neck that spreads rapidly to involve the thorax and arms in a sweater distribution; the abdomen and legs are usually spared. The face acquires a waxy, mask-like appearance. The involved areas feel indurated and woody, are nonpitting, and are not sharply demarcated from normal skin. The overlying skin is normal in color and is not atrophic.

Onset in patients with type 2 and type 3 scleredema may occur insidiously. Systemic involvement, which is uncommon and usually associated with types 2 and 3, is marked by thickening of the tongue; dysarthria; dysphagia; restriction of eye and joint movements; and pleural, pericardial, and peritoneal effusions. Electrocardiographic changes may also be observed. Laboratory data are not helpful.

Differential Diagnosis

Scleredema must be differentiated from scleroderma (see Chapter 160), morphea, myxedema, trichinosis, dermatomyositis, sclerema neonatorum, and subcutaneous fat necrosis.

Histology

Skin biopsy demonstrates an increase in dermal thickness as a result of swelling and homogenization of the collagen bundles, which are separated by large interfibrous spaces. Special stains can identify increased amounts of mucopolysaccharides in the dermis of patients with scleredema.

Treatment

In type 1 scleredema, the active phase of the disease persists for 2-8 wk; spontaneous and complete resolution usually occurs in 6 mo to 2 yr. Recurrent attacks are unusual. In type 2 and 3, disease is slowly progressive. There is no specific therapy.

LIPOID PROTEINOSIS (URBACH-WIETHE DISEASE, HYALINOSIS CUTIS ET MUCOSAE)

Etiology and Pathogenesis

Lipoid proteinosis, an autosomal recessive disorder, is caused by mutations in the *ECM-1* gene, which encodes the ECM-1 protein. ECM-1 has a functional role in the structural organization of the dermis by binding to perlecan, matrix metalloproteinase 9, and fibulin. Pathogenesis involves infiltration of hyaline material into the skin, oral cavity, larynx, and internal organs.

Clinical Manifestations

Lipoid proteinosis may be noted initially in early infancy as hoarseness. Skin lesions appear during childhood and consist of yellowish papules and nodules that may coalesce to form plaques. The classic sign is beaded papules on the eyelids. Lesions also occur on the face, forearms, neck, genitals, dorsum of the fingers, and scalp, where they result in patchy alopecia. Similar deposits are found on the lips, undersurface of the tongue, fauces, uvula, epiglottis, and vocal cords. The tongue becomes enlarged and feels firm on palpation. The patient may be unable to protrude the tongue. Pock-like atrophic scars may develop on the face. Hypertrophic, hyperkeratotic nodules occur at sites of friction, such as the elbows and knees; the palms may be diffusely thickened. The disease progresses until early adult life, but the prognosis is good. Symmetric ossification lateral to the sella turcica in the medial temporal region, identifiable roentgenographically, is pathognomonic but is not always present. Involvement of the larynx can lead to respiratory compromise, particularly in infancy, necessitating tracheostomy. Associated anomalies include dental abnormalities, epilepsy, and recurrent parotitis as a result of infiltrates in the Stensen duct. Virtually any organ can be involved.

Histology

The distinctive histologic pattern in lipoid proteinosis includes dilation of dermal blood vessels and infiltration of homogeneous eosinophilic extracellular hyaline material along capillary walls and around sweat glands. Hyaline material in homogeneous bundles, diffusely arranged in the upper dermis, produces a thickened dermis. The infiltrates appear to contain both lipid and mucopolysaccharide substances.

Treatment

There is no specific treatment for lipoid proteinosis.

MACULAR ATROPHY (ANETODERMA)

Etiology and Pathogenesis

Anetoderma is characterized by circumscribed areas of slack skin associated with loss of dermal substance. This disorder may have no associated underlying disease (primary macular atrophy) or may develop after an inflammatory skin condition. Secondary macular atrophy may be a result of direct destruction of dermal elastin or elastolysis on an immunologic basis, especially the presence of antiphospholipid antibodies, which are related to autoimmune disorders. The elastolysis may then be a result of release of elastase from inflammatory cells.

Clinical Manifestations

Lesions vary from 0.5-1.0 cm in diameter and, if inflammatory, may initially be erythematous. They subsequently become thin, wrinkled,

and blue-white or hypopigmented. The lesions often protrude as small outpouchings that, on palpation, may be readily indented into the subcutaneous tissue because of the dermal atrophy. Sites of predilection include the trunk, thighs, upper arms, and, less commonly, the neck and face. Lesions remain unchanged for life; new lesions often continue to develop for years.

Histology
All types of macular atrophy show focal loss of elastic tissue on histopathologic examination, a change that may not be recognized unless special stains are used.

Differential Diagnosis
Lesions of anetoderma occasionally resemble morphea, lichen sclerosus, focal dermal hypoplasia, atrophic scars, or end-stage lesions of chronic bullous dermatoses.

Treatment
There is no effective therapy for macular atrophy.

CUTIS LAXA (DERMATOMEGALY, GENERALIZED ELASTOLYSIS)
Etiology and Pathogenesis
Cutis laxa is a heterogenous group of disorders related to abnormalities in elastic tissue. It may be autosomal recessive (type I: *fibulin* 5 and *fibulin* 4 genes; type II: *ATP6V0A2* gene), autosomal dominant (*elastin* and *fibulin* 5 genes), X-linked (*Cu^{2+}-transporting adenosine triphosphatase, α-polypeptide*), or acquired. Acquired cutis laxa has developed after a febrile illness, inflammatory skin diseases such as lupus erythematosus or erythema multiforme, amyloidosis, urticaria, angioedema, and hypersensitivity reactions to penicillin, and in infants born to women who were taking penicillamine.

Clinical Manifestations
There may be widespread folds of lax skin, or changes may be mild and limited in extent, resembling anetoderma. Patients with severe cutis laxa have characteristic facial features, including an aged appearance with sagging jowls (bloodhound appearance; Fig. 659-8), a hooked nose with everted nostrils, a short columella, a long upper lip, and everted lower eyelids. The skin is also lax elsewhere on the body and may resemble an ill-fitting suit. Hyperelasticity and hypermobility of the joints are not present as they are in the Ehlers-Danlos syndrome. Many infants have a hoarse cry, probably as a result of laxity of the vocal cords. Tensile strength of the skin is normal.

The dominant form of cutis laxa may develop at any age and is generally benign. When it manifests in infancy, it may be associated with intrauterine growth restriction, ligamentous laxity, and delayed closure of the fontanels. Pulmonary emphysema and mild cardiovascular manifestations may also occur. Patients with the more *common recessive* form of the disease are susceptible to severe complications, such as multiple hernias, rectal prolapse, diaphragmatic atony, diverticula of the gastrointestinal and genitourinary tracts, cor pulmonale, emphysema, pneumothoraces, peripheral pulmonary artery stenosis, and aortic dilation. Characteristic facial features include downward-slanting palpebral fissures, a broad, flat nose, and large ears. Skeletal anomalies, dental caries, growth retardation, and developmental delay also occur. Such patients often have a shortened life span.

Cutis laxa–like skin changes may also be seen in association with multiple other syndromes, including De Barsy syndrome, Lenz-Majewski syndrome, hyperostotic dwarfism, SCARF (**s**keletal abnormalities, **c**utis laxa craniostenosis, **a**mbiguous genitalia, **r**etardation, **f**acial abnormalities) syndrome, wrinkling skin syndrome, and Costello syndrome.

Histology
Histologically, elastic tissue is reduced throughout the dermis, with fragmentation, distention, and clumping of the elastic fibers.

Treatment
Treatment for cutis laxa is supportive.

EHLERS-DANLOS SYNDROME
Ehlers-Danlos syndrome (EDS) is a group of genetically heterogeneous connective tissue disorders. Affected children appear normal at birth, but skin hyperelasticity, fragility of the skin and blood vessels, delayed wound healing, and joint hypermobility (Fig. 659-9) develop. The essential defect is a quantitative deficiency of fibrillar collagen. Additional features include autonomic dysfunction (hypermobility types) characterized by recurrent or chronic musculoskeletal pain, orthostatic intolerance, sudomotor dysfunction, and gastrointestinal disturbances (gastroparesis, diarrhea, constipation). Dysautonomic features may be exacerbated by vasoactive medications. In addition, patients with EDS have an increased incidence of Chiari type 1 malformations, perhaps due to hypermobility of the occipitoatlantal and atlantoaxial joints or poor connective tissue support. Basilar impression symptoms from herniation may contribute to the morbidity of EDS. In patients with a Chiari type 1 malformation there may also be a spinal cord syrinx distal to the malformation. Pulmonary complications may include pneumothorax, hemoptysis, bullous lung disease, and tracheomegaly.

Classification
EDS has been reclassified into 6 clinical recognized forms and 1 unclassified group (Table 659-1).

Figure 659-8 Pendulous folds of skin of an infant with cutis laxa.

Figure 659-9 Joint hyperextensibility in classic Ehlers-Danlos syndrome.

Table 659-1 Ehlers-Danlos Syndrome

TYPE	FORMER NAME	CLINICAL FEATURES*	INHERITANCE	OMIM†	MOLECULAR DEFECT
Classic	EDS I and II	Joint hypermobility; skin hyperextensibility; atrophic scars; smooth, velvety skin; subcutaneous spheroids	AD	130000 130010	Structure of type V collagen because of mutations in *COL5A1, COL5A2*
Hypermobility	EDS III	Joint hypermobility; some skin hyperextensibility, with or without smooth, velvety texture	AD AR	130020 225320	? Tenascin-X *(TNX)*
Vascular	EDS IV	Thin skin; easy bruising; pinched nose; acrogeria; rupture of large-caliber and medium-caliber arteries, uterus, and large bowel	AD	130050 (225350) (225360)	Deficient type III collagen *(COL3A1)*
Kyphoscoliotic	EDS VI	Joint hypermobility; congenital, progressive rupture; scoliosis; scleral fragility with globe rupture; tissue fragility, aortic dilation, MVP	AR	225400	Deficiency of lysyl hydroxylase
Arthrochalasis	EDS VII A	Joint hypermobility, severe, with subluxations, congenital hip dislocation; skin hyperextensibility; tissue fragility	AD	130060	No cleavage of amino terminus of type I procollagen because of mutations in *COL1A1* or *COL1A2*
Dermatosparaxis	EDS VII C	Severe skin fragility; decreased skin elasticity, easy bruising; hernias; premature rupture of fetal membranes	AR	225410	No cleavage of amino terminus of type I procollagen because of deficiency of peptidase
Unclassified types	EDS V	Classic features	XL	305200	?

Classic (*COL5A1, COL5A2, COL1A1* Genes; Previously EDS Type I—Gravis, EDS Type II—MITIS)

This autosomal dominant disorder is characterized by premature birth caused by rupture of membranes, skin hyperelasticity and fragility, easy bruising, generalized and severe joint hypermobility, scoliosis, and mitral valve prolapse. Insignificant lacerations may form gaping wounds that leave broad, atrophic, papyraceous scars. Additional cutaneous manifestations include molluscoid pseudotumors over pressure points from accumulations of connective tissue and piezogenic papules (fat herniation into the dermis) (Fig. 659-10). Life expectancy is not reduced.

Figure 659-10 Piezogenic papules on the medial aspects of the heels in a 41-year-old patient with Ehlers-Danlos syndrome *(top)* and his 2-year-old daughter *(bottom)*. *(From Poppe H, Hamm H: Piezogenic papules in Ehlers-Danlos syndrome.* J Pediatr *163:1788, 2013.)*

Hypermobile (*COL3A1* Gene; Previously EDS Type III)

This disorder has autosomal dominant inheritance and manifests as generalized severe joint hypermobility and minimal skin manifestations. Musculoskeletal pain is common, and osteoarthritis may develop prematurely.

Vascular (*COL3A1* Gene; Previously EDS Type IV—Arterial Ecchymotic)

This autosomal dominant disorder shows the most pronounced dermal thinning of all. Consequently, the underlying venous network is prominent. The skin has minimal hyperextensibility, and the joints are not hypermobile, except perhaps during childhood. Premature birth, extensive ecchymoses from trauma, a high incidence of keloids, rupture of the bowel (especially the colon), uterine rupture during pregnancy,

rupture of the great vessels, dissecting aortic aneurysm, and stroke all contribute to the increased morbidity and shortened life span. Patients should be advised to avoid becoming pregnant, avoid activities that raise intracranial pressure as a result of a Valsalva maneuver, such as trumpet playing, and minimize trauma to the skin. Celiprolol, a β_1 antagonist and a β_2 agonist (vasodilates), may reduce vascular events.

Kyphoscoliosis (Lysyl Hydroxylase [*PLOD* Gene] Deficiency; Previously EDS Type VI)

Patients with this autosomal recessive type have joint hyperextensibility, hypotonia, kyphoscoliosis, fragile cornea, keratoconus, skin hyperelasticity, and fragile bones. Prenatal diagnosis is available through measurement of lysyl hydroxylase activity in amniocytes. The diagnosis can also be confirmed by detection of decreased lysyl hydroxylase activity in cultured dermal fibroblasts.

Arthrochalasia (*COLA1A* Gene, Type A; *COL1A2* Gene, Type B; Previously EDS Types VIIA and B—Arthrochalasis Multiplex Congenita)

The A type is an autosomal dominant disorder characterized by short stature, marked joint hyperextensibility and dislocation, and moderate hyperelasticity and bruisability of skin. The B type is autosomal dominant and is characterized by skin hyperelasticity and marked joint hypermobility.

Dermatosparaxis (Type 1 Collagen *N*-Peptidase; Previously EDS Type VIIC)

This autosomal recessive condition that includes premature rupture of membranes; delayed closure of fontanels; skin fragility and laxity; easy bruisability; growth retardation; short limbs; umbilical hernia; and characteristic facies with micrognathia, jowls, and prominent, puffy eyelids.

Differential Diagnosis

EDS has been confused with cutis laxa, but the features of the 2 disorders differ considerably. The skin of patients with cutis laxa hangs in redundant folds, whereas the skin of those with EDS is hyperextensible and snaps back into place when stretched. Because of the marked skin fragility in EDS, minor trauma results in ecchymoses, bleeding, and poor healing with atrophic cigarette-paper scars, which are most prominent on the forehead and lower legs and over pressure points. Surgical procedures are fraught with risk; dehiscence of wounds is common.

Joint hypermobility is seen in other connective tissue disorders (Fig. 659-11). Joint hypermobility is scored with the 9 point Beighton score (Table 659-2) and can be assessed by history (Table 659-3).

Figure 659-12 provides an initial approach to the diagnosis of EDS.

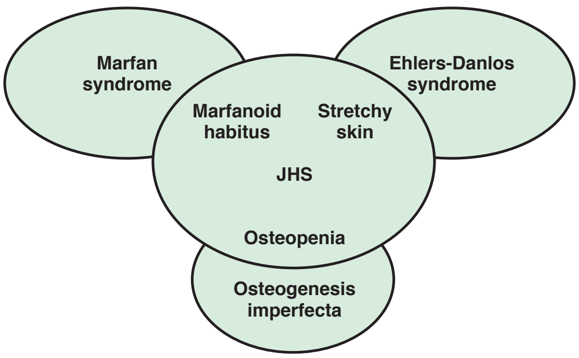

Figure 659-11 **A Venn diagram illustrating the overlap features between the 4 major heritable disorders of connective tissue.** Joint hypermobility syndrome (JHS) maintains a central position sharing key features with Marfan syndrome, osteogenesis imperfecta, and Ehlers-Danlos syndrome, and is seen as a benign forme fruste of all 3 heritable disorders of connective tissue "rolled into one." *(From Hakim A, Grahame R: Joint hypermobility.* Best Pract Res Clin Rheumatol *17:989–1004, 2003, Fig. 1.)*

Table 659-2 The Nine-Point Beighton Hypermobility Score

The ability to:	RIGHT	LEFT
1. Passively dorsiflex the fifth metacarpophalangeal joint to ≥90°	1	1
2. Oppose the thumb to the volar aspect of the ipsilateral forearm	1	1
3. Hyperextend the elbow to ≥10°	1	1
4. Hyperextend the knee to ≥10°	1	1
5. Place hands flat on the floor without bending the knees	1	
	Total 9	

One point may be gained for each side for maneuvers 1-4 so the hypermobility score will have a maximum of 9 points if all are positive.

From Hakim A, Grahame R: Joint hypermobility. Best Pract Res Clin Rheumatol *17:989–1004, 2003, Table 1.*

Table 659-3 A Five-Part Questionnaire for Identifying Hypermobility

1. Can you now (or could you ever) place your hands flat on the floor without bending your knees?
2. Can you now (or could you ever) bend your thumb to touch your forearm?
3. As a child did you amuse your friends by contorting your body into strange shapes *or* could you do the splits?
4. As a child or teenager did your shoulder or kneecap dislocate on more than one occasion?
5. Do you consider yourself double-jointed?

Answer in the affirmative to 2 or more questions suggests hypermobility with sensitivity 80-85% and specificity 80-90%

From Hakim A, Grahame R: Joint hypermobility. Best Pract Res Clin Rheumatol *17:989–1004, 2003, Table 3.*

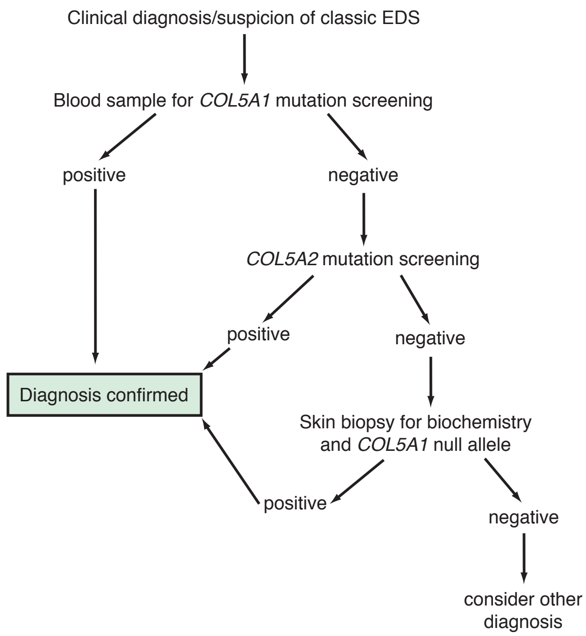

Figure 659-12 **Diagnostic flow chart for Ehlers-Danlos syndrome, classic type.** *(From De Paepe A, Malfait F: The Ehlers-Danlos syndrome, a disorder with many faces.* Clin Genet *82:1–11, 2012, Fig. 3.)*

PSEUDOXANTHOMA ELASTICUM

Etiology and Pathogenesis

Pseudoxanthoma elasticum (PXE) is a primary disorder of elastic tissue. The overwhelming majority of cases are caused by mutations in the *ABCC6* gene. The primary abnormality seen in PXE is an accumulation of mineralized tissue in the skin, Bruch membrane in the retina, and vessel walls. Although other forms of PXE have been postulated, their existence is now debated.

Clinical Manifestations

Onset of skin manifestations often occurs during childhood, but the changes produced by early lesions are subtle and may not be recognized. The characteristic **pebbly, "plucked chicken skin" cutaneous lesions** are 1-2 mm, asymptomatic, yellow papules that are arranged in a linear or reticulated pattern or in confluent plaques. Preferred sites are the flexural neck (Fig. 659-13), axillary and inguinal folds, umbilicus, thighs, and antecubital and popliteal fossae. As the lesions become more pronounced, the skin acquires a velvety texture and droops in lax, inelastic folds. The face is usually spared. Mucous membrane lesions may involve the lips, buccal cavity, rectum, and vagina. There is involvement of the connective tissue of the media, and intima of blood vessels, Bruch membrane of the eye, and endocardium or pericardium may result in visual disturbances, angioid streaks in Bruch membrane, intermittent claudication, cerebral and coronary occlusion, hypertension, and hemorrhage from the gastrointestinal tract, uterus, or mucosal surfaces. Women with PXE have an increased risk of miscarriage in the 1st trimester. Arterial involvement generally manifests in adulthood, but claudication and angina have occurred in early childhood.

Pathology

Histopathologic examination shows fragmented, swollen, and clumped elastic fibers in the middle and lower third of the dermis. The fibers stain positively for calcium. Collagen in the vicinity of the altered elastic fibers is reduced in amount and is split into small fibers. Aberrant calcification of the elastic fibers of the internal elastic lamina of arteries in PXE leads to narrowing of vessel lumina.

Treatment

There is no effective treatment for PXE, although laser therapy may help prevent retinal hemorrhage. The use of oral phosphate binders has shown promise in decreasing calcification of elastic fibers.

ELASTOSIS PERFORANS SERPIGINOSA

Etiology and Pathogenesis

Elastosis perforans serpiginosa (EPS) is characterized by the extrusion of altered elastic fibers through the epidermis. The primary abnormality is probably in the dermal elastin, which provokes a cellular response that ultimately leads to extrusion of the abnormal elastic tissue.

Clinical Manifestations

This is an unusual skin disorder in which 1-3 mm, firm, skin-colored, keratotic papules tend to cluster in arcuate and annular patterns on the posterolateral neck and limbs (Fig. 659-14) and occasionally on the face and trunk. Onset usually occurs in childhood or adolescence. A papule consists of a circumscribed area of epidermal hyperplasia that communicates with the underlying dermis by a narrow channel. There is a great increase in the amount and size of elastic fibers in the upper dermis, particularly in the dermal papillae. Approximately 30% occur in association with osteogenesis imperfecta, Marfan syndrome, PXE, EDS, Rothmund-Thomson syndrome, scleroderma, acrogeria, and Down syndrome. EPS has also occurred in association with penicillamine therapy.

Histology

Histopathology reveals a hyperplastic epidermis with extrusion of abnormal elastic fibers and a lymphocytic superficial infiltrate.

Differential Diagnosis

Differential diagnosis of EPS includes tinea corporis, perforating granuloma annulare, reactive perforating collagenosis, lichen planus, creeping eruption, and porokeratosis of Mibelli.

Treatment

Treatment of EPS is ineffective; however, the lesions are asymptomatic and may disappear spontaneously.

REACTIVE PERFORATING COLLAGENOSIS

Etiology and Pathogenesis

The primary process in reactive perforating collagenosis represents transepidermal elimination of altered collagen. A familial autosomal recessive form has been described.

Clinical Manifestations

Reactive perforating collagenosis usually manifests in early childhood as small papules on the dorsal areas of the hands and forearms, elbows, knees, and, sometimes, face and trunk. Over a period of several weeks, the papules enlarge to 5-10 mm, become umbilicated, and develop keratotic plugs in their centers (Fig. 659-15). Individual lesions resolve spontaneously in 2-4 mo, leaving hypopigmented macules or scars. Lesions may recur in crops; may undergo a linear Koebner phenomenon; and may form in response to cold temperatures or superficial trauma such as abrasions, insect bites, and acne lesions.

Figure 659-13 Confluent plaque of pebbly skin in pseudoxanthoma elasticum.

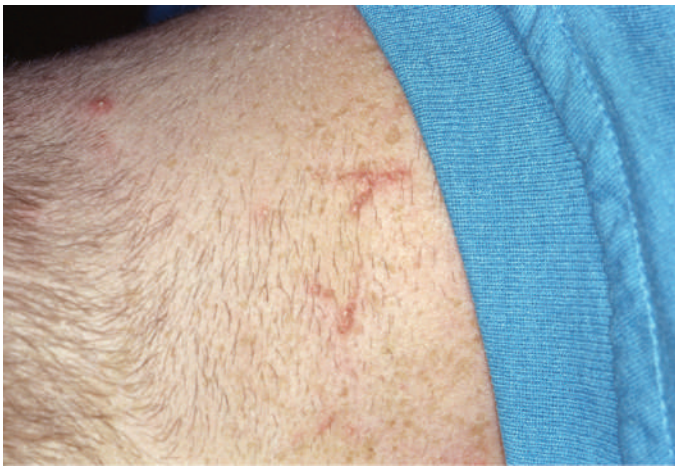

Figure 659-14 Arcuate keratotic papule of elastosis perforans serpiginosa.

Figure 659-15 Hyperkeratotic papules in reactive perforating collagenosis.

Figure 659-16 Ivory-colored papules on the upper back in Hunter syndrome.

Histology

Collagen in the papillary dermis is engulfed within a cup-shaped perforation in the epidermis. The central crater contains pyknotic inflammatory cells and keratinous debris.

Differential Diagnosis

EPS and Kyrle disease may mimic reactive perforating collagenosis.

Treatment

Reactive perforating collagenosis resolves spontaneously in 6-8 wk. Topical retinoic acid enhances the resolution.

MUCOPOLYSACCHARIDOSES

See Chapter 88.

In several of the mucopolysaccharidoses, thick, rough, inelastic skin, particularly on the extremities, and generalized hirsutism are characteristic but nonspecific features. Telangiectasias on the face, forearms, trunk, and legs have been observed in Scheie and Morquio syndromes. In some patients with Hunter syndrome, ivory-colored, distinctive firm papulonodules with a corrugated surface texture are grouped into symmetric plaques on the upper trunk (Fig. 659-16), arms, and thighs. Onset of these unusual lesions occurs in the 1st decade of life, and spontaneous disappearance has been noted.

MASTOCYTOSIS

Etiology and Pathogenesis

Mastocytosis encompasses a spectrum of disorders that range from solitary cutaneous nodules to diffuse infiltration of skin associated with involvement of other organs (Table 659-4). All of the disorders are characterized by aggregates of mast cells in the dermis. There are 4 types of mastocytoses: solitary mastocytoma, urticaria pigmentosa (2 forms), diffuse cutaneous mastocytosis, and telangiectasia macularis eruptiva perstans. The 2 forms of urticaria pigmentosa are the childhood variant, which resolves without sequelae, and the form that may start in either childhood or adult life and is associated with a mutation (most commonly the *D816V* mutation) in the stem cell factor gene. Stem cell factor (mast cell growth factor), which can be secreted by keratinocytes, stimulates the proliferation of mast cells and increases the production of melanin by melanocytes. The local and systemic manifestations of the disease are at least partly a result of the release of histamine and heparin from mast cell granules; although heparin is present in significant amounts in mast cells, coagulation disturbances occur only rarely. The vasodilator prostaglandin D_2 or its metabolite appears to exacerbate the flushing response. Serum tryptase values can be elevated.

Table 659-4 Mastocytosis Classification
Cutaneous mastocytosis:
1. Urticaria pigmentosa:
(a) Classic infantile type; (b) Chronic with stem cell factor mutations
2. Diffuse cutaneous mastocytosis
3. Mastocytoma of the skin
4. Telangiectasia macularis eruptive perstans
Systemic mastocytosis (without an associated hematologic non–mast cell disorder or leukemic mast cell disease):
1. Systemic indolent mastocytosis
2. Systemic smoldering mastocytosis
Systemic mastocytosis with an associated hematologic non–mast cell disorder:
1. Myeloproliferative syndrome
2. Myelodysplastic syndrome
3. Acute myeloid leukemia
4. Non-Hodgkin lymphoma
Systemic aggressive mastocytosis
Mast cell leukemia
Mast cell sarcoma
Extracutaneous mastocytoma

Adapted from Valent PHH, Li CY, Longley BJ, et al. World Health Organization classification of tumours, pathology and genetics of tumours of the haematopoietic and lymphoid tissues, *Lyon, France, 2001, IARC Press; and Carter MC, Metcalfe DD: Paediatric mastocytosis,* Arch Dis Child *86:315–319, 2002, Table 3.*

Clinical Manifestations

Solitary mastocytomas are usually 1-5 cm in diameter. Lesions may be present at birth or may arise in early infancy at any site. The lesions may manifest as recurrent, evanescent wheals or bullae; in time, an infiltrated, pink, yellow, or tan, rubbery plaque develops at the site of whealing or blistering (Fig. 659-17). The surface acquires a pebbly, orange peel–like texture, and hyperpigmentation may become prominent. Stroking or trauma to the nodule may lead to urtication (Darier sign) as a result of local histamine release; rarely, systemic signs of histamine release become apparent.

Figure 659-17 Solitary mastocytoma that is partially blistered.

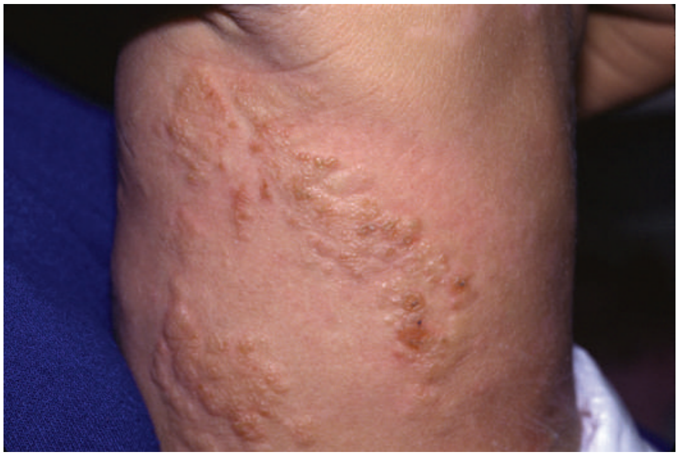

Figure 659-19 Severe blistering in diffuse cutaneous mastocytosis.

Figure 659-18 Hyperpigmented papular lesions of urticaria pigmentosa.

Urticaria pigmentosa is the most common form of mastocytosis. In the first type of urticaria pigmentosa, the classic infantile type, lesions may be present at birth but more often erupt in crops in the 1st several mo to 2 yr of age. New lesions seldom arise after age 3-4 yr. In some cases, early bullous or urticarial lesions fade, only to recur at the same site, ultimately becoming fixed and hyperpigmented. In others, the initial lesions are hyperpigmented. Vesiculation usually abates by 2 yr of age. Individual lesions range in size from a few millimeters to several centimeters and may be macular, papular, or nodular. They range in color from yellow-tan to chocolate brown and often have ill-defined borders (Fig. 659-18). Larger nodular lesions, like solitary mastocytomas, may have a characteristic orange peel texture. Lesions of urticaria pigmentosa may be sparse or numerous and are often symmetrically distributed. Palms, soles, and face are sometimes spared, as are the mucous membranes. The rapid appearance of erythema and whealing in response to vigorous stroking of a lesion can usually be elicited; dermographism of intervening normal skin is also common. Affected children can have intense pruritus. Systemic signs of histamine release, such as hypotension, syncope, headache, episodic flushing, tachycardia, wheezing, colic, and diarrhea, are uncommon and occur most frequently in the more severe types of mastocytosis. Flushing is by far the most common symptom seen.

The second type of urticaria pigmentosa may begin in infancy but typically develops in adulthood. This type does not resolve, and new lesions continue to develop throughout life. It is associated with mutations in the stem cell factor gene. Patients with this type of mastocytosis are the population in whom systemic involvement may develop.

Systemic mastocytosis is marked by an abnormal increase in the number of mast cells in other than cutaneous tissues. It occurs in approximately 5-10% of patients with mutant stem cell factor–related mastocytosis and is uncommon in children. Bone lesions may be silent but are detectable radiologically as osteoporotic or osteosclerotic areas, principally in the axial skeleton. Gastrointestinal tract involvement may produce complaints of abdominal pain, nausea, vomiting, diarrhea, steatorrhea, and bloating. Mucosal infiltrates may be detectable by barium studies or by small bowel biopsy. Peptic ulcers also occur. Hepatosplenomegaly as a result of mast cell infiltrates and fibrosis has been described, as has mast cell proliferation in lymph nodes, kidneys, periadrenal fat, and bone marrow. Abnormalities in the peripheral blood, such as anemia, leukocytosis, and eosinophilia, are noted in approximately 30% of patients. Mast cell leukemia may occur.

Diffuse cutaneous mastocytosis is characterized by diffuse involvement of the skin rather than discrete hyperpigmented lesions. Affected patients are usually normal at birth and demonstrate features of the disorder after the 1st few mo of life. Rarely, the condition may present with intense generalized pruritus in the absence of visible skin changes. The skin usually appears thickened and pink to yellow and may have a doughy feel and a texture resembling an orange peel. Surface changes are accentuated in flexural areas. Recurrent bullae (Fig. 659-19), intractable pruritus, and flushing attacks are common, as is systemic involvement.

Telangiectasia macularis eruptiva perstans is another variant that consists of telangiectatic hyperpigmented macules that are usually localized to the trunk. These lesions do not urticate when stroked. This form of the disease is seen primarily in adolescents and adults.

Differential Diagnosis

The differential diagnosis of solitary mastocytomas includes recurrent bullous impetigo, herpes simplex, congenital melanocytic nevi, and juvenile xanthogranuloma.

Urticaria pigmentosa can be confused with drug eruptions, postinflammatory pigmentary change, juvenile xanthogranuloma, pigmented nevi, ephelides, xanthomas, chronic urticaria, insect bites, and bullous impetigo. Diffuse cutaneous mastocytoma may be confused with epidermolytic hyperkeratosis.

Telangiectasia macularis eruptiva perstans must be differentiated from other causes of telangiectasia.

Table 659-5	Pharmacologic Agents and Physical Stimuli That May Exacerbate Mast Cell Mediator Release in Patients with Mastocytosis
IMMUNOLOGIC STIMULI Venoms (immunoglobulin E–mediated bee venom) Complement-derived anaphylatoxins Biologic peptides (substance P, somatostatin) Polymers (dextran)	
NONIMMUNOLOGIC STIMULI Physical stimuli (heat, cold, rubbing, trauma, sunlight) Drugs Acetylsalicylic acid and related nonsteroidal analgesics* Thiamine Ketorolac tromethamine Alcohol Vancomycin Dextromethorphan Narcotics (codeine, morphine)* Radiographic dyes (iodine containing)	
EMOTIONAL ISSUES Anxiety Sleep deprivation Stress	

*Appears to be a problem in <10% of patients.

From Carter MC, Metcalfe DD: Paediatric mastocytosis, Arch Dis Child *86:315–319, 2002, Table 4.*

Prognosis

Spontaneous involution occurs in all patients with solitary mastocytomas and classic infantile urticaria pigmentosa. The incidence of systemic manifestations in these patients is very low. The continued development of lesions past the age of 4 yr implies likely chronic disease with stem cell factor gene mutation and a higher risk for systemic involvement.

Treatment

Solitary mastocytomas usually do not require treatment. Lesions that blister may be treated with topical steroids following each blistering episode.

In urticaria pigmentosa, flushing can be precipitated by excessively hot baths, vigorous rubbing of the skin, and certain drugs, such as codeine, aspirin, morphine, atropine, ketorolac, alcohol, tubocurarine, iodine-containing radiographic dyes, and polymyxin B (Table 659-5). Avoidance of these triggering factors is advisable; it is notable that general anesthesia may be safely performed with appropriate precautions.

For patients who are symptomatic, oral antihistamines may be palliative. H_1 receptor antagonists (hydroxyzine) are the initial drugs of choice for systemic signs of histamine release. If H_1 antagonists are unsuccessful, H_2 receptor antagonists may be helpful in controlling pruritus or gastric hypersecretion. Topical steroids are of benefit in controlling skin urtication and blistering. Oral mast cell–stabilizing agents, such as cromolyn sodium or ketotifen, may also be effective for diarrhea or abdominal cramping and some systemic symptoms such as headache or muscle pain.

For patients with diffuse cutaneous mastocytosis, the treatment is the same as for urticaria pigmentosa, although in early life. Phototherapy with narrow-band UV (UVB or UVA-1) or psoralen with UVA treatment may be required to control symptoms.

Lesions of telangiectasia macularis eruptiva perstans may be cautiously treated with vascular pulsed-dye lasers.

Chapter 660

Diseases of Subcutaneous Tissue

JiaDe Yu and Beth A. Drolet

Diseases involving the subcutis are usually characterized by necrosis and/or inflammation; they may occur either as a primary event or as a secondary response to various stimuli or disease processes. The principal diagnostic criteria relate to the appearance and distribution of the lesions, associated symptoms, results of laboratory studies, histopathology, and natural history and exogenous provocative factors of these conditions.

CORTICOSTEROID-INDUCED ATROPHY

Intradermal or subcutaneous injection of a corticosteroid can produce deep atrophy accompanied by surface pigmentary changes and telangiectasia (Fig. 660-1). These changes occur approximately 2-8 wks after injection and may last for months.

660.1 Panniculitis and Erythema Nodosum

JiaDe Yu

Inflammation of fibrofatty subcutaneous tissue may primarily involve the fat lobule or, alternatively, the fibrous septum that compartmentalizes the fatty lobules. Lobular panniculitis that spares the subcutaneous vasculature includes poststeroid panniculitis, lupus erythematosus profundus, pancreatic panniculitis, α_1-antitrypsin deficiency, subcutaneous fat necrosis of the newborn, sclerema neonatorum, cold panniculitis, subcutaneous sarcoidosis, and factitial panniculitis. Lobar panniculitis with vasculitis occurs in erythema induratum and, occasionally, as a feature of Crohn disease (see Chapter 336.2). Inflammation predominantly within the septum, sparing the vasculature, may be seen in erythema nodosum (Table 660-1 and Fig. 660-2), necrobiosis lipoidica, progressive systemic sclerosis (see Chapter 160), and subcutaneous granuloma annulare (see Chapter 659). Septal panniculitis that includes inflammation of the vessels is found primarily in leukocytoclastic vasculitis and polyarteritis nodosa (see Chapter 167).

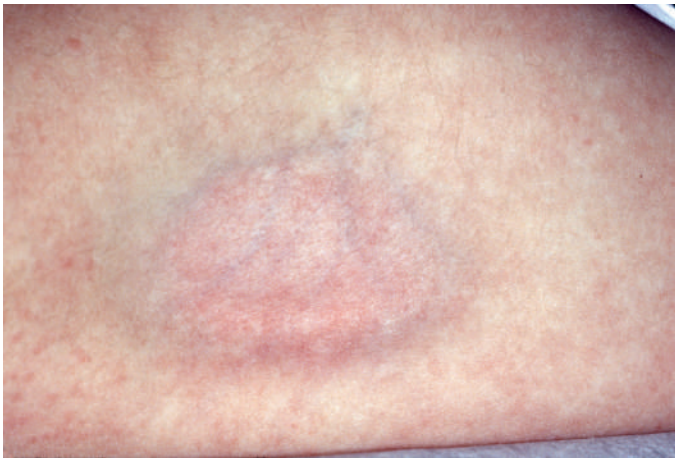

Figure 660-1 Localized fat atrophy with overlying erythema after steroid injection.

ERYTHEMA NODOSUM

Etiology and Pathogenesis

The etiology is unknown in 30-50% of pediatric cases of erythema nodosum; Table 660-1 lists other etiologies. Most common etiologies in children include: group A streptococcal infection, *Yersinia enterocolitica* gastroenteritis, medications (cephalosporins, penicillins, macrolides), and inflammatory disorders (inflammatory bowel disease); sarcoidosis should be considered in young adults.

Clinical Manifestations

Erythema nodosum is a nodular, erythematous hypersensitivity reaction that typically appears with multiple lesions on the anterior surfaces of the arms and legs in the pretibial area (more common) and less often in other cutaneous areas containing subcutaneous fat. The lesions vary in size from 1-6 cm, are symmetric, and are oval with the longer axis parallel to the extremity. They initially appear bright or dull red but progress to a brown or purple; they are painful and usually do not ulcerate (see Fig. 660-2). Initial lesions may resolve in 1-2 wk, but new lesions may continue to appear for 2-6 wk. Repeat episodes may occur weeks to months later. Prior to or immediately at the onset of lesions, there may be systemic manifestations that include fever, malaise, arthralgias (50-90%) and rheumatoid factor negative arthritis.

Table 660-1 Etiology of Erythema Nodosum
VIRUSES Epstein-Barr, hepatitis B, mumps
FUNGI Coccidioidomycosis, histoplasmosis, blastomycosis, sporotrichosis
BACTERIA AND OTHER INFECTIOUS AGENTS Group A streptococcus,* tuberculosis,* *Yersinia*, cat-scratch disease, leprosy, leptospirosis, tularemia, mycoplasma, Whipple disease, lymphogranuloma venereum, psittacosis, brucellosis
OTHER Sarcoidosis, inflammatory bowel disease,* estrogen-containing oral contraceptives,* systemic lupus erythematosus, Behçet syndrome, severe acne, Hodgkin disease, lymphoma, sulfonamides, bromides, Sweet syndrome, pregnancy, idiopathic*

*Common.

Figure 660-2 Tender red nodules with indistinct borders in a teenage girl with erythema nodosum. *(From Weston AL, Lane AT, Morelli JG: Color textbook of pediatric dermatology, ed 3, St. Louis, 2002, Mosby, p. 212.)*

Histology

A septal panniculitis with thickening of the septa with inflammatory cells infiltrate comprised of neutrophils acutely. Monocytes and histiocytes predominate in chronic erythema nodosum.

Treatment

Treatment includes that of the underlying disease as well as symptomatic relief with nonsteroidal antiinflammatory agents. Salicylates, supersaturated solution of potassium iodide (oral), colchicine, intralesional injections of steroids and, in severe, persistent, or recurrent lesions, oral steroids have been employed. The idiopathic form is a self-limited disorder. Protracted or recurrent cases may warrant further workup including antistreptolysin O/deoxyribonuclease B, complete blood count, throat culture, purified protein derivative, QuantiFERON-TB gold assay, chest radiograph, erythrocyte sedimentation rate, and C-reactive protein.

POST-STEROID PANNICULITIS

Etiology and Pathogenesis

The mechanism of the inflammatory reaction in the fat in poststeroid panniculitis is unknown.

Clinical Manifestations

Majority of the cases of post-steroid panniculitis have been reported in children. The disorder occurs in children who have received high-dose corticosteroids. In 1-2 wk after discontinuation of the drug, multiple subcutaneous nodules usually appear on the cheeks, although other areas may be involved. Nodules range in size from 0.5-4.0 cm, are erythematous or skin colored, and may be pruritic or painful.

Histology

A lobular panniculitis with a mixed infiltrate of lymphocytes, histiocytes, and neutrophils is seen. Scattered swollen adipocytes with eosinophilic, needle-shaped crystals are also seen. The epidermis, dermis, and fibrous septa of the fat are normal. Vasculitis is not seen.

Treatment

Treatment of poststeroid panniculitis is unnecessary because the lesions remit spontaneously over a period of months without scarring.

LUPUS ERYTHEMATOSUS PROFUNDUS (LUPUS ERYTHEMATOSUS PANNICULITIS)

Etiology and Pathogenesis

It is unknown what separates those patients in whom lupus erythematosus profundus develops from other patients with systemic lupus erythematosus. This variant of chronic cutaneous lupus erythematosus is rare in childhood. Recent studies show only 2-5% of patients with lupus erythematosus profundus have associated systemic lupus erythematosus. Mean age of onset in reported pediatric cases is 9.8 yr.

Clinical Manifestations

Lupus erythematosus profundus manifests as 1 to several firm, tender, well-defined, purple plaques or nodules 1-3 cm in diameter. Majority of pediatric cases involve the face and proximal upper extremities. This condition may occur in patients with systemic or discoid lupus erythematosus and may precede or follow the development of other cutaneous lesions. The overlying skin is usually normal but may be erythematous, atrophic, poikilodermatous, or hyperkeratotic (Fig. 660-3). On healing, a shallow depression generally remains or, rarely, soft pink areas of anetoderma result.

Figure 660-3 Deep nodule of lupus profundus with overlying hyperkeratotic lesion of discoid lupus erythematosus.

Histology
The histopathologic changes in lupus erythematosus profundus are distinctive and may allow the clinician to make the diagnosis in the absence of other cutaneous lesions of lupus erythematosus. The panniculitis is characterized by a mostly nodular dense infiltrate of lymphocytes and plasma cells. Necrosis of the fat lobule is characteristic. A dense perivascular and periappendiceal lymphocytic infiltrate is seen in the dermis. Lichenoid changes may be identified at the epidermal–dermal junction. Histopathologic differentiation from subcutaneous panniculitis–like T-cell lymphoma may be difficult. Results of lupus band and antinuclear antibody tests are usually positive.

Treatment
Nodules tend to be persistent and frequently ulcerate. Long-term follow-up for possible systemic involvement is warranted. There is no consensus on the utility of laboratory testing. antinuclear antibody is positive in only a small subset of patients. Few case reports show slight neutropenia, leukopenia, and mildly elevated liver function tests. Hydroxychloroquine (2-5 mg/kg/day) is the **treatment of choice** for lupus erythematosus profundus. Intralesional corticosteroids may worsen the residual lipoatrophy. Immunosuppressive agents are indicated only for treatment of other severe manifestations of systemic lupus erythematosus. Avoidance of sun exposure and trauma is also important.

α_1-ANTITRYPSIN DEFICIENCY
Etiology and Pathogenesis
Individuals with α_1-antitrypsin deficiency have severe homozygous deficiency or, rarely, a partial deficiency of the protease inhibitor α_1-antitrypsin, which inhibits trypsin activity and the activity of elastase, serine proteases, collagenase, factor VIII, and kallikrein (see Chapter 393). Panniculitis occurs with severe α_1-antitrypsin deficiency or the Z subtype.

Clinical Manifestations
Cellulitis-like areas or tender, red nodules occur on the trunk or proximal extremities (see Chapter 393). Nodules tend to ulcerate spontaneously and discharge an oily yellow fluid. Panniculitis may be associated with other manifestations of the disease, such as panacinar emphysema, noninfectious hepatitis, cirrhosis, persistent cutaneous vasculitis, cold contact urticaria, and acquired angioedema. Diagnosis can be substantiated by a decreased level of serum α_1-antitrypsin activity.

Histology
Extensive septal and lobular neutrophilic infiltrate with necrosis of the fat is observed.

Treatment
Treatment of the panniculitis in with α_1-antitrypsin deficiency is part of the overall treatment of the disease (see Chapter 393).

PANCREATIC PANNICULITIS
Etiology and Pathogenesis
Pathogenesis of pancreatic panniculitis appears to be multifactorial, involving liberation of the lipolytic enzymes lipase, trypsin, and amylase into the circulation, causing adipocyte membrane damage and intracellular lipolysis. There is no correlation, however, between the occurrence of panniculitis and the serum concentration of pancreatic enzymes.

Clinical Manifestations
Pancreatic panniculitis manifests most commonly on the pretibial regions, thighs, or buttocks as tender, erythematous nodules that may be fluctuant and occasionally discharge an oily yellowish substance. It appears most often in males with alcoholism but may also occur in patients with pancreatitis as a result of cholelithiasis or abdominal trauma, with rupture of a pancreatic pseudocyst, with pancreatic ductal adenocarcinoma, or with pancreatic acinar cell carcinoma. Associated features may include polyarthritis (pancreatitis-panniculitis-polyarthritis syndrome). In almost 65% of patients, abdominal signs are absent or mild, making the diagnosis difficult.

Histology
Microscopic changes consist of multiple foci of fat necrosis that contain ghost cells with thick, shadowy walls and no nuclei. A polymorphous inflammatory infiltrate surrounds the areas of fat necrosis.

Treatment
The primary pancreatic disorder must be treated. The arthritis may be chronic and responds poorly to treatment with nonsteroidal antiinflammatory drugs and oral corticosteroids.

SUBCUTANEOUS FAT NECROSIS
Etiology and Pathogenesis
The cause of subcutaneous fat necrosis (SCFN) is unknown. The disease in infants may be a result of ischemic injury from various perinatal complications, such as maternal preeclampsia, birth trauma, asphyxia, and prolonged hypothermia. Whole-body cooling for neonatal encephalopathy is increasingly associated with SCFN. Susceptibility is attributed to differences in composition between the subcutaneous tissue of young infants and that of older infants, children, and adults. Neonatal fat solidifies at a relatively high temperature because of its relatively greater concentration of high-melting-point saturated fatty acids, such as palmitic and stearic acids.

Clinical Manifestations
This inflammatory disorder of adipose tissue occurs primarily in the 1st 4 wk of life in full-term or postterm infants. Typical lesions are asymptomatic, indurated, erythematous to violaceous, sharply demarcated plaques or nodules on the cheeks, buttocks, back, thighs, or upper arms (Fig. 660-4). Lesions may be focal or extensive and are generally asymptomatic, although they may be tender during the acute phase. Uncomplicated lesions involute spontaneously within weeks to months, usually without scarring or atrophy. Calcium deposition may occasionally occur within areas of fat necrosis, which may sometimes result in rupture and drainage of liquid material. These areas may heal with atrophy. A rare but potentially life-threatening complication is **hypercalcemia**. It manifests at 1-6 mo of age (in a review of 20 cases, average age at onset was 6.7 wk) as lethargy, poor feeding, vomiting, failure to thrive, irritability, seizures, shortening of the QT interval on electrocardiography, or renal failure. The origin of the hypercalcemia is unknown, but an accepted hypothesis is that the macrophages present produce 1,25-dihydroxyvitamin D_3 which, in turn, increases calcium uptake. Infants with SCFN should be followed for several months to monitor for delayed hypercalcemia.

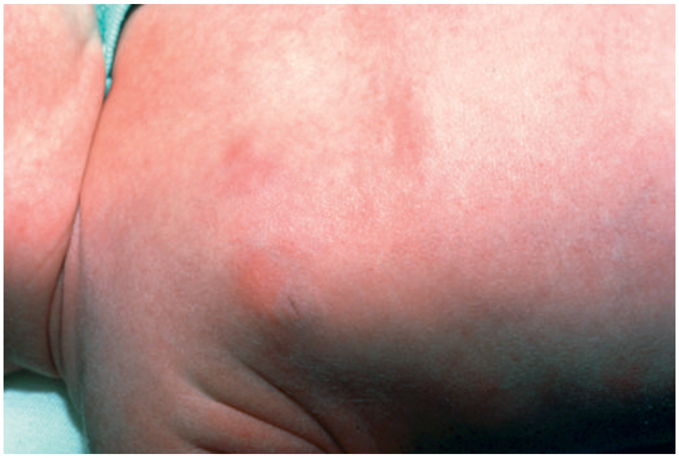

Figure 660-4 Red-purple nodular infiltration of the skin of the chest caused by subcutaneous fat necrosis.

Histology
Histopathologic changes in SCFN are diagnostic, consisting of: necrosis of fat; a granulomatous cellular infiltrate composed of lymphocytes, histiocytes, multinucleated giant cells, and fibroblasts; and radially arranged clefts of crystalline triglyceride within fat cells and multinucleated giant cells. Calcium deposits are commonly found in areas of fat necrosis.

Differential Diagnosis
SCFN can be confused with sclerema neonatorum, panniculitis, cellulitis, and hematoma.

Treatment
Because the lesions are self-limited, therapy is not required for uncomplicated cases of SCFN. Needle aspiration of fluctuant lesions may prevent rupture and subsequent scarring but is rarely needed. Treatment of hypercalcemia is aimed at enhancing renal calcium excretion with hydration and furosemide (1-2 mg/kg/dose) and at limiting dietary calcium and vitamin D intake. Reduction of intestinal calcium absorption and alteration of vitamin D metabolism may be accomplished by administration of corticosteroids (0.5-1.0 mg/kg/day). Pamidronate (0.25-0.5 mg/kg/day) has been used in severe cases.

SCLEREMA NEONATORUM
Etiology and Pathogenesis
Although the cause remains unknown, 4 theories of pathogenesis for sclerema neonatorum have been proposed. It is theorized that sclerema neonatorum results from hardening of the subcutaneous fat because of a decrease in body temperature as a consequence of circulatory shock; a defect in lipolytic enzymes or in lipid transport; association with an underlying severe disease; or a special form of edema affecting the connective tissue that supports the adipocytes.

Clinical Manifestations
This uncommon disorder of adipose tissue manifests abruptly in preterm, gravely ill infants as diffuse, yellowish white woody induration of the skin. It begins on the legs and buttocks then quickly progresses to other areas, sparing palms and soles. Affected skin becomes stony in consistency, cold, and nonpitting. The face assumes a masklike expression, and joint mobility may be compromised because of inflexibility of the skin.

Histology
Histopathologic changes in sclerema neonatorum consist of increases in the size of fat cells and in the width of the fibrous connective tissue septa. In contrast to SCFN, with which this disorder is most apt to be confused, fat necrosis, inflammation, giant cells, and calcium crystals are generally absent.

Treatment
Sclerema neonatorum is almost always associated with serious illness, such as sepsis, congenital heart disease, multiple congenital anomalies, or hypothermia. The appearance of sclerema in a sick infant should be regarded as an ominous prognostic sign. The outcome depends on the response of the underlying disorder to treatment.

COLD PANNICULITIS
Etiology and Pathogenesis
The pathogenic mechanism of cold panniculitis may be similar to that of SCFN, involving a greater propensity of fat to solidify in infants than in older children and adults as a result of the higher percentage of saturated fatty acids in the subcutaneous fat of infants. Lesions occur in infants after prolonged cold exposure, especially on the cheeks, or after prolonged application of a cold object such as an ice cube, ice bag, or fruit ice pop to any area of the skin.

Clinical Manifestations
Ill-defined, erythematous to bluish, indurated plaques or nodules arise within hours to a couple days of exposure on exposed surfaces (face, arms, legs), persist for 2-3 wk, and heal without residua.

Histology
Histopathologic examination reveals an infiltrate of lymphoid and histiocytic cells around blood vessels at the dermal–subdermal junction and in the fat lobules; by the 3rd day, some of the fat cells in the subcutis may have ruptured and coalesced into cystic structures.

Differential Diagnosis
Cold panniculitis may be confused with facial cellulitis caused by *Haemophilus influenzae* type b. Unlike in buccal cellulitis, the area may be cold to the touch, and the patient is afebrile and appears well.

Treatment
Treatment is unnecessary because cold panniculitis spontaneously resolves. Recurrence of the lesions is common, emphasizing the importance of parental education in treating affected patients.

CHILBLAINS (PERNIO)
Etiology and Pathogenesis
Vasospasm of arterioles from damp cold exposure with resultant hypoxemia and localized perivascular mononuclear inflammation appears to be responsible for chilblains. The disease is associated with cryoglobulins, lupus erythematosus with antiphospholipid antibodies, anorexia nervosa, and thin body habitus.

Clinical Manifestations
The condition is characterized by localized symmetric erythematous to purplish edematous plaques and nodules in areas exposed to cold, typically acral areas (distal hands and feet, ears, face; see Chapter 76). Lesions develop 12-24 hr after cold exposure and may be associated with itching, burning, or pain. Blister formation and ulceration are rare.

Histology
Histopathologic examination reveals marked dermal edema and a perivascular and periappendiceal, predominantly T-cell lymphocytic infiltrate in the papillary and reticular dermis.

Differential Diagnosis
Raynaud phenomenon is more acute in nature than chilblains, with characteristic color changes and no chronic lesions. Frostbite due to extreme cold exposure is painful and involves freezing of the tissue with resultant tissue necrosis.

Treatment
Most cases of chilblains resolve spontaneously but can last 2-3 wk. Prevention is the treatment of choice. Nifedipine (0.25-0.5 mg/kg tid,

maximum 10 mg/dose) may be used in severe cases. Unusual or persistent cases of perniosis in children may warrant further work-up including antinuclear antibody titer, cryoglobulins, complete blood count, and cold agglutinins.

FACTITIAL PANNICULITIS

Etiology and Pathogenesis

Factitial panniculitis results from subcutaneous injection by the patient or a proxy of a foreign substance, the most common types of which are organic materials, such as milk and feces; drugs, such as the opiates and pentazocine; oily materials, such as mineral oil and paraffin; and the synthetic polymer povidone.

Clinical Manifestations

Indurated plaques, ulcers, or nodules that liquefy and drain may be noted clinically in factitial panniculitis.

Histology

The histopathology is variable, depending on the injected substance, but may include the presence of birefringent crystals, oil cysts surrounded by fibrosis and inflammation, and an acute inflammatory reaction with fat necrosis. Vessels are characteristically spared.

Treatment

Treatment of factitial panniculitis must address the primary reason the patient is performing the self-destructive act. Munchausen syndrome by proxy should be considered in young children.

660.2 Lipodystrophy

JiaDe Yu

Several rare conditions are associated with loss of fatty tissue in a partial or generalized distribution and can be familial or acquired. Loss of adipose at certain sites is often accompanied by fat redistribution and consequent hypertrophy of adipose at other sites. Extent of fatty tissue loss or expansion correlates with the degree of clinical and metabolic abnormalities.

PARTIAL LIPODYSTROPHY

Partial lipodystrophy may be familial or acquired. Loss of adipose tissue is not preceded by an inflammatory phase, and histopathologic examination reveals only absence of subcutaneous fat.

There are 5 forms of familial partial lipodystrophy (FPLD):

- **Type I (FPLD1–Kobberling)** is characterized by loss of adipose tissue confined to the extremities and gluteal region. Fat distribution of the face, neck, and trunk may be normal or increased. Hyperlipidemia, insulin-resistant diabetes mellitus, and eruptive xanthomas may be seen. The gene is unknown, but only females are affected.
- **Type 2 (FPLD2–Dunnigan)** is the most common form of FPLD and caused by mutations in the *laminin A/C* gene leading to premature death of adipocytes. Fat distribution is normal in childhood, but atrophy commences with puberty. Lipodystrophy is seen in the trunk, gluteal region, and extremities. Adipose tissue accumulates in the face and neck and may also be seen in the axillae, back, labia majora, and infraabdominal region. Insulin-resistant diabetes mellitus and hypertriglyceridemia develop, but high-density lipoprotein and cholesterol levels are low. Both males and females are affected, but the diagnosis may be more difficult in males owing to body habitus.
- **Type 3 (FPLD3)** is caused by mutations in the peroxisome proliferation–activated receptor γ *(PPARG)* gene inhibiting adipocyte differentiation. Lipodystrophy is seen in the distal limbs and gluteal region. Insulin-resistant diabetes mellitus, primary amenorrhea, acanthosis nigricans, hypertension, and fatty infiltration of the liver are present.
- **Type 4 (FPLD4)** and **Type 5 (FPLD5)** are caused by mutations in *AKT2* and *Perilipin-1 (PLIN1)*, respectively. Both types are also characterized by loss of subcutaneous fat primarily from the extremities.

Acquired partial lipodystrophy (Barraquer-Simons syndrome) is caused by mutations in the *LMNB2* gene. Females are more commonly affected. Fat loss begins in childhood or adolescence and progresses in a cephalotruncal direction, beginning on the face and sparing the lower extremities. Excess fat deposition is seen in the hips and legs, especially in females. Low levels of complement C3 are almost universally seen because of the presence of C3 nephritic factor that stabilizes C3 convertase, allowing for unopposed activation of the alternate complement pathway leading to decreased level of C3. Membranous proliferative glomerulonephritis and other autoimmune diseases may develop. Insulin-resistant diabetes mellitus is rare.

GENERALIZED LIPODYSTROPHY

Generalized lipodystrophy may also be congenital or acquired.

Congenital generalized lipodystrophy is seen in 4 forms:

- **Type 1 (Berardinelli-Seip congenital lipodystrophy type 1 [BSCL1])** is an autosomal recessive disorder caused by mutations in the 1-acylglycerol-3-phosphate-*O*-acyltransferase *(AGPAT2)* gene.
- **Type 2 (Berardinelli-Seip congenital lipodystrophy type 2 [BSCL2])** is also autosomal recessive and caused by mutations in the seipin gene.
- **Type 3 *(CAV1)*** is autosomal recessive and caused by mutations in the caveolin 1 gene.
- **Type 4 (*PTRF*)** is autosomal recessive and caused by mutations in the polymerase I and transcript release factor gene. In addition to the classic phenotype of congenital generalized lipodystrophy, these patients also have muscular dystrophy and cardiac conduction abnormalities (QT prolongation).

Marked lipodystrophy occurs at birth or in early infancy with prominent muscularity. Diabetes mellitus, hypertriglyceridemia, hepatic steatosis, acanthosis nigricans, and muscular hypertrophy occur. Congenital generalized lipodystrophy type 1 and type 2 are the most common, with the latter having a more severe phenotype characterized by extensive fat loss, cardiomyopathy, intellectual impairment, and premature death in ≈15% of cases.

Acquired generalized lipodystrophy is more common in females. The most common associated disorder is juvenile dermatomyositis (78%). Panniculitis preceding the loss of fat is seen in 17% of affected individuals. More than half of the children may have other complications, including acanthosis nigricans, hyperpigmentation, hepatomegaly, hypertension, protuberant abdomen, and hyperlipidemia.

Localized lipoatrophy can be idiopathic or secondary to subcutaneous medication injections, pressure, and panniculitis. Unlike generalized or partial lipodystrophy, localized lipoatrophy involve a small part of the body and have no accompanying metabolic derangements. Idiopathic localized lipoatrophy manifests as annular atrophy at the ankles; a bandlike semicircular depression 2-4 cm in diameter on the thighs, abdomen, and/or upper groin or as a centrifugally spreading, depressed, bluish plaque with an erythematous margin. **Insulin lipoatrophy** usually occur approximately 6 mo to 2 yr after initiation of relatively high doses of insulin. A dimple or well-circumscribed depression at or surrounding the site of injection is typically seen. Biopsy reveals a marked decrease or absence of subcutaneous tissue, without inflammation or fibrosis. In some patients, hypertrophy occurs clinically. In these cases, the mid-dermal collagen is replaced by hypertrophic fat cells on histopathologic sections. A recent study shows that adipocytes chronically exposed to high insulin concentrations become insulin-resistant, leading to lipolysis and atrophy. Lesions may also be prevented by frequent alteration of injection sites.

Chapter 661

Disorders of the Sweat Glands

Kari L. Martin

Eccrine glands are found over nearly the entire skin surface and provide the primary means, through evaporation of the water in sweat, of cooling the body. These glands have no anatomic relationship to hair follicles and secrete a relatively large amount of odorless aqueous sweat. In contrast, apocrine sweat glands are limited in distribution to the axillae, anogenital skin, mammary glands, ceruminous glands of the ear, Moll glands in the eyelid, and selected areas of the face and scalp. Each apocrine gland duct enters the pilosebaceous follicle at the level of the infundibulum and secretes a small amount of a complex, viscous fluid that, on alteration by microorganisms, produces a distinctive body odor. Some disorders of these 2 types of sweat glands are similar pathogenetically, whereas others are unique to a given gland.

ANHIDROSIS

Neuropathic anhidrosis results from a disturbance in the neural pathway from the control center in the brain to the peripheral efferent nerve fibers that activate sweating. Disorders in this category, which are characterized by generalized anhidrosis, include tumors of the hypothalamus and damage to the floor of the third ventricle. Pontine or medullary lesions may produce anhidrosis of the ipsilateral face or neck and ipsilateral or contralateral anhidrosis of the rest of the body. Peripheral or segmental neuropathies, caused by leprosy, amyloidosis, diabetes mellitus, alcoholic neuritis, or syringomyelia, may be associated with anhidrosis of the innervated skin. Various autonomic disorders are also associated with altered eccrine sweat gland function.

At the level of the sweat gland, anticholinergics (drugs such as atropine and scopolamine) may paralyze the sweat glands. Acute intoxication with barbiturates or diazepam has produced necrosis of sweat glands, resulting in anhidrosis with or without erythema and bullae. Eccrine glands are largely absent throughout the skin or are present in a localized area among patients with **hypohidrotic ectodermal dysplasia** or **localized congenital absence of sweat glands,** respectively. Infiltrative or destructive disorders that may produce atrophy of sweat glands by pressure or scarring include scleroderma, acrodermatitis chronica atrophicans, radiodermatitis, burns, Sjögren syndrome, multiple myeloma, and lymphoma. Obstruction of sweat glands may occur in miliaria and in a number of inflammatory and hyperkeratotic disorders, such as the ichthyoses, psoriasis, lichen planus, pemphigus, porokeratosis, atopic dermatitis, and seborrheic dermatitis. Occlusion of the sweat pore may also occur with the topical agents aluminum and zirconium salts, formaldehyde, or glutaraldehyde.

Diverse disorders that are associated with anhidrosis by unknown mechanisms include dehydration; toxic overdose with lead, arsenic, thallium, fluorine, or morphine; uremia; cirrhosis; endocrine disorders such as Addison disease, diabetes mellitus, diabetes insipidus, and hyperthyroidism; and inherited conditions such as autonomic neuropathies, Fabry disease, Franceschetti-Jadassohn syndrome, which combines features of incontinentia pigmenti and hypohidrotic ectodermal dysplasia, congenital insensitivity to pain with anhidrosis syndrome, and familial anhidrosis with neurolabyrinthitis.

Anhidrosis may be complete, but in many cases, what appears clinically to be anhidrosis is actually **hypohidrosis** caused by anhidrosis of many, but not all, eccrine glands. Compensatory, localized hyperhidrosis of the remaining functional sweat glands may occur, particularly in diabetes mellitus and miliaria. The primary complication of anhidrosis is **hyperthermia,** seen primarily in anhidrotic ectodermal dysplasia or in otherwise normal preterm or full-term neonates who have immature eccrine glands.

HYPERHIDROSIS

Etiology and Pathogenesis

Hyperhidrosis is excessive sweating beyond what is physiologically necessary for temperature control and occurs in 3% of the population with about half having axillary hyperhidrosis. The numerous disorders that may be associated with increased production of eccrine sweat may also be classified into those with neural mechanisms involving an abnormality in the pathway from the neural regulatory centers to the sweat gland and those that are nonneurally mediated and occur by direct effects on the sweat glands (Table 661-1).

Clinical Manifestations

The average age at onset of hyperhidrosis is 14-25 yr. The excess sweating may be continuous or may occur in response to emotional stimuli. In severe cases, sweat may be seen to drip constantly from the hands.

Treatment

Excessive sweating of the palms and soles (volar hyperhidrosis) and axillary sweating may respond to 20% aluminum chloride in anhydrous ethanol applied under occlusion for several hours, iontophoresis, injection with botulinum toxin, therapy with oral anticholinergics, or in severe, refractory cases, cervicothoracic or lumbar sympathectomy. Reports of successful treatment of hyperhidrosis with microwave technology are available, but studies are faulted with small sample size and lack of controls.

Table 661-1 Causes of Hyperhidrosis

CORTICAL	Cardiovascular:
Emotional	Heart failure
Familial dysautonomia	Shock
Congenital ichthyosiform erythroderma	Vasomotor
Epidermolysis bullosa	Cold injury
Nail-patella syndrome	Raynaud phenomenon
Jadassohn-Lewandowsky syndrome	Rheumatoid arthritis
Pachyonychia congenita	Neurologic:

Obesity	Klippel-Trenaunay syndrome
Pheochromocytoma	Glomus tumor
Porphyria	Blue rubber-bleb nevus syndrome
Pregnancy	
Rickets	
Infantile scurvy	

MILIARIA

Etiology and Pathogenesis

Miliaria results from retention of sweat in occluded eccrine sweat ducts. The keratinous plug does not form until the later stages of the disease and therefore does not appear to be the primary cause of the sweat duct obstruction. The initial obstruction is postulated to be caused by swelling of the ductal epidermal cells, perhaps from imbibition of water. Retrograde pressure may result in rupture of the duct and leakage of sweat into the epidermis and/or the dermis. The eruption is most often induced by hot, humid weather, but it may also be caused by high fever. Infants who are dressed too warmly may demonstrate this eruption indoors, even during the winter.

Clinical Manifestations

In **miliaria crystallina,** asymptomatic, noninflammatory, pinpoint, clear vesicles may suddenly erupt in profusion over large areas of the body surface, leaving brawny desquamation on healing (Fig. 661-1). This type of miliaria occurs most frequently in newborn infants because of the relative immaturity and delayed patency of the sweat duct and the tendency for infants to be nursed in relatively warm, humid conditions. It may also occur in older patients with hyperpyrexia.

Miliaria rubra is a less superficial eruption characterized by erythematous, minute papulovesicles that may impart a prickling sensation. The lesions are usually localized to sites of occlusion or to flexural areas, such as the neck, groin, and axillae, where friction may have a role in their pathogenesis. Involved skin may become macerated and eroded. Lesions of miliaria rubra, however, are extrafollicular.

Repeated attacks of miliaria rubra may lead to **miliaria profunda,** which is caused by rupture of the sweat duct deeper in the skin, at the level of the dermal–epidermal junction. Severe, extensive miliaria rubra or miliaria profunda may result in disturbance of heat regulation. Lesions of miliaria rubra may become infected, particularly in malnourished or debilitated infants, leading to development of **periporitis staphylogenes,** which involves extension of the process from the sweat duct into the sweat gland.

Histology

Histologically, miliaria crystallina reveals an intracorneal or subcorneal vesicle in communication with the sweat duct, whereas in miliaria rubra, one sees focal areas of spongiosis and spongiotic vesicle formation in close proximity to sweat ducts that generally contain a keratinous plug.

Differential Diagnosis

The clarity of the fluid, superficiality of the vesicles, and absence of inflammation permit differentiation of miliaria crystalline from other blistering disorders. Miliaria rubra may be confused with or superimposed on other diaper area eruptions, including candidosis and folliculitis.

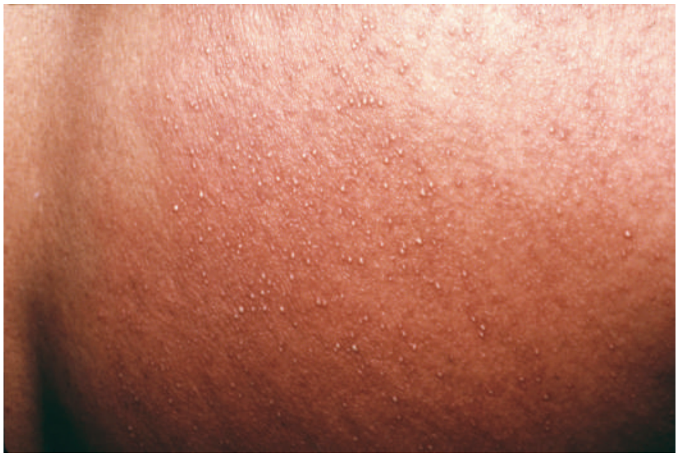

Figure 661-1 Superficial clear vesicles of miliaria crystallina.

Treatment

All forms of miliaria respond dramatically to cooling of the patient by regulation of environmental temperatures and by removal of excessive clothing; administration of antipyretics is also beneficial to patients with fever. Topical agents are usually ineffective and may exacerbate the eruption.

BROMHIDROSIS

The excessive odor that characterizes bromhidrosis may result from alteration of either apocrine or eccrine sweat. Apocrine bromhidrosis develops after puberty as a result of the formation of short-chain fatty acids and ammonia by the action of anaerobic diphtheroids on axillary apocrine sweat. Eccrine bromhidrosis is caused by microbiologic degradation of stratum corneum that has become softened by excessive eccrine sweat. The soles of the feet and the intertriginous areas are the primary affected sites. Hyperhidrosis, warm weather, obesity, intertrigo, and diabetes mellitus are predisposing factors. **Treatments** that may be helpful include cleansing with germicidal soaps, topical clindamycin or erythromycin, or topical application of aluminum or zirconium. Treatment of any associated hyperhidrosis is mandatory.

HIDRADENITIS SUPPURATIVA

Etiology and Pathogenesis

Hidradenitis suppurativa is a disease of the apocrine gland–bearing areas of the skin. Pathogenesis of hidradenitis suppurativa is controversial. It is believed that it is a primary inflammatory disorder of the hair follicle and not solely an alteration of apocrine glands. It is considered a part of the follicular occlusion tetrad, along with acne conglobata, dissecting cellulites of the scalp, and pilonidal sinus. The natural history of the disease involves progressive dilation below the follicular obstruction, leading to rupture of the duct, inflammation, sinus tract formation, and destructive scarring.

Clinical Manifestations

Hidradenitis suppurativa is a chronic, inflammatory, suppurative disorder of the follicular units in the axillae, the anogenital area, and, occasionally, the scalp, posterior aspect of the ears, female breasts, and periumbilical area. Onset of clinical manifestations is sometimes preceded by pruritus or discomfort and usually occurs during puberty or early adulthood. Solitary or multiple painful erythematous nodules, deep abscesses, and contracted scars are sharply confined to areas of skin containing apocrine glands. When the disease is severe and chronic, sinus tracts, ulcers, and thick, linear fibrotic bands develop. Hidradenitis suppurativa tends to persist for many years, punctuated by relapses and partial remissions. Complications include cellulitis, ulceration, and burrowing abscesses that may perforate adjacent structures, forming fistulas to the urethra, bladder, rectum, or peritoneum. Episodic inflammatory arthritis develops in some patients.

Histology

Early lesions are characterized by a keratinous plug in the apocrine duct or hair follicle orifice and by cystic distention of the follicle. The process generally but not necessarily extends into the apocrine gland. Later changes include inflammation within and around apocrine glands. Scarring may obliterate skin appendages.

Differential Diagnosis

Early lesions of hidradenitis suppurativa are often mistaken for infected epidermal cysts, furuncles, scrofuloderma, actinomycosis, cat-scratch disease, granuloma inguinale, or lymphogranuloma venereum. Sharp localization to areas of the body that bear apocrine glands, however, should suggest hidradenitis. When involvement is limited to the anogenital region, the condition may be difficult to distinguish from Crohn disease.

Treatment

Conservative management includes cessation of smoking, weight loss, and avoidance of irritation of the affected area. Warm compresses and topical antiseptic or antibacterial soaps may also be helpful. For mild,

early disease, topical clindamycin 1% may be helpful. For more-severe disease, therapy may be initiated with doxycycline (100 mg bid) or minocycline (100 mg bid). Some patients require intermittent or long-term antibiotic treatment. Combination therapy with clindamycin and rifampin is helpful in some patients. Oral retinoids (1 mg/kg/day) for 5-6 mo may also be effective. Oral contraceptive agents, which contain a high estrogen : progesterone ratio and low androgenicity of the progesterone, are another alternative. Laser hair ablation has proven helpful in some studies as well. Systemic immunosuppressants (infliximab, adalimumab, cyclosporine) and medications targeted at glucose metabolism and the metabolic syndrome (metformin) have been helpful. Surgical measures may be required for control or cure, especially in localized, recalcitrant cases.

FOX-FORDYCE DISEASE

Etiology and Pathogenesis

The cause of Fox-Fordyce disease is unknown.

Clinical Manifestations

This disease is most common in females and manifests during puberty to the 3rd decade of life as pruritus in the axillae. Pruritus is exacerbated by emotional stress and stimuli that induce apocrine sweating. Dome-shaped, skin-colored to slightly hyperpigmented, follicular papules develop in the pruritic areas.

Histology

Histopathologically, one sees keratinous plugging of the distal apocrine duct, rupture of the intraepidermal portion of the apocrine duct, periductal microvesicle formation, and periductal acanthosis.

Treatment

Fox-Fordyce disease is difficult to treat. Oral contraceptive pills and topical corticosteroids or retinoic acid may help some patients.

Table 662-1	Causes of and Conditions Associated with Hypertrichosis

INTRINSIC FACTORS
Racial and familial forms such as hairy ears, hairy elbows, intraphalangeal hair, or generalized hirsutism

EXTRINSIC FACTORS
Local trauma
Malnutrition
Anorexia nervosa
Long-standing inflammatory dermatoses
Drugs: Diazoxide, phenytoin, corticosteroids, Cortisporin, cyclosporine, androgens, anabolic agents, hexachlorobenzene, minoxidil, psoralens, penicillamine, streptomycin

HAMARTOMAS OR NEVI
Congenital pigmented nevocytic nevus, hair follicle nevus, Becker nevus, congenital smooth muscle hamartoma, fawn-tail nevus associated with diastematomyelia

ENDOCRINE DISORDERS
Virilizing ovarian tumors, Cushing syndrome, acromegaly, hyperthyroidism, hypothyroidism, congenital adrenal hyperplasia, adrenal tumors, gonadal dysgenesis, male pseudohermaphroditism, non–endocrine hormone–secreting tumors, polycystic ovary syndrome

CONGENITAL AND GENETIC DISORDERS
Hypertrichosis lanuginosa, mucopolysaccharidosis, leprechaunism, congenital generalized lipodystrophy, de Lange syndrome, trisomy 18, Rubinstein-Taybi syndrome, Bloom syndrome, congenital hemihypertrophy, gingival fibromatosis with hypertrichosis, Winchester syndrome, lipoatrophic diabetes (Lawrence-Seip syndrome), fetal hydantoin syndrome, fetal alcohol syndrome, congenital erythropoietic or variegate porphyria (sun-exposed areas), porphyria cutanea tarda (sun-exposed areas), Cowden syndrome, Seckel syndrome, Gorlin syndrome, partial trisomy 3q, Ambras syndrome

Chapter 662
Disorders of Hair

Kari L. Martin

Disorders of hair in infants and children may be a result of intrinsic disturbances of hair growth, underlying biochemical or metabolic defects, inflammatory dermatoses, or structural anomalies of the hair shaft. Excessive and abnormal hair growth is referred to as hypertrichosis or hirsutism. **Hypertrichosis** is excessive hair growth at inappropriate locations; hirsutism is an androgen-dependent male pattern of hair growth in women. **Hypotrichosis** is deficient hair growth. Hair loss, partial or complete, is called *alopecia*. Alopecia may be classified as nonscarring or scarring; the latter type is rare in children and, if present, is most often caused by prolonged or untreated inflammatory conditions, such as pyoderma and tinea capitis.

HYPERTRICHOSIS

Hypertrichosis is rare in children and may be localized or generalized and permanent or transient. Table 662-1 lists some of the many causes of hypertrichosis.

HYPOTRICHOSIS AND ALOPECIA

Table 662-2 lists some of the disorders associated with hypotrichosis and alopecia. True alopecia is rarely congenital; it is more often related

Table 662-2	Disorders Associated with Alopecia and Hypotrichosis

Congenital total alopecia: Atrichia with papules, Moynahan alopecia syndrome
Congenital localized alopecia: Aplasia cutis, triangular alopecia, sebaceous nevus
Hereditary hypotrichosis: Marie-Unna syndrome, hypotrichosis with juvenile macular dystrophy, hypotrichosis–Mari type, ichthyosis with hypotrichosis, cartilage-hair hypoplasia, Hallermann-Streiff syndrome, trichorhinophalangeal syndrome, ectodermal dysplasia "pure" hair and nail and other ectodermal dysplasias
Diffuse alopecia of endocrine origin: Hypopituitarism, hypothyroidism, hypoparathyroidism, hyperthyroidism
Alopecia of nutritional origin: Marasmus, kwashiorkor, iron deficiency, zinc deficiency (acrodermatitis enteropathica), gluten-sensitive enteropathy, essential fatty acid deficiency, biotinidase deficiency
Disturbances of the hair cycle: Telogen effluvium
Toxic alopecia: Anagen effluvium
Autoimmune alopecia: Alopecia areata
Traumatic alopecia: Traction alopecia, trichotillomania
Cicatricial alopecia: Lupus erythematosus, lichen planopilaris, pseudopelade, morphea (en coup de saber) dermatomyositis, infection (kerion, favus, tuberculosis, syphilis, folliculitis, leishmaniasis, herpes zoster, varicella), acne keloidalis, follicular mucinosis, sarcoidosis
Hair shaft abnormalities: Monilethrix, pili annulati, pili torti, trichorrhexis invaginata, trichorrhexis nodosa, woolly hair syndrome, Menkes disease, trichothiodystrophy, trichodento-osseous syndrome, uncombable hair syndrome (spun-glass hair, pili trianguli et canaliculi)

Table 662-3 Helpful Historical Clues in Diagnosis of Hair Disorders

to an inflammatory dermatosis, mechanical factors, drug ingestion, infection, endocrinopathy, nutritional disturbance, or disturbance of the hair cycle. Any inflammatory condition of the scalp, such as atopic dermatitis or seborrheic dermatitis, if severe enough, may result in partial alopecia; hair growth returns to normal if the underlying condition is treated successfully, unless the hair follicle has been permanently damaged.

Hair loss in childhood should be divided into the following 4 categories: congenital diffuse, congenital localized, acquired diffuse, and acquired localized.

Acquired localized hair loss is the most common type of hair loss seen in childhood. Three conditions—traumatic alopecia, alopecia areata, tinea capitis—are predominantly seen (Tables 662-3 and 662-4).

Figure 662-1 Traction alopecia.

TRAUMATIC ALOPECIA (TRACTION ALOPECIA, HAIR PULLING, TRICHOTILLOMANIA)

Traction Alopecia

Traction alopecia is common and is seen in almost 20% of African-American schoolgirls. It is caused by trauma to hair follicles from tight braids or ponytails, headbands, rubber bands, curlers, or rollers (Fig. 662-1). There is a greater risk of traction alopecia if hair trauma is combined with chemically relaxed hair. Broken hairs and inflammatory follicular papules in circumscribed patches at the scalp margins are characteristic and may be subtended by regional lymphadenopathy. Children and parents must be encouraged to avoid devices that cause trauma to the hair and, if necessary, to alter the hairstyle. Otherwise, scarring of hair follicles may occur.

Hair Pulling

Hair pulling in childhood is usually an acute reactional process related to emotional stress or a habit (especially in young children). It may also be seen in trichotillomania (obsessive–compulsive disorder) and as part of more severe psychiatric disorders usually in adolescents.

Trichotillomania

Etiology and Pathogenesis. The diagnostic criteria for trichotillomania include visible hair loss attributable to pulling; mounting tension preceding hair pulling; gratification or release of tension after hair pulling; and absence of hair pulling attributable to hallucinations, delusions, or an inflammatory skin condition.

Clinical Manifestations. Compulsive pulling, twisting, and breaking of hair produces irregular areas of incomplete hair loss, most often on the crown and in the occipital and parietal areas of the scalp. Occasionally, eyebrows, eyelashes, and body hair are traumatized. Some plaques of alopecia may have a linear outline. The hairs remaining within the areas of loss are of various lengths (Fig. 662-2) and are typically blunt-tipped because of breakage. The scalp usually appears normal, although hemorrhage, crusting (Fig. 662-3), and chronic folliculitis may also occur. Trichophagy, resulting in **trichobezoars,** may complicate this disorder.

Differential Diagnosis. Acute reactional hair pulling, tinea capitis, and alopecia areata must be considered in the differential diagnosis of trichotillomania (see Tables 662-3 and 662-4).

Histology. Histologic changes include coexistent normal and damaged follicles, perifollicular hemorrhage, atrophy of some follicles, and catagen transformation of hair. In late stages, perifollicular fibrosis may occur. Long-term repeated trauma may result in irreversible damage and permanent alopecia.

Figure 662-2 Hair pulling. Hairs are broken off at various lengths.

Figure 662-4 Circular patch of alopecia areata with normal-appearing scalp.

Figure 662-3 Hemorrhage and crusting secondary to hair pulling.

Figure 662-5 Alopecia totalis: total loss of scalp hair.

Treatment. Trichotillomania is closely related to obsessive-compulsive disorder and may be an expression of it for some children. When trichotillomania occur secondary to **obsessive–compulsive disorder**, clomipramine 50-150 mg/day or fluoxetine 40-80 mg/day may be helpful, particularly when combined with behavioral interventions (see Chapter 24). *N*-Acetylcysteine may also be helpful.

ALOPECIA AREATA

Etiology and Pathogenesis

Alopecia areata is a T-cell driven autoimmune disorder producing nonscarring alopecia. The cause is unknown. It is hypothesized that in genetically susceptible individuals, loss of immune privilege of the hair follicle allows for T-cell inflammation against anagen hairs, follicles, leading to stoppage of hair growth.

Clinical Manifestations

Alopecia areata is characterized by rapid and complete loss of hair in round or oval patches on the scalp (Fig. 662-4) and on other body sites. In alopecia totalis, all the scalp hair is lost (Fig. 662-5); alopecia universalis involves all body and scalp hair. The lifetime incidence of alopecia areata is 0.1-0.2% of the population. More than half of affected patients are younger than 20 yr.

The skin within the plaques of hair loss appears normal. Alopecia areata is associated with atopy and with nail changes such as pits (Fig. 662-6), longitudinal striations, and leukonychia. **Autoimmune diseases** such as Hashimoto thyroiditis, Addison disease, pernicious anemia, ulcerative colitis, myasthenia gravis, collagen vascular diseases,

Figure 662-6 Multiple nail pits in alopecia areata.

and vitiligo may also be seen. An increased incidence of alopecia areata has been reported in patients with Down syndrome (5-10%).

Differential Diagnosis

Tinea capitis, seborrheic dermatitis, trichotillomania, traumatic alopecia, and lupus erythematosus should be considered in the differential diagnosis of alopecia areata (see Tables 662-3 and 662-4).

Histology

A perifollicular infiltrate of inflammatory round cells is found in biopsy specimens from active areas of alopecia areata.

Treatment

The course is unpredictable, but spontaneous resolution in 6-12 mo is usual, particularly when relatively small, stable patches of alopecia are present. Recurrences are common. Onset at a young age, extensive or prolonged hair loss, and numerous episodes are usually poor prognostic signs. Alopecia universalis, alopecia totalis, and alopecia ophiasis (Fig. 662-7)—a type of alopecia areata in which hair loss is circumferential—are also less likely to resolve. Therapy is difficult to evaluate because the course is erratic and unpredictable. The use of high- or superpotency topical corticosteroids is effective in some patients. Intradermal injections of steroid (triamcinolone 5 mg/mL) every 4-6 wk may also stimulate hair growth locally, but this mode of treatment is impractical in young children or in patients with extensive hair loss. Systemic corticosteroid therapy (prednisone 1 mg/kg/day) is associated with good results; the permanence of cure is questionable, however, and the side effects of chronic oral corticosteroids are a serious deterrent. Some patients may maintain hair growth by switching to a more appropriate long-term immunosuppressant such as methotrexate. Additional therapies that are sometimes effective include short-contact anthralin, topical minoxidil, and contact sensitization with squaric acid dibutylester or diphencyprone. In general, parents and patients can be reassured that spontaneous remission of alopecia areata usually occurs. New hair growth may initially be of finer caliber and lighter color, but replacement by normal terminal hair can be expected.

ACQUIRED DIFFUSE HAIR LOSS

Telogen Effluvium

Telogen effluvium manifests as sudden loss of large amounts of hair, often with brushing, combing, and washing of hair. Diffuse loss of scalp hair occurs from premature conversion of growing, or anagen, hairs, which normally constitute 80-90% of hairs, to resting, or telogen, hairs. Hair loss is noted 6 wk to 3 mo after the precipitating cause, which may include childbirth; a febrile episode; surgery; acute blood loss, including blood donation; sudden severe weight loss; discontinuation of high-dose corticosteroids or oral contraceptives; and psychiatric stress. Telogen effluvium also accounts for the loss of hair by infants in the 1st few mo of life; friction from bed sheets, particularly in infants with pruritic, atopic skin, may exacerbate the problem. There is no inflammatory reaction; the hair follicles remain intact, and telogen bulbs can be demonstrated microscopically on shed hairs. Because >50% of the scalp hair is rarely involved, alopecia is usually not severe. Parents should be reassured that normal hair growth will return within approximately 3-6 mo.

Figure 662-7 Ophiasis pattern of alopecia areata.

Toxic Alopecia (Anagen Effluvium)

Anagen effluvium is an acute, severe, diffuse inhibition of growth of anagen follicles, resulting in loss of >80-90% of scalp hair. Hairs become dystrophic, and the hair shaft breaks at the narrowed segment. Loss is diffuse, rapid (1-3 wk after treatment), and temporary, as regrowth occurs after the offending agent is discontinued. Causes of anagen effluvium include radiation; cancer chemotherapeutic agents such as antimetabolites, alkylating agents, and mitotic inhibitors; thallium; thiouracil; heparin; the coumarins; boric acid; and hypervitaminosis A.

CONGENITAL DIFFUSE HAIR LOSS

Congenital diffuse hair loss is defined as congenitally thin hair diffusely related to either hypoplasia of hair follicles or to structural defects in hair shafts.

Structural Defects of Hair

Structural defects of the hair shaft may be congenital, reflect known biochemical aberrations, or relate to damaging grooming practices. All the defects can be demonstrated by microscopic examination of affected hairs, particularly with scanning and transmission electron microscopy, though many can even be seen by simple trichogram done in the office.

Trichorrhexis Nodosa

Congenital trichorrhexis nodosa is an autosomal dominant condition. The hair is dry, brittle, and lusterless, with irregularly spaced grayish white nodes on the hair shaft. Microscopically, the nodes have the appearance of two interlocking brushes (Fig. 662-8*A*). The defect results from a fracture of the hair shaft at the nodal points caused by disruption of the cells in the hair cortex. Trichorrhexis nodosa has also been observed in some infants with Menkes syndrome, trichothiodystrophy, citrullinemia, and argininosuccinic aciduria.

Acquired Trichorrhexis Nodosa

Acquired trichorrhexis nodosa, the most common cause of hair breakage, occurs in 2 forms. Proximal defects are found most frequently in African-American children, whose complaint is not of alopecia but of failure of the hair to grow. The hair is short, and longitudinal splits, knots, and whitish nodules can be demonstrated in hair mounts. Easy breakage is demonstrated by gentle traction on the hair shafts. A history of other affected family members may be obtained. The problem may be caused by a combination of genetic predisposition and the cumulative mechanical trauma of rough combing and brushing, hair-straightening procedures, and "permanents." Patients must be cautioned to avoid damaging grooming techniques. A soft, natural-bristle brush and a wide-toothed comb should be used. The condition is self-limited, with resolution in 2-4 yr, if patients avoid damaging practices. Distal trichorrhexis nodosa is seen more frequently in white and Asian children. The distal portion of the hair shaft is thinned, ragged, and faded; white specks, sometimes mistaken for nits, may be noted along the shaft. Hair mounts reveal the paintbrush defect and the sites of excessive fragility and breakage. Localized areas of the moustache or beard may also be affected. Avoidance of traumatic grooming, regular trimming of affected ends, and the use of cream rinses to lessen tangling ameliorate this condition.

Pili Torti

Patients with pili torti present with spangled, brittle, coarse hair of different lengths over the entire scalp. There is a structural defect in which the hair shaft is grooved and flattened at irregular intervals and is twisted on its axis to various degrees. Minor twists that occur in normal hair should not be misconstrued as pili torti. Curvature of the hair follicle apparently leads to the flattening and rotation of the hair shaft. The genetic defect in isolated pili torti is unknown, and both autosomal dominant and recessive forms have been described. **Syndromes** in which the hair shaft abnormalities of pili torti are seen in association with other cutaneous and systemic abnormalities include Menkes kinky hair syndrome, Björnstad syndrome (pili torti with deafness; *BCS1L* gene), and multiple ectodermal dysplasia syndromes.

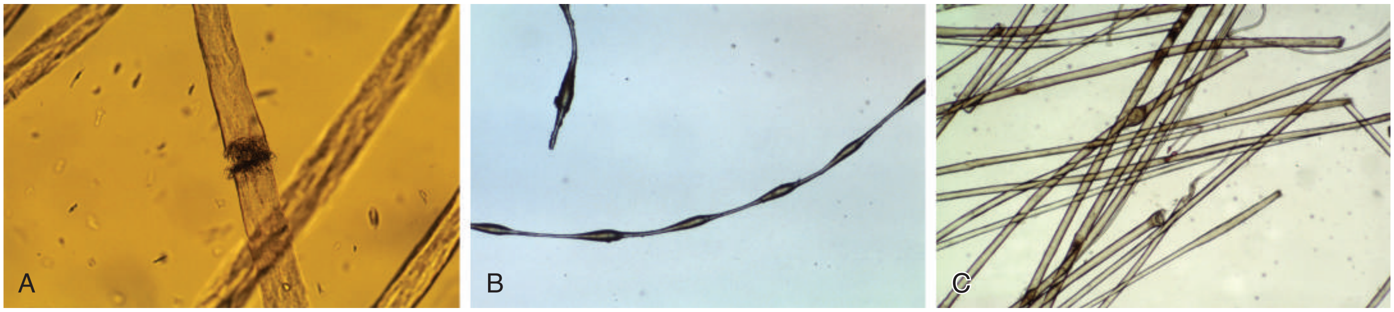

Figure 662-8 **A,** Microscopic hair fracture in trichorrhexis nodosa. **B,** Beading of hair in monilethrix. **C,** Cup-like abnormality of hair in Netherton syndrome.

Menkes Kinky Hair Syndrome (Trichopoliodystrophy)

Males with Menkes kinky hair syndrome, an X-linked recessive trait, are born to an unaffected mother after a normal pregnancy. Neonatal problems include hypothermia, hypotonia, poor feeding, seizures, and failure to thrive. Hair is normal to sparse at birth but is replaced by short, fine, brittle, light-colored hair that may have features of trichorrhexis nodosa, pili torti, or monilethrix. The skin is hypopigmented and thin, cheeks typically appear plump, and the nasal bridge is depressed. Progressive psychomotor retardation is noted in early infancy. Mutations in the *ATP7A* gene, encoding a copper-transporting adenosine triphosphatase protein, cause Menkes kinky hair syndrome. It is a result of maldistribution of the copper in the body. Copper uptake across the brush-border of the small intestine is increased, but copper transport from these cells into the plasma is defective, resulting in low total body copper stores. Parenteral administration of copper-histidine is helpful if begun in the 1st 2 mo of life.

Monilethrix

The hair shaft defect known as monilethrix is inherited as an autosomal dominant trait with variable age of onset, severity, and course. Mutations in the hair keratins HB1, HB3, and HB6 have been identified in autosomal dominant cases, and mutations in desmoglein 4 are found in autosomal recessive cases. The hair appears dry, lusterless, and brittle, and it fractures spontaneously or with mild trauma. Eyebrows, lashes, body and pubic hair, and scalp hair may be affected. Monilethrix may be present at birth, but the hair is usually normal at birth and is replaced in the 1st few mo of life by abnormal hairs; the condition is sometimes first apparent in childhood. Follicular papules may appear on the nape of the neck and the occiput and, occasionally, over the entire scalp. Short, fragile beaded hairs that emerge from the horny follicular plugs give a distinctive appearance. Keratosis pilaris and koilonychia of fingernails and toenails may also be present. Microscopically, a distinctive, regular beading pattern of the hair shaft is evident, characterized by elliptic nodes that are separated by narrower internodes (see Fig. 662-8*B*). Not all hairs have nodes, and both normal and beaded hairs may break. Patients should be advised to handle the hair gently to minimize breakage. Treatment is generally ineffective.

Trichothiodystrophy

Hair in trichothiodystrophy is sparse, short, brittle, and uneven; the scalp hair, eyebrows, or eyelashes may be affected. Microscopically, the hair is flattened, folded, and variable in diameter; has longitudinal grooving; and has nodal swellings that resemble those seen in trichorrhexis nodosa. Under a polarizing microscope, distinctive alternating dark and light bands are seen. The abnormal hair has a cystine content that is <50% of normal because of a major reduction in and altered composition of constituent high-sulfur matrix proteins. Trichothiodystrophy may occur as an isolated finding or in association with various syndrome complexes that include intellectual impairment, short stature, ichthyosis, nail dystrophy, dental caries, cataracts, decreased fertility, neurologic abnormalities, bony abnormalities, and immunodeficiency (*TTDN1* gene). Some patients are photosensitive and have impairment of DNA repair mechanisms, similar to that seen in groups B and D xeroderma pigmentosum; the incidence of skin cancers, however, is not increased. Patients with trichothiodystrophy tend to resemble one another, with a receding chin, protruding ears, raspy voice, and sociable, outgoing personality. Trichoschisis, a fracture perpendicular to the hair shaft, is characteristic of the many syndromes that are associated with trichothiodystrophy. Perpendicular breakage of the hair shaft has also been described in association with other hair abnormalities, particularly monilethrix.

Trichorrhexis Invaginata (Bamboo Hair)

Short, sparse, fragile hair without apparent growth is characteristic of trichorrhexis invaginata, which is found primarily in association with Netherton syndrome (see Chapter 658). It has also been reported in other ichthyosiform dermatoses. The distal portion of the hair is invaginated into the cup-like proximal portion, forming a fragile nodal swelling (see Fig. 662-8*C*).

Pili Annulati

Alternate light and dark bands of the hair shaft characterize pili annulati. When viewed under the light microscope, the region of the hair shaft that appeared bright in reflected light instead appears dark in the transmitted light as a result of focal aggregates of abnormal air-filled cavities within the shaft. The hair is not fragile. The defect may be autosomal dominant or sporadic in inheritance. Pseudopili annulati is a variant of normal blond hair; an optical effect caused by the refraction and reflection of light from the partially twisted and flattened shaft creates the impression of banding.

Woolly Hair Disease

Woolly hair diseases manifest at birth as peculiarly tight, curly, abnormal hair in a non-black person. Autosomal dominant and recessive (*PKRY5* gene) types have been described. Woolly hair nevus, a sporadic form, involves only a circumscribed portion of the scalp hair. The affected hair is fine, tightly curled, and light colored, and it grows poorly. Microscopically, an affected hair is oval and shows twisting of 180 degrees on its axis.

Uncombable Hair Syndrome (Spun-Glass Hair)

The hair of patients with uncombable hair syndrome appears disorderly, is often silvery blond (Fig. 662-9), and may break because of repeated, futile efforts to control it. The condition is probably autosomal dominant in inheritance. Eyebrows and eyelashes are normal. A longitudinal depression along the hair shaft is a constant feature, and most hair follicles and shafts are triangular (pili trianguli et canaliculi). The shape of the hair varies along its length, however, preventing the hairs from lying flat.

Chapter **663**

Disorders of the Nails

Kari L. Martin

Nail abnormalities in children may be manifestations of generalized skin disease, skin disease localized to the periungual region, systemic disease, drugs, trauma, or localized bacterial and fungal infections (Table 663-1). Nail anomalies are also common in certain congenital disorders (Table 663-2).

ABNORMALITIES IN NAIL SHAPE OR SIZE

Anonychia is absence of the nail plate, usually a result of a congenital disorder or trauma. It may be an isolated finding or may be associated with malformations of the digits. **Koilonychia** is flattening and concavity of the nail plate with loss of normal contour, producing a spoon-shaped nail (Fig. 663-1). Koilonychia occurs as an autosomal dominant trait or in association with iron-deficiency anemia, Plummer-Vinson syndrome, or hemochromatosis. The nail plate is relatively thin for the 1st yr or 2 of life and, consequently, may be spoon-shaped in otherwise normal children.

Congenital nail dysplasia, an autosomal dominant disorder, manifests at birth as longitudinal streaks and thinning of the nail plate. There is platyonychia and koilonychia, which may overgrow the lateral folds and involve all nails of the toes and fingers.

Nail–patella syndrome is an autosomal dominant disorder in which the nails are 30-50% of their normal size and often have triangular or pyramidal lunulae. The thumbnails are always involved, although in some cases only the ulnar half of the nail may be affected or may be missing. The nails from the index finger to the little finger are progressively less damaged. The patella is also smaller than usual, and this anomaly may lead to knee instability. Bony spines arising from the posterior aspect of the iliac bones, overextension of joints, skin laxity, and renal anomalies may also be present. Nail–patella syndrome is caused by mutations in the transcription factor *LMX1B* gene.

For a discussion of **pachyonychia congenita**, see Chapter 658.

Habit tic deformity consists of a depression down the center of the nail with numerous horizontal ridges extending across the nail from it. One or both thumbs are usually involved as a result of chronic rubbing and picking at the nail with an adjacent finger.

Table 663-1 White Nail or Nail Bed Changes

DISEASE	CLINICAL APPEARANCE
Anemia	Diffuse white
Arsenic	Mees lines: transverse white lines
Cirrhosis	Terry nails: most of nail, zone of pink at distal end (see Fig. 663-3)
Congenital leukonychia (autosomal dominant; variety of patterns)	Syndrome of leukonychia, knuckle pads, deafness; isolated finding; partial white
Darier disease	Longitudinal white streaks
Half-and-half nail	Proximal white, distal pink azotemia
High fevers (some diseases)	Transverse white lines
Hypoalbuminemia	Muehrcke lines: stationary paired transverse bands
Hypocalcemia	Variable white
Malnutrition	Diffuse white
Pellagra	Diffuse milky white
Punctate leukonychia	Common white spots
Tinea and yeast	Variable patterns
Thallium toxicity (rat poison)	Variable white
Trauma	Repeated manicure: transverse striations
Zinc deficiency	Diffuse white

From Habif TP, editor: Clinical dermatology, *ed 4, Philadelphia, 2004, Mosby, p. 887.*

Table 663-2 Congenital Diseases with Nail Defects

Large nails	Pachyonychia congenita, Rubinstein-Taybi syndrome, hemihypertrophy
Smallness or absence of nails	Ectodermal dysplasias, nail-patella, dyskeratosis congenita, focal dermal hypoplasia, cartilage-hair hypoplasia, Ellis–van Creveld, Larsen, epidermolysis bullosa, incontinentia pigmenti, Rothmund-Thomson, Turner, popliteal web, trisomy 13, trisomy 18, Apert, Gorlin-Pindborg, long arm 21 deletion, otopalatodigital, fetal alcohol, fetal hydantoin, elfin facies, anonychia, acrodermatitis enteropathica
Other	Congenital malalignment of the great toenails, familial dystrophic shedding of the nails

Clubbing of the nails (hippocratic nails) is characterized by swelling of each distal digit, an increase in the angle between the nail plate and the proximal nail fold (Lovibond angle) to >180 degrees, and a spongy feeling when one pushes down and away from the interphalangeal joint, because of an increase in fibrovascular tissue between the matrix and the phalanx (Fig. 663-2). The pathogenesis is not known. Nail clubbing is seen in association with diseases of numerous organ systems, including pulmonary, cardiovascular (cyanotic heart disease), gastrointestinal (celiac disease, inflammatory bowel disease), and hepatic (chronic hepatitis) systems, as well as in healthy individuals as an idiopathic or familial finding.

CHANGES IN NAIL COLOR

Leukonychia is a white opacity of the nail plate that may involve the entire plate or may be punctate or striate (see Table 663-1). The nail

Figure 663-1 Spoon nails (koilonychia). Most cases are a variant of normal. *(From Habif TP, editor:* Clinical dermatology, *ed 4, Philadelphia, 2004, Mosby, p. 885.)*

Figure 663-2 Finger clubbing. The distal phalanges are enlarged to a rounded bulbous shape. The nail enlarges and becomes curved, hard, and thickened. *(From Habif TP, editor:* Clinical dermatology, *ed 4, Philadelphia, 2004, Mosby, p. 885.)*

Figure 663-3 Terry nails. The nail bed is white with only a narrow zone of pink at the distal end. *(From Habif TP, editor:* Clinical dermatology, *ed 4, Philadelphia, 2004, Mosby, p. 885.)*

Figure 663-4 Green/black discoloration at the edge of the nails secondary to *Pseudomonas* infection.

plate itself remains smooth and undamaged. Leukonychia can be traumatic or associated with infections such as leprosy and tuberculosis, dermatoses such as lichen planus and Darier disease, malignancies such as Hodgkin disease, anemia, and arsenic poisoning (Mees lines). Leukonychia of all nail surfaces is an uncommon hereditary autosomal dominant trait that may be associated with congenital epidermal cysts and renal calculi. Paired parallel white bands that do not change position with growth of the nail and thus reflect a change in the nail bed are associated with hypoalbuminemia and are called Muehrcke lines. When the proximal portion of the nail is white and the distal 20-50% of the nail is red, pink, or brown, the condition is called half-and-half nails or Lindsay nails; this is seen most commonly in patients with renal disease but may occur as a normal variant. White nails of **cirrhosis,** or Terry nails (Fig. 663-3), are characterized by a white ground-glass appearance of the entire or the proximal end of the nail and a normal pink distal 1-2 mm of the nail; this finding is associated with hypoalbuminemia.

Black pigmentation of an entire nail plate or linear bands of pigmentation (melanonychia striata) is common in African-American (90%) and Asian (10-20%) individuals, but is unusual in white individuals (<1%). Most often, the pigment is melanin, which is produced by melanocytes of a junctional nevus in the nail matrix and nail bed and is of no consequence. Extension or alteration in the pigment should be evaluated by biopsy because of the possibility of malignant change.

Bluish black to greenish nails may be caused by *Pseudomonas* infection (Fig. 663-4), particularly in association with onycholysis or chronic paronychia. The coloration is caused by subungual debris and pyocyanin pigment from the bacterial organisms.

Yellow nail syndrome manifests as thickened, excessively curved, slow-growing yellow nails without lunulae. All nails are affected in most cases. Associated systemic diseases include bronchiectasis, recurrent bronchitis, chylothorax, and focal edema of the limbs and face. Deficient lymphatic drainage, caused by hypoplastic lymphatic vessels, is believed to lead to the manifestations of this syndrome.

Splinter hemorrhages most often result from minor trauma but may also be associated with subacute bacterial endocarditis, vasculitis, Langerhans cell histiocytosis, severe rheumatoid arthritis, peptic ulcer disease, hypertension, chronic glomerulonephritis, cirrhosis, scurvy, trichinosis, malignant neoplasms, and psoriasis.

NAIL SEPARATION

Onycholysis indicates separation of the nail plate from the distal nail bed. Common causes are trauma, long-term exposure to moisture, hyperhidrosis, cosmetics, psoriasis, fungal infection (distal onycholysis), atopic or contact dermatitis, porphyria, drugs (bleomycin, vincristine, retinoid agents, indomethacin, chlorpromazine [Thorazine]), and drug-induced phototoxicity from tetracyclines (Fig. 663-5) or chloramphenicol.

Beau lines are transverse grooves in the nail plate (Fig. 663-6) that represent a temporary disruption of formation of the nail plate. The

Figure 663-5 Distal onycholysis secondary to oral tetracycline usage and ultraviolet light exposure.

Figure 663-6 Beau lines. Longitudinal disruption of nail.

lines first appear a few weeks after the event that caused the disruption in nail growth. A single transverse ridge appears at the proximal nail fold in most 4-6 wk old infants and works its way distally as the nail grows; this line may reflect metabolic changes after delivery. At other ages, Beau lines are usually indicative of periodic trauma or episodic shutdown of the nail matrix secondary to a systemic disease such as hand-foot-and-mouth disease, measles, mumps, pneumonia, or zinc deficiency. **Onychomadesis** is an exaggeration of Beau lines leading to proximal separation of the nail bed (Fig. 663-7).

NAIL CHANGES ASSOCIATED WITH SKIN DISEASE

Nail changes may be particularly associated with various other diseases. Nail changes of **psoriasis** most characteristically include pitting, onycholysis, yellow-brown discoloration, and thickening. Nail changes in lichen planus include violaceous papules in the proximal nail fold and nail bed, leukonychia, longitudinal ridging, thinning of the entire nail plate, and pterygium formation, which is abnormal adherence of the cuticle to the nail plate or, if the plate is destroyed focally, to the nail bed. Postinfectious reactive arthritis syndromes may include painless erythematous induration of the base of the nail fold; subungual parakeratotic scaling; and thickening, opacification, or ridging of the nail plate. Dermatitis that involves the nail folds may produce dystrophy, roughening, and coarse pitting of the nails. Nail changes are more common in atopic dermatitis than in other forms of dermatitis that affect the hands. Darier disease is characterized by red or white streaks that extend longitudinally and cross the lunula. Where the streak meets the distal end of the nail, a V-shaped notch may be present. Total

Figure 663-7 Onychomadesis. Proximal nail bed separation.

Figure 663-8 Dystrophy of all nails in trachyonychia.

leukonychia may also occur. Transverse rows of fine pits are characteristic of alopecia areata. In severe cases, the entire nail surface may be rough. Patients with acrodermatitis enteropathica may have transverse grooves (Beau lines) and nail dystrophy as a result of periungual dermatitis.

TRACHYONYCHIA (20-NAIL DYSTROPHY)

Trachyonychia is characterized by longitudinal ridging, pitting, fragility, thinning, distal notching, and opalescent discoloration of all the nails (Fig. 663-8). Patients have no associated skin or systemic diseases and no other ectodermal defects. Its occasional association with alopecia areata has led some authorities to suggest that trachyonychia may reflect an abnormal immunologic response to the nail matrix, whereas histopathologic studies have suggested that it may be a manifestation of lichen planus, psoriasis, or spongiotic (eczematous) inflammation of the nail matrix. The disorder must be differentiated from fungal infections, psoriasis, nail changes of alopecia areata, and nail dystrophy secondary to eczema. Eczema and fungal infections rarely produce changes in all the nails simultaneously. The disorder is self-limited and eventually remits by adulthood.

NAIL INFECTION

Fungal infection (onychomycosis)of the nails has been classified into 4 types. *White superficial onychomycosis* manifests as diffuse or speckled white discoloration of the surface of the toenails. It is caused primarily by *Trichophyton mentagrophytes,* which invades the nail plate. The organism may be scraped off the nail plate with a blade, but **treatment** is best accomplished by the addition of a topical azole antifungal agent. *Distal subungual onychomycosis* involves foci of onycholysis under the distal nail plate or along the lateral nail groove, followed by development of hyperkeratosis and yellow-brown discoloration. The process extends proximally, resulting in nail plate thickening,

Figure 663-9 Discoloration, hyperkeratosis, and crumbling of nail secondary to dermatophyte infection.

Figure 663-10 Acute paronychia secondary to *Staphylococcus aureus*.

crumbling (Fig. 663-9), and separation from the nail bed. *Trichophyton rubrum* and, occasionally, *T. mentagrophytes* infect the toenails; fingernail disease is almost exclusively caused by *T. rubrum,* which may be associated with superficial scaling of the plantar surface of the feet and often of one hand. The dermatophytes are found most readily at the most proximal area of the nail bed or adjacent ventral portion of the involved nail plates. **Topical therapies** such as ciclopirox 8% lacquer or amorolfine 5% lacquer, may be effective for solitary nail infection. Topical efinaconazole 10% may also be effective; laser treatment is an expensive but safe alternative to oral therapy. Because of its long half-life in the nail, oral itraconazole may be effective when given as pulse therapy (1 wk of each month for 3-4 mo). Dosage is weight dependent. Oral daily terbinafine is also quite effective. Either agent is superior to griseofulvin, fluconazole, or ketoconazole. The risks, the most concerning of which is hepatic toxicity, and costs of oral therapy are minimized with the use of pulsed dosing.

Proximal white subungual onychomycosis occurs when the organism, generally *T. rubrum,* enters the nail through the proximal nail fold, producing yellow-white portions of the undersurface of the nail plate. The surface of the nail is unaffected. This occurs almost exclusively in immunocompromised patients and is a well-recognized manifestation of AIDS. Treatment includes oral terbinafine or itraconazole.

Candidal onychomycosis involves the entire nail plate in patients with chronic mucocutaneous candidiasis. It is also commonly seen in patients with AIDS. The organism, generally *Candida albicans,* enters distally or along the lateral nail folds, rapidly involves the entire thickness of the nail plate, and produces thickening, crumbling, and deformity of the plate. Topical azole antifungal agents may be sufficient for treatment of candidal onychomycosis in an immunocompetent host, but oral antifungal agents are necessary for treatment of patients with immune deficiencies. Table 663-3 outlines the differential diagnosis of onychomycosis.

PARONYCHIAL INFLAMMATION

Paronychial inflammation may be acute or chronic and generally involves 1 or 2 nail folds on the fingers. **Acute paronychia** manifests as erythema, warmth, edema, and tenderness of the proximal nail fold, most commonly as a result of pathogenic staphylococci, streptococci, or candidal (Fig. 663-10). Warm soaks and oral agents are generally effective; incision and drainage may be occasionally necessary. Development of chronic paronychia follows prolonged immersion in water (Fig. 663-11), such as occurs in finger or thumb sucking, exposure to irritating solutions, nail fold trauma, or diseases, including Raynaud phenomenon, collagen vascular diseases, and diabetes. Swelling of the proximal nail fold is followed by separation of the nail fold from the underlying nail plate and suppuration. Foreign material, embedded in the dermis of the nail fold, becomes a nidus for inflammation and infection with *Candida* species and mixed bacterial flora. A combination of attention to predisposing factors, meticulous drying of the hands, and long-term topical antifungal agents and topical potent corticosteroids may be required for successful treatment of chronic paronychia.

Table 663-3	Differential Diagnosis of Onychomycosis
Psoriasis • As in onychomycosis: onycholysis, subungual hyperkeratosis, splinter hemorrhages, leuconychia, dystrophy • Pitting • Oil drop sign (a translucent yellow-red discoloration seen in the nail bed) • Other cutaneous features of psoriasis, family history of psoriasis Lichen planus • Cutaneous disease at other sites • Thin nail plate and ridging • Dorsal pterygium—scarring at proximal aspect of nail Trauma • Nail plate can appear abnormal • Nail bed should be normal • Distal onycholysis with repeated trauma • Single nail affected, shape of nail changed, homogenous alteration of nail color Eczema • Irregular buckled nails with ridging • Cutaneous signs of eczema Yellow nail syndrome • Nail plate is discolored green-yellow • Nails are hard with elevated longitudinal curvature • Nails may be shed, painful • Associations with bronchiectasis, lymphoedema, and chronic sinusitis Lamellar onychoschizia (lamellar splitting) • History of repeated soaking in water • Usually distal portion of nail Periungual squamous cell carcinoma/Bowens disease • Single nail, warty changes of nail fold, ooze from edge of nail Malignant melanoma • Black discoloration of nail plate or nail bed • Pigment can extend onto nail fold • Can get associated bleeding Myxoid (mucous) cyst • Cyst at base of nail, groove in nail extending length of nail Alopecia areata • Pits, longitudinal ridging, brittleness • Hair loss

Ingrown nail occurs when the lateral edge of the nail, including spicules that have separated from the nail plate, penetrates the soft

Figure 663-11 Chronic paronychia with erythema and lateral nail fold separation.

tissue of the lateral nail fold. Erythema, edema, and pain, most often involving the lateral great toes, are noted acutely; recurrent episodes may lead to formation of granulation tissue. Predisposing factors include (1) congenital malalignment (especially of the great toes); (2) compression of the side of the toe from poorly fitting shoes, particularly if the great toes are abnormally long and the lateral nail folds are prominent; and (3) improper cutting of the nail in a curvilinear manner rather than straight across. **Management** includes proper fitting of shoes; allowing the nail to grow out beyond the free edge before cutting it straight across; warm water soaks; oral antibiotics if cellulitis affects the lateral nail fold; and, in severe, recurrent cases, application of silver nitrate to granulation tissue, nail avulsion, or excision of the lateral aspect of the nail followed by matricectomy.

PARONYCHIAL TUMORS

Tumors in the paronychial area include pyogenic granulomas, mucous cysts, subungual exostoses, and junctional nevi. Periungual fibromas that appear in late childhood should suggest a diagnosis of tuberous sclerosis.

Chapter 664

Disorders of the Mucous Membranes

Michelle L. Bayer and Beth A. Drolet

The mucous membranes may be involved in developmental disorders, genodermatoses, infections, acute and chronic skin diseases, or benign and malignant tumors.

ANGULAR CHEILITIS

Angular cheilitis (perlèche) is characterized by inflammation and fissuring at the corners of the mouth, often with associated erosion, maceration, and crusting (Fig. 664-1). Chapping or moisture collection at the angles of the mouth predispose children to developing angular cheilitis. Children who are chronic lip lickers or who have excessive salivation or drooling related to neurologic deficits, orthodontic appliances, or mouth breathing are at increased risk. Atopic dermatitis or contact dermatitis related to toothpaste, chewing gum, mouthwash, or cosmetics are also common causes. Nutritional deficiencies are a less-frequent etiology. Protection can be provided by frequent application of a bland ointment such as petrolatum. Candidosis should be treated with an appropriate antifungal agent, and contact dermatitis of the perioral skin should be treated with a low-potency topical corticosteroid ointment preparation and frequent use of petrolatum or a similar emollient. Correction of the underlying predisposing factors (if possible) will prevent recurrence.

Figure 664-1 Angular cheilitis.

Figure 664-2 Aphthous ulceration on lower lip.

APHTHOUS STOMATITIS (CANKER SORES)

Aphthous stomatitis consists of solitary or multiple painful ulcerations occur on the labial (Fig. 664-2), buccal, lingual, sublingual, palatal, or gingival mucosa (see Chapter 315). Lesions may manifest initially as erythematous, indurated papules that erode rapidly to form sharply circumscribed, necrotic ulcers with a gray fibrinous exudate and an erythematous halo. Minor aphthous ulcers are 2-10 mm in diameter and heal spontaneously in 7-10 days. Major aphthous ulcers are >10 mm in diameter, take from 10-30 days to heal, and may heal with scarring. A third type of aphthous ulceration is herpetiform in appearance, manifesting as a few to numerous grouped 1-2 mm lesions which tend to coalesce into plaques and heal over 7-10 days. Approximately 30% of patients with recurrent lesions have a family history of the disorder (see Chapter 315 for the differential diagnosis).

The etiology of aphthous stomatitis is multifactorial; the condition probably represents an oral manifestation of a number of conditions. Altered local regulation of the cell-mediated immune system, after activation and accumulation of cytotoxic T cells, may contribute to the

localized mucosal breakdown. It is a common misconception that aphthous stomatitis is a manifestation of herpes simplex virus infection. Recurrent herpes infections remain localized to the lips and rarely cross the mucocutaneous junction; involvement of the oral mucosa occurs only in primary infections.

Treatment of aphthous stomatitis is palliative. The majority of mild cases do not require therapy. Relief of pain, particularly before eating, may be achieved with the use of a topical anesthetic such as viscous lidocaine or an oral rinse with a combined solution of elixir of diphenhydramine, viscous lidocaine, and an oral antacid. Caution must be taken to avoid hot food and drink after topical anesthetic use. A superpotent topical corticosteroid in a mucosa-adhering agent may help reduce inflammation, and topical tetracycline mouthwash may also hasten healing. In severe, debilitating cases, systemic therapy with corticosteroids, colchicine, dapsone, or thalidomide may be helpful.

FORDYCE SPOTS

Fordyce spots (Fordyce granules) are asymptomatic, 1-3 mm, yellow-white macules and papules on the vermilion lips and buccal mucosa. They are a common clinical finding and represent a normal anatomic variant of sebaceous glands. They can present in either sex from infancy to adulthood and may become more prominent during puberty due to the influence of androgens. No therapy is required.

EPSTEIN PEARLS (GINGIVAL CYSTS OF THE NEWBORN)

Epstein pearls are white, keratin-containing cysts on the palatal or alveolar mucosa of approximately 80% of neonates. They are epidermal inclusion cysts that form when the soft and hard palates fuse and are analogous to facial milia. They cause no symptoms and are generally shed within a few weeks; no therapy is necessary.

MUCOCELE

Mucus retention cysts are painless, fluctuant, tense, 2-10 mm, bluish papules on the lips (Fig. 664-3), tongue, palate, or buccal mucosa. Traumatic severance of the duct of a minor salivary gland leads to submucosal retention of mucus secretion. Lesions on the floor of the mouth are known as ranulas when the sublingual or submandibular salivary gland ducts are involved. Fluctuations in size are typical, and the lesions may disappear temporarily after traumatic rupture. Recurrence is prevented by surgical excision of the mucus deposit and associated salivary gland(s).

FISSURED TONGUE

Fissured tongue (scrotal tongue, or lingua plicata) is a common benign developmental anomaly of the tongue. The dorsal tongue has many folds with deep grooves and a pebbled appearance. Fissured tongue can be seen in individuals with Melkersson-Rosenthal syndrome and Down syndrome, and it is often seen in association with geographic tongue. Food particles and debris may become trapped in the fissures, resulting in irritation, inflammation, and halitosis. Careful cleansing with a mouth rinse and soft-bristled toothbrush is recommended.

GEOGRAPHIC TONGUE (BENIGN MIGRATORY GLOSSITIS)

Geographic tongue consists of single or multiple sharply demarcated, irregular, smooth red patches surrounded by an elevated yellowish-white serpiginous border on the dorsum of the tongue. Onset is rapid, and the pattern may change over hours to days. The smooth patches correspond to atrophic filiform papillae, and the elevated margins represent hypertrophic papillae (Fig. 664-4). The etiology of this condition remains unclear. Lesions are typically asymptomatic, but some patients may experience a burning sensation or sensitivity to spicy, hot, or cold foods. No therapy other than reassurance is necessary.

BLACK HAIRY TONGUE

Black hairy tongue is a dark coating on the dorsum of the tongue caused by hyperplasia and elongation of the filiform papillae; overgrowth of chromogenic bacteria and fungi and entrapped pigmented residues that adsorb to microbial plaque and desquamating keratin may contribute to the dark coloration. Changes often begin posteriorly and extend anteriorly on the dorsum of the tongue. The condition is most common in adults but may also manifest during adolescence. Poor oral hygiene, lack of oral feeding, treatment with systemic antibiotics such as tetracycline (which promote the growth of *Candida* spp.), and smoking are predisposing factors. Improved oral hygiene and brushing with a soft-bristled toothbrush may be all that is necessary for treatment.

ORAL HAIRY LEUKOPLAKIA

Oral hair leukoplakia occurs in approximately 25% of patients with AIDS but is rare in the pediatric population. It manifests as corrugated and shaggy white plaques on the lateral margins of the tongue which cannot be removed by rubbing. The lesions occasionally may spread to the ventral tongue surface, floor of the mouth, tonsillar pillars, and pharynx. The condition is caused by Epstein-Barr virus, which is present in the upper layer of the affected epithelium. The plaques have no malignant potential. The disorder occurs predominantly in HIV-infected patients but may also be found in individuals who are immunosuppressed for other reasons, such as organ transplantation, leukemia, chemotherapy, and long-term use of inhaled steroids. The condition is generally asymptomatic and does not require therapy.

ACUTE NECROTIZING ULCERATIVE GINGIVITIS (VINCENT STOMATITIS, FUSOSPIROCHETAL GINGIVITIS, TRENCH MOUTH)

Acute necrotizing ulcerative gingivitis manifests as painful punched-out ulceration, necrosis, and bleeding of the interdental papillae. A

Figure 664-3 Mucocele on lower lip.

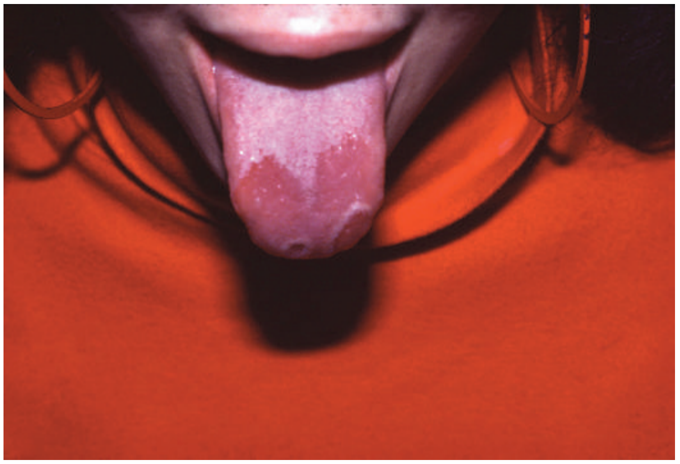

Figure 664-4 Geographic tongue.

grayish white pseudomembrane may cover the ulcerations. Lesions may spread to involve the buccal mucosa, lips, tongue, tonsils, and pharynx and may be associated with dental pain, a bad taste, low-grade fever, and lymphadenopathy. It occurs most commonly in the 2nd or 3rd decade, particularly in the context of poor dental hygiene, poor nutrition, smoking, and stress.

NOMA

Noma is a severe form of fusospirillary gangrenous stomatitis that occurs primarily in malnourished, impoverished children 2-5 yr of age who have had a preceding illness such as measles, scarlet fever, tuberculosis, malignancy, or immunodeficiency. The disease is most prevalent in Africa, but also occurs in Asia and Latin America. Sporadic cases associated with immunodeficiency have been reported in developed countries. It manifests as a painful, red, indurated papule on the alveolar margin, followed by ulceration and mutilating gangrenous destruction of tissue in the oronasal region. The process may also involve the scalp, neck, shoulders, perineum, and vulva. Noma neonatorum manifests in the 1st mo of life as gangrenous lesions of the lips, nose, mouth, and anal regions. Affected infants are usually small for gestational age, malnourished, premature, and frequently ill (particularly with *Pseudomonas aeruginosa* sepsis). Care consists of nutritional support, conservative debridement of necrotic soft tissues, empirical broad-spectrum antibiotics such as penicillin and metronidazole, and, in the case of noma neonatorum, antipseudomonal antibiotics (see Chapter 46).

COWDEN SYNDROME (MULTIPLE HAMARTOMA SYNDROME)

Cowden syndrome is an autosomal dominant condition caused by loss-of-function mutations in the *PTEN* tumor-suppressor gene. Mucocutaneous lesions typically appear in the 2nd or 3rd decade. Oral papillomas are 1-3 mm smooth, pink or whitish papules on the palatal, gingival, buccal, and labial mucosae and may coalesce into a cobblestone appearance. Numerous flesh-colored papules also develop on the face, particularly around the mouth, nose, and ears. These papules are most commonly trichilemmomas, a benign neoplasm of the hair follicle. Associated findings may include acral keratoses, thyroid adenoma, goiter, gastrointestinal polyps, fibrocystic breast nodules, and carcinoma of the breast or thyroid.

Chapter 665

Cutaneous Bacterial Infections

665.1 Impetigo

Anna M. Juern and Beth A. Drolet

ETIOLOGY/PATHOGENESIS

Impetigo is the most common skin infection in children throughout the world. There are 2 classic forms of impetigo: nonbullous and bullous.

Staphylococcus aureus is the predominant organism of nonbullous impetigo in the United States; group A β-hemolytic streptococci (GABHS) are implicated in the development of some lesions. The staphylococcal types that cause nonbullous impetigo are variable but are not generally from phage group 2, the group that is associated with scalded skin and toxic shock syndromes. Staphylococci generally spread from the nose to normal skin and then infect the skin. In contrast, the skin becomes colonized with GABHS an average of 10 days before development of impetigo. The skin serves as the source for acquisition of GABHS and the probable primary source for spread of impetigo. Lesions of nonbullous impetigo that grow staphylococci in culture cannot be distinguished clinically from those that grow pure cultures of GABHS.

Bullous impetigo is always caused by *S. aureus* strains that produce exfoliative toxins. The staphylococcal exfoliative toxins (ETA, ETB, ETD) blister the superficial epidermis by hydrolyzing human desmoglein 1, resulting in a subcorneal vesicle. This is also the target antigen of the autoantibodies in pemphigus foliaceus (see Chapters 181 and 183).

CLINICAL MANIFESTATIONS

Nonbullous Impetigo

Nonbullous impetigo accounts for more than 70% of cases. Lesions typically begin on the skin of the face or on extremities that have been traumatized. The most common lesions that precede nonbullous impetigo are insect bites, abrasions, lacerations, chickenpox, scabies pediculosis, and burns. A tiny vesicle or pustule forms initially and rapidly develops into a honey-colored crusted plaque that is generally <2 cm in diameter (Fig. 665-1). The infection may be spread to other parts of the body by the fingers, clothing, and towels. Lesions are associated with little to no pain or surrounding erythema, and constitutional symptoms are generally absent. Pruritus occurs occasionally, regional adenopathy is found in up to 90% of cases, and leukocytosis is present in approximately 50%.

Bullous Impetigo

Bullous impetigo is mainly an infection of infants and young children. Flaccid, transparent bullae develop most commonly on skin of the face, buttocks, trunk, perineum, and extremities. **Neonatal bullous impetigo** can begin in the diaper area. Rupture of a bulla occurs easily, leaving a narrow rim of scale at the edge of shallow, moist erosion. Surrounding erythema and regional adenopathy are generally absent. Unlike those of nonbullous impetigo, lesions of bullous impetigo are a manifestation of localized staphylococcal scalded skin syndrome and develop on intact skin.

Differential Diagnosis

The differential diagnosis of **nonbullous impetigo** includes viruses (herpes simplex, varicella-zoster), fungi (tinea corporis, kerion),

Figure 665-1 Multiple crusted and oozing lesions of impetigo.

arthropod bites, and parasitic infestations (scabies, pediculosis capitis), all of which may become impetiginized.

The differential diagnosis of **bullous impetigo** in neonates includes epidermolysis bullosa, bullous mastocytosis, herpetic infection, and early scalded skin syndrome. In older children, allergic contact dermatitis, burns, erythema multiforme, linear immunoglobulin A dermatosis, pemphigus, and bullous pemphigoid must be considered, particularly if the lesions do not respond to therapy.

COMPLICATIONS

Potential but very rare complications of either nonbullous or bullous impetigo include osteomyelitis, septic arthritis, pneumonia, and septicemia. Positive blood culture results are very rare in otherwise healthy children with localized lesions. Cellulitis has been reported in up to 10% of patients with nonbullous impetigo and rarely follows the bullous form. Lymphangitis, suppurative lymphadenitis, guttate psoriasis, and scarlet fever occasionally follow streptococcal disease. There is no correlation between number of lesions and clinical involvement of the lymphatics or development of cellulitis in association with streptococcal impetigo.

Infection with nephritogenic strains of GABHS may result in **acute poststreptococcal glomerulonephritis** (see Chapter 511.1). The clinical character of impetigo lesions is not predictive of the development of poststreptococcal glomerulonephritis. The most commonly affected age group is children 3-7 yr of age. The latent period from onset of impetigo to development of poststreptococcal glomerulonephritis averages 18-21 days, which is longer than the 10-day latency period after pharyngitis. Poststreptococcal glomerulonephritis occurs epidemically after either pharyngeal or skin infection. Impetigo-associated epidemics have been caused by M groups 2, 49, 53, 55, 56, 57, and 60. Strains of GABHS that are associated with endemic impetigo in the United States have little or no nephritogenic potential. Acute rheumatic fever does not occur as a result of impetigo.

TREATMENT

The decision on how to treat impetigo depends on the number of lesions and their locations. Topical therapy with mupirocin 2%, and retapamulin 1% 2-3 times a day for 10-14 days is acceptable for localized disease caused by *S. aureus.*

Systemic therapy with oral antibiotics should be prescribed for patients with streptococcal or widespread involvement of staphylococcal infections; when lesions are near the mouth, where topical medication may be licked off; or in cases with evidence of deep involvement, including cellulitis, furunculosis, abscess formation, or suppurative lymphadenitis. Cephalexin, 25-50 mg/kg/day in 3-4 divided doses for 7-10 days, is an excellent choice for initial therapy. No evidence suggests that a 10-day course of therapy is superior to a 7-day course. The emergence of methicillin-resistant *S. aureus* (MRSA) dictates that if a satisfactory clinical response is not achieved within 7 days, a culture should be performed and an appropriate antibiotic based on drug sensitivity should be given for an additional 7 days. If MRSA is suspected, clindamycin, doxycycline or sulfamethoxazole-trimethoprim is indicated.

Bibliography is available at Expert Consult.

665.2 Subcutaneous Tissue Infections

Anna M. Juern and Beth A. Drolet

The principal determinations for soft-tissue infections is whether it is *nonnecrotizing* or *necrotizing,* as well as *purulent* or *nonpurulent* (see Fig. 665-1). The former responds to antibiotic therapy alone, whereas the latter requires prompt surgical removal of all devitalized tissue in addition to antimicrobial therapy. Necrotizing soft-tissue infections are life-threatening conditions that are characterized by rapidly advancing local tissue destruction and systemic toxicity. Tissue necrosis distinguishes them from cellulitis. In cellulitis, an inflammatory infectious process involves subcutaneous tissue but does not destroy it. Necrotizing soft-tissue infections characteristically manifest with a paucity of early cutaneous signs relative to the rapidity and degree of destruction of the subcutaneous tissues.

CELLULITIS

Etiology

Cellulitis is characterized by infection and inflammation of loose connective tissue, with limited involvement of the dermis and relative sparing of the epidermis. A break in the skin from previous trauma, surgery, or an underlying skin lesion predisposes to cellulitis. Cellulitis is also more common in individuals with lymphatic stasis, diabetes mellitus, or immunosuppression.

Streptococcus pyogenes (group A streptococcus) and *S. aureus* are the most common etiologic agents. In patients who are immunocompromised or have diabetes mellitus, a number of other bacterial or fungal agents may be involved, notably *Pseudomonas aeruginosa; Aeromonas hydrophila* and, occasionally, other Enterobacteriaceae; *Legionella* spp.; the Mucorales, particularly *Rhizopus* spp., *Mucor* spp., and *Absidia* spp.; and *Cryptococcus neoformans.* Children with relapsed nephrotic syndrome may experience cellulitis caused by *Escherichia coli.* In children age 3 mo to 5 yr, *Haemophilus influenzae* type b was once an important cause of facial cellulitis, but its incidence has declined significantly since the institution of immunization against this organism.

Clinical Manifestations

Cellulitis manifests clinically as an area of edema, warmth, erythema, and tenderness. The lateral margins tend to be indistinct because the process is deep in the skin, primarily involving the subcutaneous tissues in addition to the dermis. Application of pressure may produce pitting. Although distinction cannot be made with certainty in any particular patient, cellulitis due to *S. aureus* tends to be more localized and may suppurate, whereas infections caused by *S. pyogenes* (group A streptococci) tend to spread more rapidly and may be associated with lymphangitis. Regional adenopathy and constitutional signs and symptoms such as fever, chills, and malaise are common. Complications of cellulitis are uncommon but include subcutaneous abscess, bacteremia, osteomyelitis, septic arthritis, thrombophlebitis, endocarditis, and necrotizing fasciitis. Lymphangitis or glomerulonephritis can also follow infection with *S. pyogenes.*

Diagnosis

Aspirates from the site of inflammation, skin biopsy, and blood cultures allow identification of the causal organism in approximately 25% of cases of cellulitis. Blood cultures are usually negative in immunocompetent patients with mild to moderate infection. Yield of the causative organism is approximately 30% when the site of origin of the cellulitis is apparent, such as an abrasion or ulcer. An aspirate taken from the point of maximum inflammation yields the causal organism more often than a leading-edge aspirate. Lack of success in isolating an organism stems primarily from the low number of organisms present within the lesion. *Ultrasonography is used if an associated subcutaneous abscess is suspected.*

The differential diagnosis should include an exuberant immune-allergic reaction to insect bites particularly mosquito bites (Skeeter syndromes) (see Chapter 146). The skeeter syndrome is characterized by swelling disproportionate to erythremia; there is pruritus but usually no tenderness. In addition, cold panniculitis may appear as an erythematous but usually nontender swelling after exposure to cold, such as sledding or eating a cold Popsicle (see Chapter 660.1).

Treatment

Empirical therapy for cellulitis should be directed by the history of the illness, the location and severity of the cellulitis, and the age and immune status of the patient (Fig. 665-2). Cellulitis in a neonate should prompt a full sepsis evaluation, followed by initiation of empirical intravenous therapy with a β-lactamase–stable antistaphylococcal antibiotic such as methicillin or vancomycin and an aminoglycoside such as gentamicin or a cephalosporin such as cefotaxime. Treatment of

Three newer agents, oritavancin, tedizolid, and dalbavancin, are also effective agents in SSTIs, including those caused by methicillin-resistant *Staphylococcus aureus. C & S,* culture and sensitivity; *I & D,* incision and drainage; *MRSA,* methicillin-resistant *Staphylococcus aureus; MSSA,* methicillin-susceptible *Staphylococcus aureus; Rx,* treatment; *TMP/SMX,* trimethoprim-sulfamethoxazole. *(Modified from Stevens DL, Bisno AL, Chambers HF, et al: Practice guidelines for the diagnosis and management of skin and soft tissue infections: 2014 update by the Infectious Diseases Society of America.* Clin Infect Dis *59:147–159, 2014, Fig. 1.)*

cellulitis in an infant or child younger than about 5 yr of age should provide coverage for *S. pyogenes* and *S. aureus* as well as *H. influenzae* type b and *Streptococcus pneumoniae.* The evaluation should include a blood culture, and if the infant is younger than 1 yr of age, if signs of systemic toxicity are present, or if an adequate examination cannot be carried out, a lumbar puncture should also be performed. In most cases of cellulitis on an extremity, regardless of age, *S. aureus* and *S. pyogenes* are the cause and bacteremia is highly unlikely in an otherwise well-appearing child. Blood cultures should be performed if sepsis is suspected.

If fever, lymphadenopathy, and other constitutional signs are absent (white blood cell count <15,000), treatment of cellulitis on an extremity may be initiated orally on an outpatient basis with a penicillinase-resistant penicillin such as dicloxacillin or cloxacillin or a first-generation cephalosporin such as cephalexin or, if MRSA is suspected, with clindamycin. If improvement is not noted or the disease progresses significantly in the 1st 24-48 hr of therapy, parenteral therapy is necessary. If fever, lymphadenopathy, or constitutional signs are present, parenteral therapy should be initiated. Oxacillin or nafcillin is effective in most cases, although if systemic toxicity is significant, consideration should be given to the addition of clindamycin or vancomycin. Three new agents for skin and skin structure infections have been approved by the FDA in adults. Dalbavancin (intravenous given once weekly; active against MRSA; *S. pyogenes*, and vancomycin-resistant enterococcus and *S. aureus*), tedizolid (oral or IV given bid, active against MRSA, *S. pyogenes*, coagulase-negative *Staphylococcus*), and oritavancin (IV; active against MRSA, *S. pyogenes*). Once the erythema, warmth, edema, and fever have decreased significantly, a 10-day course of treatment may be completed on an outpatient basis. Immobilization and elevation of an affected limb, particularly early in the course of therapy, may help reduce swelling and pain. *If present, a subcutaneous abscess should be drained.*

NECROTIZING FASCIITIS

Etiology

Necrotizing fasciitis is a subcutaneous tissue infection that involves the deep layer of superficial fascia but may spare adjacent epidermis, deep fascia, and muscle.

Relatively few organisms possess sufficient virulence to cause necrotizing fasciitis when acting alone. The majority (55-75%) of cases of necrotizing fasciitis are polymicrobial in nature (synergistic necrotizing fasciitis), with an average of 4 different organisms isolated. The

organisms most commonly isolated in polymicrobial necrotizing fasciitis are *S. aureus*, streptococcal species, *Klebsiella* species, *E. coli,* and anaerobic bacteria.

The rest of the cases and the most fulminant infections, associated with toxic shock syndrome and a high case fatality rate, are usually caused by *S. pyogenes* (group A streptococcus) (see Chapter 183). Streptococcal necrotizing fasciitis may occur in the absence of toxic shock–like syndrome and is potentially fatal and associated with substantial morbidity. Necrotizing fasciitis can occasionally be caused by *S. aureus; Clostridium perfringens; Clostridium septicum; P. aeruginosa; Vibrio* spp., particularly *Vibrio vulnificus;* and fungi of the order Mucorales, particularly *Rhizopus* spp., *Mucor* spp., and *Absidia* spp. Necrotizing fasciitis has also been reported, on rare occasions, to result from non–group A streptococci such as group B, C, F, or G streptococci, *S. pneumoniae,* or *H. influenzae* type b.

Infections caused by any 1 organism or combination of organisms cannot be distinguished clinically from one another, although development of **crepitans** signals the presence of *Clostridium* spp. or Gram-negative bacilli such as *E. coli, Klebsiella, Proteus,* or *Aeromonas.*

Clinical Manifestations

Necrotizing fasciitis may occur anywhere on the body. Polymicrobial infections tend to occur on perineal and trunk areas. The incidence of necrotizing fasciitis is highest in hosts with systemic or local tissue immunocompromise, such as those with diabetes mellitus, neoplasia, or peripheral vascular disease as well as those who have recently undergone surgery, who abuse intravenous drugs, or who are undergoing immunosuppressive treatment, particularly with corticosteroids. The infection can also occur in healthy individuals after minor puncture wounds, abrasions, or lacerations; blunt trauma; surgical procedures, particularly of the abdomen, gastrointestinal or genitourinary tracts, or the perineum; or hypodermic needle injection.

There has been a resurgence of fulminant necrotizing soft-tissue infections caused by *S. pyogenes,* which may occur in previously healthy individuals. Streptococcal necrotizing fasciitis is classically located on an extremity. There may be a history of recent trauma to or operation in the area. Necrotizing fasciitis due to *S. pyogenes* may also occur after superinfection of varicella lesions. Children with this disease have tended to display onset, recrudescence, or persistence of high fever and signs of toxicity after the 3rd or 4th day of varicella. Common predisposing conditions in neonates are omphalitis and balanitis after circumcision.

Necrotizing fasciitis begins with acute onset of local, and at times tense, edema, erythema, tenderness, and heat. Fever is usually present, and pain, tenderness, and constitutional signs are disproportionate to cutaneous signs, especially with involvement of fascia and muscle. Lymphangitis and lymphadenitis may or may not be present. The infection advances along the superficial fascial plane, and initially there are few cutaneous signs to herald the serious nature and extent of the subcutaneous tissue necrosis that is occurring. Skin changes may appear over 24-48 hr as nutrient vessels are thrombosed and cutaneous ischemia develops. Early clinical findings include ill-defined cutaneous erythema and edema that extends beyond the area of erythema. Additional signs include formation of bullae filled initially with straw-colored and later bluish to hemorrhagic fluid, and darkening of affected tissues from red to purple to blue. Skin anesthesia and, finally, frank tissue gangrene and slough develop owing to the ischemia and necrosis. Vesiculation or bulla formation, ecchymoses, crepitus, anesthesia, and necrosis are ominous signs indicative of advanced disease. Children with varicella lesions may initially show no cutaneous signs of superinfection with invasive *S. pyogenes,* such as erythema or swelling. Significant systemic toxicity may accompany necrotizing fasciitis, including shock, organ failure, and death. Advance of the infection in this setting can be rapid, progressing to death within hours. Patients with involvement of the superficial or deep fascia and muscle tend to be more acutely and systemically ill and have more rapidly advancing disease than those with infection confined solely to subcutaneous tissues above the fascia. In an extremity, a **compartment syndrome** may develop, manifesting as tight edema, pain on motion, and loss of distal sensation and pulses; this is a surgical emergency.

Diagnosis

Definitive diagnosis of necrotizing fasciitis is made by surgical exploration, which should be undertaken as soon as the diagnosis is suspected. Necrotic fascia and subcutaneous tissue are gray and offer little resistance to blunt probing. Although CT and MRI aids in delineating the extent and tissue planes of involvement, this procedure should not delay surgical intervention. Frozen-section incisional biopsy specimens obtained early in the course of the infection can aid management by decreasing the time to diagnosis and helping establish margins of involvement. Gram staining of tissue can be particularly useful if chains of Gram-positive cocci, indicative of infection with *S. pyogenes,* are seen.

Treatment

Early supportive care, surgical debridement, and parenteral antibiotic administration are mandatory for necrotizing fasciitis. All devitalized tissue should be removed to freely bleeding edges, and repeat exploration is generally indicated within 24-36 hr to confirm that no necrotic tissue remains. This procedure may need to be repeated on several occasions until devitalized tissue has ceased to form. Meticulous daily wound care is also paramount.

Parenteral antibiotic therapy should be initiated as soon as possible with broad-spectrum agents against all potential pathogens. Initial empirical therapy should be instituted with vancomycin, linezolid, daptomycin, or quinupristin to cover Gram-positive and piperacillin-tazobactam to cover Gram-negative organisms. An alternative is to add ceftriaxone with metronidazole to cover mixed aerobic–anaerobic organisms. Therapy should then be based on sensitivity of isolated organisms. Penicillin with clindamycin is indicated for documented group A streptococcal necrotizing fasciitis. Some centers employ hyperbaric oxygen therapy, although it should not delay resuscitation or surgical debridement.

Prognosis

The combined case fatality rate among children and adults with necrotizing fasciitis and syndrome due to polymicrobial infection or *S. pyogenes* has been as high as 60%. Death is less common in children, however, and in cases not complicated by toxic shock–like syndrome.

665.3 Staphylococcal Scalded Skin Syndrome (Ritter Disease)

Anna M. Juern and Beth A. Drolet

ETIOLOGY AND PATHOGENESIS

Staphylococcal scalded skin syndrome is caused predominantly by phage group 2 staphylococci, particularly strains 71 and 55, which are present at localized sites of infection. Foci of infection include the nasopharynx and, less commonly, the umbilicus, urinary tract, a superficial abrasion, conjunctivae, and blood. The clinical manifestations of staphylococcal scalded skin syndrome are mediated by hematogenous spread, in the absence of specific antitoxin antibody of staphylococcal epidermolytic or exfoliative toxins A or B. The toxins have reproduced the disease in both animal models and human volunteers. Decreased renal clearance of the toxins may account for the fact that the disease is most common in infants and young children, as well as lack of protection from antitoxin antibodies. Epidermolytic toxin A is heat stable and is encoded by bacterial chromosomal genes. Epidermolytic toxin B is heat labile and is encoded on a 37.5-kb plasmid. The site of blister cleavage is subcorneal. The epidermolytic toxins produce the split by binding to and cleaving desmoglein 1. Intact bullae are consistently

sterile, unlike those of bullous impetigo, but culture specimens should be obtained from all suspected sites of localized infection and from the blood to identify the source for elaboration of the epidermolytic toxins.

CLINICAL MANIFESTATIONS

Staphylococcal scalded skin syndrome, which occurs predominantly in infants and children younger than 5 yr of age, includes a range of disease from localized bullous impetigo to generalized cutaneous involvement with systemic illness. Onset of the rash may be preceded by malaise, fever, irritability, and exquisite tenderness of the skin. **Scarlatiniform erythema** develops diffusely and is accentuated in flexural and periorificial areas. The conjunctivae are inflamed and occasionally become purulent. The brightly erythematous skin may rapidly acquire a wrinkled appearance, and in severe cases, sterile, flaccid blisters and erosions develop diffusely. Circumoral erythema is characteristically prominent, as is radial crusting and fissuring around the eyes, mouth, and nose. At this stage, areas of epidermis may separate in response to gentle shear force (Nikolsky sign; Fig. 665-3). As large sheets of epidermis peel away, moist, glistening, denuded areas become apparent, initially in the flexures and subsequently over much of the body surface (Fig. 665-4). This development may lead to secondary cutaneous infection, sepsis, and fluid and electrolyte disturbances. The desquamative phase begins after 2-5 days of cutaneous erythema; healing occurs without scarring in 10-14 days. Patients may have pharyngitis, conjunctivitis, and superficial erosions of the lips, but intraoral mucosal surfaces are spared. Although some patients appear ill, many are reasonably comfortable except for the marked skin tenderness.

DIFFERENTIAL DIAGNOSIS

A presumed **abortive** form of the disease manifests as diffuse, scarlatiniform, tender erythroderma that is accentuated in the flexural areas but does not progress to blister formation. In patients with this form, Nikolsky sign may be absent. Although the exanthem is similar to that of streptococcal scarlet fever, strawberry tongue and palatal petechiae are absent. Staphylococcal scalded skin syndrome may be mistaken for a number of other blistering and exfoliating disorders, including bullous impetigo, epidermolysis bullosa, epidermolytic hyperkeratosis, pemphigus, drug eruption, erythema multiforme, and drug-induced toxic epidermal necrolysis. Toxic epidermal necrolysis can often be distinguished by a history of drug ingestion, the presence of Nikolsky sign only at sites of erythema, absence of perioral crusting, full-thickness epidermal necrosis, and a blister cleavage plane in the lowermost epidermis.

HISTOLOGY

A subcorneal, granular layer split can be identified on skin biopsy. Absence of an inflammatory infiltrate is characteristic. Histology is identical to that seen in pemphigus foliaceus and subcorneal pustular dermatosis.

Figure 665-4 Infant with staphylococcal scalded skin syndrome.

TREATMENT

Systemic therapy, given either orally in cases of localized involvement or parenterally with a semisynthetic penicillinase-resistant penicillin or vancomycin if MRSA is considered, should be prescribed. Clindamycin should be added to inhibit bacterial protein (toxin) synthesis. The skin should be gently moistened and cleansed. Application of an emollient provides lubrication and decreases discomfort. Topical antibiotics are unnecessary. In neonates, or in infants or children with severe infection, hospitalization is mandatory, with attention to fluid and electrolyte management, infection control measures, pain management, and meticulous wound care with contact isolation. In particularly severe disease, care in an intensive care or burn unit is required. Recovery is usually rapid, but complications such as excessive fluid loss, electrolyte imbalance, faulty temperature regulation, pneumonia, septicemia, and cellulitis may cause increased morbidity.

Bibliography is available at Expert Consult.

665.4 Ecthyma

Anna M. Juern and Beth A. Drolet

See also Chapters 181, 183, 205.

Ecthyma resembles nonbullous impetigo in onset and appearance but gradually evolves into a deeper, more chronic infection. The initial lesion is a vesicle or vesicular pustule with an erythematous base that erodes through the epidermis into the dermis to form an ulcer with elevated margins. The ulcer becomes obscured by a dry, heaped-up, tightly adherent crust (Fig. 665-5) that contributes to the persistence of the infection and scar formation. Lesions may be spread by autoinoculation, may be as large as 4 cm, and occur most frequently on the

Figure 665-6 Large vegetating lesion of pyoderma vegetans.

legs. Predisposing factors include the presence of pruritic lesions, such as insect bites, scabies, or pediculosis, that are subject to frequent scratching; poor hygiene; and malnutrition. Complications include lymphangitis, cellulitis, and, rarely, poststreptococcal glomerulonephritis. The causative agent is usually GABHS; *S. aureus* is also cultured from most lesions but is probably a secondary pathogen. Crusts should be softened with warm compresses and removed. Systemic antibiotic therapy, as for impetigo, is indicated; almost all lesions are responsive to treatment with penicillin.

Ecthyma gangrenosa is a necrotic ulcer covered with a gray-black eschar. It is usually a sign of *P. aeruginosa* sepsis and usually occurs in immunosuppressed patients. Neutropenia is a risk factor for ecthyma gangrenosum. Ecthyma gangrenosum occurs in up to 6% of patients with systemic *P. aeruginosa* infection but can also occur as a primary cutaneous infection by inoculation. The lesion begins as a red or purpuric macule that vesiculates and then ulcerates. There is a surrounding rim of pink to violaceous skin. The punched-out ulcer develops raised edges with a dense, black, depressed, crusted center. Lesions may be single or multiple. Patients with bacteremia commonly have lesions in apocrine areas. Clinically similar lesions may also develop as a result of infection with other agents, such as *S. aureus, A. hydrophila, Enterobacter* spp., *Proteus* spp., *Burkholderia cepacia, Serratia marcescens, Aspergillus* spp., Mucorales, *E. coli,* and *Candida* spp. There is bacterial invasion of the adventitia and media of dermal veins but not arteries. The intima and lumina are spared. Blood and skin biopsy specimens for culture should be obtained, and empirical broad-spectrum, systemic therapy that includes coverage for *Pseudomonas* (i.e., aminoglycoside and an antipseudomonal penicillin) should be initiated as soon as possible.

Bibliography is available at Expert Consult.

665.5 Other Cutaneous Bacterial Infections

Anna M. Juern and Beth A. Drolet

BLASTOMYCOSIS-LIKE PYODERMA (PYODERMA VEGETANS)

Blastomycosis-like pyoderma is an exuberant cutaneous reaction to bacterial infection that occurs primarily in children who are malnourished and immunosuppressed. The organisms most commonly isolated from lesions are *S. aureus* and group A streptococcus, but several other organisms have been associated with these lesions, including *P. aeruginosa, Proteus mirabilis,* diphtheroids, *Bacillus* spp., and *C. perfringens.* Crusted, hyperplastic plaques on the extremities are characteristic, sometimes forming from the coalescence of many pinpoint, purulent, crusted abscesses (Fig. 665-6). Ulceration and sinus tract formation

Figure 665-7 Cutaneous blastomycosis. Verrucous, crusted, erythematous plaque on the chin in a 15 yr old boy with respiratory symptoms and bone pain. *(From Paller AS, Mancini AJ, editors:* Hurwitz clinical pediatric dermatology, *ed 3, Philadelphia, 2006, Elsevier, Fig. 14-13.)*

may develop, and additional lesions may appear at sites distant from the site of inoculation. Regional lymphadenopathy is common, but fever is not. Histopathologic examination reveals pseudoepitheliomatous hyperplasia and abscesses composed of neutrophils and/or eosinophils. Giant cells are usually lacking. The **differential diagnosis** includes deep fungal infection, particularly blastomycosis (Fig. 665-7) and tuberculous and atypical mycobacterial infection. Underlying immunodeficiency should be ruled out, and the selection of antibiotics should be guided by susceptibility testing because the response to antibiotics is often poor.

BLISTERING DISTAL DACTYLITIS

Blistering distal dactylitis is a superficial blistering infection of the volar fat pad on the distal portion of the finger or thumb (Fig. 665-8). More than 1 finger may be involved, as may the volar surfaces of the proximal phalanges, palms, and toes. Blisters are filled with a watery purulent fluid that contains polymorphonuclear leukocytes and, usually, chains of Gram-positive cocci. Patients commonly have no preceding history of trauma, and systemic symptoms are generally absent. Poststreptococcal glomerulonephritis has not occurred after blistering distal dactylitis. The infection is caused most commonly by group A streptococcus but has also occurred as a result of infection with *S. aureus.* If left untreated, blisters may continue to enlarge and

extend to the paronychial area. The infection responds to incision and drainage and a 10-day course of systemic cephalosporin therapy.

PERIANAL INFECTIOUS DERMATITIS

Perianal infectious dermatitis presents most commonly in boys (70% of cases) between the ages of 6 mo and 10 yr as perianal dermatitis (90% of cases) and pruritus (80% of cases; Fig. 665-9). The incidence of perianal infectious dermatitis is not known precisely but ranges from 1 in 2,000 to 1 in 218 patient visits. The rash is superficial, erythematous, well marginated, nonindurated, and confluent from the anus outward. Acutely (<6 wk), the rash tends to be bright red, moist, and tender to touch. At this stage, a white pseudomembrane may be present. As the rash becomes more chronic, the perianal eruption may consist of painful fissures, a dried mucoid discharge, or psoriasiform plaques with yellow peripheral crust. In girls, the perianal rash may be associated with vulvovaginitis. In boys, the penis may be involved. Approximately 50% of patients have rectal pain, most commonly described as burning inside the anus during defecation, and 33% have blood-streaked stools. Fecal retention is a frequent behavioral response to the infection. Patients also have presented with guttate psoriasis. Although local induration or edema may occur, constitutional symptoms such as fever, headache, and malaise are absent, suggesting that subcutaneous involvement, as in cellulitis, is absent. Familial spread of perianal infectious dermatitis is common, particularly when family members bathe together or use the same water.

Perianal infectious dermatitis is usually caused by GABHS, but it may also be caused by *S. aureus.* The index case and family members should undergo culture; follow-up cultures to document bacteriologic cure after a course of treatment are recommended.

The **differential diagnosis** of perianal infectious dermatitis includes psoriasis, seborrheic dermatitis, candidiasis, pinworm infestation, sexual abuse, and inflammatory bowel disease.

For GABHS perianal infectious dermatitis, treatment with a 7-day course of cefuroxime (20 mg/kg/day in 2 divided doses) is superior to treatment with penicillin. Concomitant topical mupirocin ointment 2-3 times a day also may be used. If *S. aureus* is cultured, treatment should be based on sensitivities.

ERYSIPELAS

See Chapter 183.

Figure 665-10 **Folliculitis.** Multiple follicular pustules.

FOLLICULITIS

Folliculitis, or superficial infection of the hair follicle, is most often caused by *S. aureus* (Bockhart impetigo). The lesions are typically small, discrete, dome-shaped pustules with an erythematous base, located at the ostium of the pilosebaceous canals (Fig. 665-10). Hair growth is unimpaired, and the lesions heal without scarring. Favored sites include the scalp, buttocks, and extremities. Poor hygiene, maceration, drainage from wounds and abscesses, and shaving of the legs can be provocative factors. Folliculitis can also occur as a result of tar therapy or occlusive wraps. The moist environment encourages bacterial proliferation. In HIV-infected patients, *S. aureus* may produce confluent erythematous patches with satellite pustules in intertriginous areas and violaceous plaques composed of superficial follicular pustules in the scalp, axillae, or groin. The **differential diagnosis** include *Candida,* which may cause satellite follicular papules and pustules surrounding erythematous patches of intertrigo, and *Malassezia furfur,* which produces 2-3 mm, pruritic, erythematous, perifollicular papules and pustules on the back, chest, and extremities, particularly in patients who have diabetes mellitus or are taking corticosteroids or antibiotics.

Diagnosis is made by examining potassium hydroxide–treated scrapings from lesions. Detection of *Malassezia* may require a skin biopsy, demonstrating clusters of yeast and short, branching hyphae ("macaroni and meatballs") in widened follicular ostia mixed with keratinous debris.

Topical antibiotic therapy (e.g., clindamycin 1% lotion or solution twice a day) is usually all that is needed for mild cases, but more severe cases may require use of a systemic antibiotic such as dicloxacillin or cephalexin. Bacterial culture should be performed in treatment-resistant cases. In chronic recurrent folliculitis, daily application of a benzoyl peroxide 5% gel or wash may facilitate resolution.

Folliculitis barbae (sycosis barbae) is a deeper, more severe recurrent inflammatory form of folliculitis caused by *S. aureus* that involves the entire depth of the follicle. Erythematous follicular papules and pustules develop on the chin, upper lip, and angle of the jaw, primarily in young black males. Papules may coalesce into plaques, and healing may occur with scarring. Affected individuals are frequently found to be *S. aureus* carriers. **Treatment** with warm saline compresses and topical antibiotics such as mupirocin generally clears the infection. More extensive, recalcitrant cases may require therapy with β-lactamase–resistant systemic antibiotics for several weeks, and elimination of *S. aureus* from sites of carriage.

Pseudomonal folliculitis (hot tub folliculitis) is attributable to *P. aeruginosa,* predominantly serotype O-11. It occurs after exposure to poorly chlorinated hot tubs/whirlpools and swimming pools, as well as to a contaminated water slide, or loofah sponge. The lesions are pruritic papules and pustules or deeply erythematous to violaceous nodules that develop 8-48 hr after exposure and are most dense in areas covered by a bathing suit (Fig. 665-11). Patients occasionally experience fever, malaise, and lymphadenopathy. The organism is readily cultured from pus. The eruption usually resolves spontaneously in 1-2 wk, often leaving postinflammatory hyperpigmentation. Consideration should be given to use of systemic antibiotics (ciprofloxacin) in adolescent patients with constitutional symptoms. Immunocompromised children are susceptible to complications of *Pseudomonas* folliculitis (cellulitis) and should avoid hot tubs.

FURUNCLES AND ABSCESSES

Etiology

The causative agent in furuncles ("boils") and carbuncles is usually *S. aureus,* which penetrates abraded perifollicular skin. Conditions predisposing to furuncle formation include obesity, hyperhidrosis, maceration, friction, and preexisting dermatitis. Furunculosis is also more common in individuals with low serum iron levels, diabetes, malnutrition, HIV infection, or other immunodeficiency states. Recurrent furunculosis is frequently associated with carriage of *S. aureus* in the nares, axillae, or perineum or close contact with someone such as a family member who is a carrier. Other bacteria or fungi may occasionally cause furuncles or carbuncles.

Community-acquired MRSA abscesses can also complicate folliculitis. Community-acquired MRSA infections commonly affect children and young adults, especially athletes where spread of the infection is enhanced by skin-to-skin contact. Infection can also be spread by crowding conditions, shared personal hygiene items, and a compromised skin barrier. They may occur in any location, however, they are most common on the lower abdomen, buttocks, and legs. Abscesses which are a common manifestation of community-acquired MRSA should be incised and drained. If oral antibiotics are needed, those with coverage against MRSA are recommended and commonly include oral trimethoprim-sulfamethoxazole (8-12 mg trimethoprim/kg/day in divided doses every 12 hr) or clindamycin (10-20 mg/kg/day in divided doses 3 times daily). To reduce colonization and hence reinfection, bleach baths for patients, and mupirocin intranasally in patients and in family members has been recommended.

Clinical Manifestations

This follicular lesion may originate from a preceding folliculitis or may arise initially as a deep-seated, tender, erythematous, perifollicular nodule. Although lesions are initially indurated, central necrosis and suppuration follow, leading to rupture and discharge of a central core of necrotic tissue and destruction of the follicle (Fig. 665-12). Healing occurs with scar formation. Sites of predilection are the hair-bearing areas on the face, neck, axillae, buttocks, and groin. Pain may be intense if the lesion is situated in an area where the skin is relatively fixed, such as in the external auditory canal or over the nasal cartilages. Patients with furuncles usually have no constitutional symptoms; bacteremia may occasionally ensue. Rarely, lesions on the upper lip or cheek may lead to cavernous sinus thrombosis. Infection of a group of contiguous follicles, with multiple drainage points, accompanied by inflammatory changes in surrounding connective tissue is a **carbuncle**. Carbuncles may be accompanied by fever, leukocytosis, and bacteremia.

Treatment

Treatment for furuncle and carbuncle includes regular bathing with antimicrobial soaps (chlorhexidine) and wearing of loose-fitting clothing to minimize predisposing factors for furuncle formation. Frequent application of a hot, moist compress may facilitate drainage of lesions. Large lesions may be drained by a small incision. Carbuncles and large or numerous furuncles should be treated with systemic antibiotics chosen on the basis of culture and sensitivity testing results.

PITTED KERATOLYSIS

Pitted keratolysis occurs most frequently in humid tropical and subtropical climates, particularly in individuals whose feet are moist for prolonged periods, for example, as a result of hyperhidrosis, prolonged wearing of boots, or immersion in water. It occurs most commonly in young males from early adolescence to the late 20s. The lesions consist

Figure 665-11 Papules and pustules in hot tub folliculitis.

Figure 665-12 Rupture and discharge of pus in a furuncle.

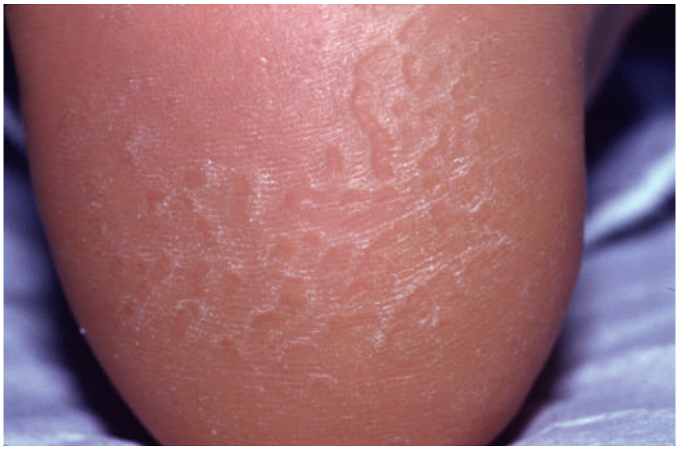

Figure 665-13 Superficial erosions of the horny layer in pitted keratolysis.

of 1-7 mm, irregularly shaped, superficial erosions of the horny layer on the soles, particularly at weight-bearing sites (Fig. 665-13). Brownish discoloration of involved areas may be apparent. A rare variant manifests as thinned, erythematous to violaceous plaques in addition to the typical pitted lesions. The condition is frequently malodorous, and is painful in approximately 50% of cases. The most likely etiologic agent is *Corynebacterium (Kytococcus) sedentarius.* Treatment of hyperhidrosis is mandatory with prescription-strength aluminum chloride products or 40% formaldehyde in petrolatum ointment. Avoidance of moisture and maceration produces slow, spontaneous resolution of the infection. Topical or systemic erythromycin and topical imidazole creams are standard therapy.

ERYTHRASMA

Erythrasma is a benign chronic superficial infection caused by *Corynebacterium minutissimum.* Predisposing factors include heat, humidity, obesity, skin maceration, diabetes mellitus, and poor hygiene. Approximately 20% of affected patients have involvement of the toe webs. Other frequently affected sites are moist, intertriginous areas such as the groin and axillae. The inframammary and perianal regions are occasionally involved. Sharply demarcated, irregularly bordered, slightly scaly, brownish red patches are characteristic of the disease. Mild pruritus is the only constant symptom. *C. minutissimum* is a complex of related organisms that produce porphyrins that fluoresce brilliant coral red under ultraviolet light. The diagnosis is readily made, and erythrasma is differentiated from dermatophyte infection and from tinea versicolor on Wood lamp examination. Bathing within 20 hr of Wood lamp examination, however, may remove the water-soluble porphyrins. Staining of skin scrapings with methylene blue or Gram stain reveals the pleomorphic, filamentous coccobacillary forms.

Effective **treatment** can be achieved with topical erythromycin, clindamycin, miconazole, or a 10-14 day course of oral erythromycin or an oral tetracycline.

ERYSIPELOID

A rare cutaneous infection, erysipeloid is caused by inoculation of *Erysipelothrix rhusiopathiae* from handling contaminated animals, birds, fish, or their products. The localized cutaneous form is most common, characterized by well-demarcated diamond-shaped erythematous to violaceous patches at sites of inoculation. Local symptoms are generally not severe, constitutional symptoms are rare, and the lesions resolve spontaneously after weeks but can recur at the same site or develop elsewhere weeks to months later. The diffuse cutaneous form manifests as lesions at several areas of the body in addition to the site of inoculation. It is also self-limited. The systemic form, caused by hematogenous spread, is accompanied by constitutional symptoms and may include endocarditis, septic arthritis, cerebral infarct and abscess, meningitis, and pulmonary effusion. Diagnosis is confirmed by skin biopsy, which reveals the Gram-positive organisms, and culture. The **treatment** of choice is parenteral penicillin or erythromycin.

TUBERCULOSIS OF THE SKIN

See Chapters 215 and 217.

Cutaneous tuberculosis infection occurs worldwide, particularly in association with HIV infection, malnutrition, and poor sanitary conditions. Primary cutaneous tuberculosis is rare in the United States. All forms of cutaneous disease are caused by *Mycobacterium tuberculosis, Mycobacterium bovis,* and occasionally by the bacillus Calmette-Guérin (BCG), an attenuated vaccine form of *M. bovis.* The manifestations caused by a given organism are indistinguishable from one another. After invasion of the skin, mycobacteria either multiply intracellularly within macrophages, leading to progressive disease, or are controlled by the host immune reaction.

Primary cutaneous tuberculosis (tuberculous chancre) results when *M. tuberculosis* or *M. bovis* gains access to the skin or mucous membranes through trauma in a previously uninfected individual without immunity to the organism. Sites of predilection are the face, lower extremities, and genitals. The initial lesion develops 2-4 wk after introduction of the organism into the damaged tissue. A red-brown papule gradually enlarges to form a shallow, firm, sharply demarcated ulcer. Satellite abscesses may be present. Some lesions acquire a crust resembling impetigo, and others become heaped up and verrucous at the margins. The primary lesion can also manifest as a painless ulcer on the conjunctiva, gingiva, or palate and occasionally as a painless acute paronychia. Painless regional adenopathy may appear several weeks after the development of the primary lesion and may be accompanied by lymphangitis, lymphadenitis, or perforation of the skin surface, forming **scrofuloderma**. Untreated lesions heal with scarring within 12 mo but may reactivate, may form lupus vulgaris, or, rarely, may progress to the acute miliary form. Therefore, antituberculous therapy is indicated (see Chapter 215).

M. tuberculosis or *M. bovis* can be cultured from the skin lesion and local lymph nodes, but acid-fast staining of histologic sections, particularly of a well-controlled infection, often does not reveal the organism. The **differential diagnosis** is broad, including a syphilitic chancre; deep fungal or atypical mycobacterial infection; leprosy; tularemia; cat-scratch disease; sporotrichosis; nocardiosis; leishmaniasis; reaction to foreign substances such as zirconium, beryllium, silk or nylon sutures, talc, and starch; papular acne rosacea; and lupus miliaris disseminatus faciei.

Scrofuloderma results from enlargement, cold abscess formation, and breakdown of a lymph node, most frequently in a cervical chain, with extension to the overlying skin from underlying foci of tuberculous infection. Linear or serpiginous ulcers and dissecting fistulas and subcutaneous tracts studded with soft nodules may develop. Spontaneous healing may take years, eventuating in cordlike keloid scars. Lupus vulgaris may also develop. Lesions may also originate from an underlying infected joint, tendon, bone, or epididymis. The **differential diagnosis** includes syphilitic gumma, deep fungal infections, actinomycosis, and hidradenitis suppurativa. The course is indolent, and constitutional symptoms are typically absent. Antituberculous therapy is indicated (see Chapter 215).

Direct cutaneous inoculation of the tubercle bacillus into a previously infected individual with a moderate to high degree of immunity initially produces a small papule with surrounding inflammation. **Tuberculosis verrucosa cutis** (warty tuberculosis) forms when the papule becomes hyperkeratotic and warty, and several adjacent papules coalesce or a single papule expands peripherally to form a brownish red to violaceous, exudative, crusted verrucous plaque. Irregular extension of the margins of the plaque produces a serpiginous border. Children have the lesions most commonly on the lower extremities after trauma and contact with infected material such as sputum or soil. Regional lymph nodes are involved only rarely. Spontaneous healing with atrophic scarring takes place over months to years. Healing is also gradual with antituberculous therapy.

Lupus vulgaris is a rare, chronic, progressive form of cutaneous tuberculosis that develops in individuals with a moderate to high

degree of tuberculin sensitivity induced by previous infection. The incidence is greater in cool, moist climates, particularly in females. Lupus vulgaris develops as a result of direct extension from underlying joints or lymph nodes; through lymphatic or hematogenous spread; or, rarely, by cutaneous inoculation with BCG vaccine. It most commonly follows cervical adenitis or pulmonary tuberculosis. Approximately 33% of cases are preceded by scrofuloderma, and 90% of cases manifest on the head and neck, most commonly on the nose or cheek. Involvement of the trunk is uncommon. A typical solitary lesion consists of a soft, brownish red papule that has an apple-jelly color when examined by diascopy. Peripheral expansion of the papule or, occasionally, the coalescence of several papules forms an irregular lesion of variable size and form. One or several lesions may develop, including nodules or plaques that are flat and serpiginous, hypertrophic and verrucous, or edematous in appearance. Spontaneous healing occurs centrally, and lesions characteristically reappear within the area of atrophy. Chronicity is characteristic, and persistence and progression of plaques over many years is common. Lymphadenitis is present in 40% of those with lupus vulgaris, and 10-20% has infection of the lungs, bones, or joints. Extensive deformities may be caused by vegetative masses and ulceration involving the nasal, buccal, or conjunctival mucosa; the palate; the gingiva; or the oropharynx. Squamous cell carcinoma, with a relatively high metastatic potential, may develop, usually after several years of the disease. After a temporary impairment in immunity, particularly after measles infection (lupus exanthematicus), multiple lesions may form at distant sites as a result of hematogenous spread from a latent focus of infection. The histopathology reveals a tuberculoid granuloma without caseation; organisms are extremely difficult to demonstrate. The **differential diagnosis** includes sarcoidosis, atypical mycobacterial infection, blastomycosis, chromoblastomycosis, actinomycosis, leishmaniasis, tertiary syphilis, leprosy, hypertrophic lichen planus, psoriasis, lupus erythematosus, lymphocytoma, and Bowen disease. Small lesions can be excised. Antituberculous drug therapy usually halts further spread and induces involution.

Orificial tuberculosis (tuberculosis cutis orificialis) appears on the mucous membranes and periorificial skin after autoinoculation of mycobacteria from sites of progressive infection. It is a sign of advanced internal disease and carries a poor prognosis and occurs in s sensitized host with impaired cellular immunity. Lesions appear as painful, yellowish or red nodules that form punched-out ulcers with inflammation and edema of the surrounding mucosa. **Treatment** consists of identification of the source of infection and initiation of antituberculous therapy.

Miliary tuberculosis (hematogenous primary tuberculosis) rarely manifests cutaneously and occurs most commonly in infants and in individuals who are immunosuppressed after chemotherapy or infection with measles or HIV. The eruption consists of crops of symmetrically distributed, minute, erythematous to purpuric macules, papules, or vesicles. The lesions may ulcerate, drain, crust, and form sinus tracts or may form subcutaneous gummas, especially in malnourished children with impaired immunity. Constitutional signs and symptoms are common, and a leukemoid reaction or aplastic anemia may develop. Tubercle bacilli are readily identified in an active lesion. A fulminant course should be anticipated, and aggressive antituberculous therapy is indicated.

Single or multiple metastatic tuberculous abscesses (**tuberculous gummas**) may develop on the extremities and trunk by hematogenous spread from a primary focus of infection during a period of decreased immunity, particularly in malnourished and immunosuppressed children. The fluctuant, nontender, erythematous subcutaneous nodules may ulcerate and form fistulas.

Vaccination with BCG characteristically produces a papule approximately 2 wk after vaccination. The papule expands in size, typically ulcerates within 2-4 mo, and heals slowly with scarring. In 1-2 per million vaccinations, a complication caused specifically by the BCG organism occurs, including regional lymphadenitis, lupus vulgaris, scrofuloderma, and subcutaneous abscess formation.

Tuberculids are skin reactions that exhibit tuberculoid features histologically but do not contain detectable mycobacteria. The lesions appear in a host who usually has moderate to strong tuberculin reactivity, has a history of previous tuberculosis of other organs, and usually shows a therapeutic response to antituberculous therapy. The cause of tuberculids is poorly understood. Most affected patients are in good health with no clear focus of disease at the time of the eruption. The most commonly observed tuberculid is the papulonecrotic tuberculid. Recurrent crops of symmetrically distributed, asymptomatic, firm, sterile, dusky-red papules appear on the extensor aspects of the limbs, the dorsum of the hands and feet, and the buttocks. The papules may undergo central ulceration and eventually heal, leaving sharply delineated, circular, depressed scars. The duration of the eruption is variable, but it usually disappears promptly after treatment of the primary infection. Lichen scrofulosorum, another form of tuberculid, is characterized by asymptomatic, grouped, pinhead-sized, often follicular pink or red papules that form discoid plaques, mainly on the trunk. Healing occurs without scarring.

Atypical mycobacterial infection may cause cutaneous lesions in children. *Mycobacterium marinum* is found in saltwater, freshwater, and diseased fish. In the United States, it is most commonly acquired from tropical fish tanks and swimming pools. Traumatic abrasion of the skin serves as a portal of entry for the organism. Approximately 3 wk after inoculation, a single reddish papule develops and enlarges slowly to form a violaceous nodule or, occasionally, a warty plaque (Fig. 665-14). The lesion occasionally breaks down to form a crusted ulcer or a suppurating abscess. Sporotrichoid erythematous nodules along lymphatics may also suppurate and drain. Lesions are most common on the elbows, knees, and feet of swimmers, and on the hands and fingers in persons with aquarium-acquired infection. Systemic signs and symptoms are absent. Regional lymph nodes occasionally become slightly enlarged but do not break down. Rarely, the infection becomes disseminated, particularly in an immunosuppressed host. A biopsy specimen of a fully developed lesion demonstrates a granulomatous infiltrate with tuberculoid architecture. Treatment options include tetracycline, doxycycline, minocycline, clarithromycin, and rifampin plus ethambutol. Application of heat to the affected site may be a useful adjunctive therapy (see Chapter 217).

Mycobacterium kansasii primarily causes pulmonary disease; skin disease is rare, often occurring in an immunocompromised host. Most commonly, sporotrichoid nodules develop after inoculation of traumatized skin. Lesions may develop into ulcerated, crusted, or verrucous plaques. The organism is relatively sensitive to antituberculous medications, which should be chosen on the basis of susceptibility testing.

Mycobacterium scrofulaceum causes cervical lymphadenitis (scrofuloderma) in young children, typically in the submandibular region. Nodes enlarge over several weeks, ulcerate, and drain. The local reaction is nontender and circumscribed, constitutional symptoms are absent, and there generally is no evidence of lung or other organ involvement. Other atypical mycobacteria may cause a similar

Figure 665-14 Violaceous, warty plaque of *Mycobacterium marinum* infection.

presentation, including *Mycobacterium avium* complex, *Mycobacterium kansasii,* and *Mycobacterium fortuitum.* **Treatment** is accomplished by excision and administration of antituberculous drugs (see Chapter 217).

Mycobacterium ulcerans (Buruli ulcer) causes a painless subcutaneous nodule after inoculation of abraded skin. Most infections occur in children in tropical rain forests. The nodule usually ulcerates, develops undermined edges, and may spread over large areas, most commonly on an extremity. Local necrosis of subcutaneous fat, producing a septal panniculitis, is characteristic. Ulcers persist for months to years before healing spontaneously with scarring and sometimes with lymphedema. Constitutional symptoms and lymphadenopathy are absent. Diagnosis is made by culturing the organism at 32-33°C (89.6-91.4°F). **Treatment of choice** is early excision of the lesion. Local heat therapy and oral chemotherapy may benefit some patients.

M. avium complex, composed of more than 20 subtypes, most commonly causes chronic pulmonary infection. Cervical lymphadenitis and osteomyelitis occur occasionally, and papules or purulent leg ulcers occur rarely by primary inoculation. Skin lesions may be an early sign of disseminated infection. The lesions may take various forms, including erythematous papules, pustules, nodules, abscesses, ulcers, panniculitis, and sporotrichoid spread along lymphatics. For treatment, see Chapter 217.

M. fortuitum complex causes disease in an immunocompetent host principally by primary cutaneous inoculation after traumatic injury, injection, or surgery. A nodule, abscess, or cellulitis develops 4-6 wk after inoculation. In an immunocompromised host, numerous subcutaneous nodules may form, break down, and drain. **Treatment** is based on identification and susceptibility testing of the organism.

Chapter 666
Cutaneous Fungal Infections

Anna M. Juern and Beth A. Drolet

TINEA VERSICOLOR

A common, innocuous, chronic fungal infection of the stratum corneum, tinea versicolor is caused by the dimorphic yeast *Malassezia globosa*. The synonyms *Pityrosporum ovale* and *Pityrosporum orbiculare* were used previously to identify the causal organism.

Etiology

M. globosa is part of the indigenous flora, predominantly in the yeast form, and is found particularly in areas of skin that are rich in sebum production, and is part of normal skin flora. Proliferation of filamentous forms occurs in the disease state. Predisposing factors include a warm, humid environment, excessive sweating, occlusion, high plasma cortisol levels, immunosuppression, malnourishment, and genetically determined susceptibility. The disease is most prevalent in adolescents and young adults.

Clinical Manifestations

The lesions of tinea versicolor vary widely in color. In white individuals, they are typically reddish brown, whereas in black individuals they may be either hypopigmented or hyperpigmented. The characteristic macules are covered with a fine scale. They often begin in a perifollicular location, enlarge, and merge to form confluent patches, most commonly on the neck, upper chest, back, and upper arms (Fig. 666-1). Facial lesions are common in adolescents; lesions occasionally appear on the forearms, dorsum of the hands, and pubis. There may be little or no pruritus. Involved areas do not tan after sun exposure. A papulopustular perifollicular variant of the disorder may occur on the back, chest, and sometimes the extremities.

Figure 666-1 Hyperpigmented, sharply demarcated macules of varying sizes on the upper trunk characteristic of tinea versicolor.

Differential Diagnosis

Examination with a Wood lamp discloses a yellowish gold fluorescence. A potassium hydroxide (KOH) preparation of scrapings is diagnostic, demonstrating groups of thick-walled spores and myriad short, thick, angular hyphae resembling macaroni/spaghetti and meatballs. Skin biopsy, including culture and special stains for fungi (periodic acid–Schiff), are often necessary to make the diagnosis in cases of primarily follicular involvement. Microscopically, organisms and keratinous debris can be seen within dilated follicular ostia.

Tinea versicolor must be distinguished from dermatophyte infections, seborrheic dermatitis, pityriasis alba, and secondary syphilis. Tinea versicolor may mimic nonscaling pigmentary disorders, such as postinflammatory pigmentary change, if a patient has removed the scales by scrubbing. *M. globosa* folliculitis must be distinguished from the other forms of folliculitis.

Treatment

Many therapeutic agents can be used to treat this disease successfully. The causative agent, a normal human saprophyte, is not eradicated from the skin, however, and the disorder recurs in predisposed individuals. Appropriate topical therapy may include 1 of the following: selenium 2% shampoo applied for 10 minutes before rinsing for 2 wk; ketoconazole 2% shampoo 3 times a wk for a month or a single application daily for 3 days; and terbinafine spray once to twice daily for 1-2 wk. Antifungal creams are available and can be used; however, these can be impractical to apply given the large surface of skin involved. Oral therapy may be more convenient and may be achieved successfully with ketoconazole or fluconazole, 400 mg, repeated in 1 wk, or itraconazole, 200 mg/24 hr for 5-7 days. Recurrent episodes continue to respond promptly to these agents. Oral therapy is particularly helpful in those with severe disease or recurrent disease, or in those where topical therapies have failed. Maintenance therapy with selenium sulfide shampoo or ketoconazole 2% shampoo once a week may be used.

DERMATOPHYTOSES

Dermatophytoses are caused by a group of closely related filamentous fungi with a propensity for invading the stratum corneum, hair, and nails. The 3 principal genera responsible for infections are *Trichophyton, Microsporum,* and *Epidermophyton.*

Etiology

Trichophyton spp. cause lesions of all keratinized tissue, including skin, nails, and hair. *Trichophyton rubrum* is the most common dermatophyte pathogen. *Microsporum* spp. principally invade the hair, and the *Epidermophyton* spp. invade the intertriginous skin. Dermatophyte infections are designated by the word **tinea** followed by the Latin word for the anatomic site of involvement. The dermatophytes are also classified according to source and natural habitat. Fungi acquired from the soil are called *geophilic*. They infect humans sporadically, inciting an inflammatory reaction. Dermatophytes that are acquired from animals are *zoophilic*. Transmission may be through direct contact or indirectly by infected animal hair or clothing. Infected animals are frequently asymptomatic. Dermatophytes acquired from humans are referred to as *anthropophilic*. These infestations range from chronic low-grade to acute inflammatory disease. *Epidermophyton* infections are transmitted only by humans, but various species of *Trichophyton* and *Microsporum* can be acquired from both human and nonhuman sources.

Epidemiology

Host defense has an important influence on the severity of the infection. Disease tends to be more severe in individuals with diabetes mellitus, lymphoid malignancies, immunosuppression, and states with high plasma cortisol levels, such as Cushing syndrome. Some dermatophytes, most notably the zoophilic species, tend to elicit more severe, suppurative inflammation in humans. Some degree of resistance to reinfection is acquired by most infected persons and may be associated with a delayed hypersensitivity response. No relationship has been demonstrated, however, between antibody levels and resistance to infection. The frequency and severity of infection are also affected by the geographic locale, the genetic susceptibility of the host, and the virulence of the strain of dermatophyte. Additional local factors that predispose to infection include trauma to the skin, hydration of the skin with maceration, occlusion, and elevated temperature.

Occasionally, a secondary skin eruption, referred to as a dermatophytid or "id" reaction, appears in sensitized individuals and has been attributed to circulating fungal antigens derived from the primary infection. The eruption is characterized by grouped papules (Fig. 666-2) and vesicles and, occasionally, by sterile pustules. Symmetric urticarial lesions and a more generalized maculopapular eruption also can occur. Id reactions are most often associated with tinea pedis but also occur with tinea capitis.

Tinea Capitis

Clinical Manifestations

Tinea capitis is a dermatophyte infection of the scalp most often caused by *Trichophyton tonsurans,* occasionally by *Microsporum canis*, and, much less commonly, by other *Microsporum* and *Trichophyton* spp. It is particularly common in black children age 4-14 yr. In *Microsporum* and some *Trichophyton* infections, the spores are distributed in a sheath-like fashion around the hair shaft (**ectothrix** infection), whereas *T. tonsurans* produces an infection within the hair shaft (endothrix). **Endothrix** infections may continue past the anagen phase of hair growth into telogen and are more chronic than infections with ectothrix organisms that persist only during the anagen phase. *T. tonsurans* is an anthropophilic species acquired most often by contact with infected hairs and epithelial cells that are on such surfaces as theater seats, hats, and combs. Dermatophyte spores may also be airborne within the immediate environment, and high carriage rates have been demonstrated in noninfected schoolmates and household members. *M. canis* is a zoophilic species that is acquired from cats and dogs.

The clinical presentation of tinea capitis varies with the infecting organism. Endothrix infections such as those caused by *T. tonsurans* create a pattern known as "black-dot ringworm," characterized initially by many small circular patches of alopecia in which hairs are broken off close to the hair follicle (Fig. 666-3). Another clinical variant manifests as diffuse scaling, with minimal hair loss secondary. It strongly resembles seborrheic dermatitis, psoriasis, or atopic dermatitis (Fig. 666-4). *T. tonsurans* may also produce a chronic and more diffuse alopecia. Lymphadenopathy is common (Fig. 666-5). A severe inflammatory response produces elevated, boggy granulomatous masses (**kerions**), which are often studded with pustules (Fig. 666-6*A*). Fever, pain, and regional adenopathy are common, and permanent scarring and alopecia may result (Fig. 666-6B). The zoophilic organism *M. canis* or the geophilic organism *Microsporum gypseum* also may cause kerion formation. The pattern produced by *Microsporum audouinii*, the most

Figure 666-4 Tinea capitis mimicking seborrheic dermatitis.

Figure 666-5 Lymphadenopathy associated with tinea capitis.

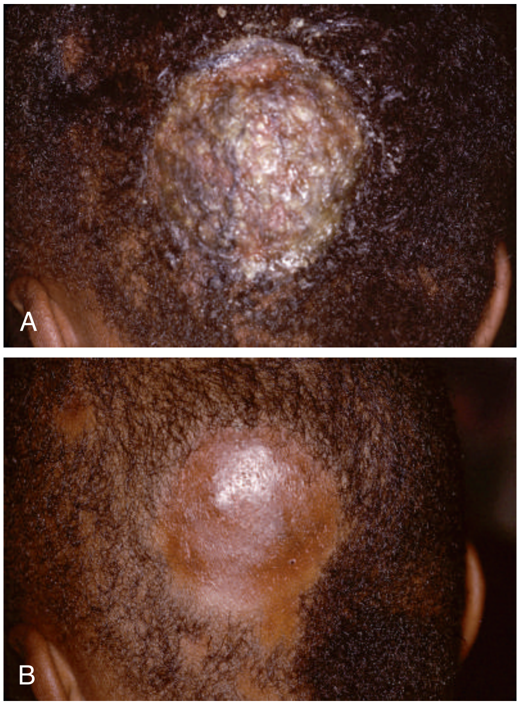

Figure 666-6 **A,** Kerion. Boggy granulomatous mass of the scalp. **B,** Scarring after kerion.

common cause of tinea capitis in the 1940s and 1950s, is characterized initially by a small papule at the base of a hair follicle. The infection spreads peripherally, forming an erythematous and scaly circular plaque (**ringworm**) within which the infected hairs become brittle and broken. Numerous confluent patches of alopecia develop, and patients may complain of severe pruritus. *M. audouinii* infection is no longer common in the United States. **Favus** is a chronic form of tinea capitis that is rare in the United States and is caused by the fungus *Trichophyton schoenleinii.* Favus starts as yellowish red papules at the opening of hair follicles. The papules expand and coalesce to form cup-shaped, yellowish, crusted patches that fluoresce dull green under a Wood lamp.

Differential Diagnosis

Tinea capitis can be confused with seborrheic dermatitis, psoriasis, alopecia areata, trichotillomania, and certain dystrophic hair disorders. When inflammation is pronounced, as in kerion, primary or secondary bacterial infection must also be considered. In adolescents, the patchy, moth-eaten type of alopecia associated with secondary syphilis may resemble tinea capitis. If scarring occurs, discoid lupus erythematosus and lichen planopilaris must also be considered in the differential diagnosis.

The important diagnostic procedures for the various dermatophyte diseases include examination of infected hairs with a Wood lamp, microscopic examination of KOH preparations of infected material, and identification of the etiologic agent by culture. Hairs infected with common *Microsporum* spp. fluoresce a bright blue-green. Most *Trichophyton*-infected hairs do not fluoresce.

Microscopic examination of a KOH preparation of infected hair from the active border of a lesion discloses tiny spores surrounding the hair shaft in *Microsporum* infections and chains of spores within the hair shaft in *T. tonsurans* infections. Fungal elements are not usually seen in scales. A specific etiologic diagnosis of tinea capitis may be obtained by planting broken off infected hairs on Sabouraud medium with reagents to inhibit growth of other organisms. Such identification may require 2 wk or more.

Treatment

Oral administration of griseofulvin microcrystalline (20-25 mg/kg/24 hr, or 10-15 mg/kg per day if the ultramicrosize form is used) is the recommended treatment for all forms of tinea capitis. Absorption of griseofulvin is enhanced by ingestion of a fatty meal and should be recommended for the patient. It may be necessary for 8-12 wk and should be terminated only after fungal culture results are negative. Treatment for 1 mo after a negative culture result minimizes the risk of recurrence. Adverse reactions to griseofulvin are rare but include nausea, vomiting, headache, blood dyscrasias, phototoxicity, and hepatotoxicity. Terbinafine is also effective at a dosage of 3-6 mg/kg/24 hr for 4-6 wk or possibly in pulse therapy, although it has limited activity against *M. canis.* The oral granules formulation of terbinafine is approved by the FDA for tinea capitis in children 4 yr of age and older. Oral itraconazole is useful in instances of griseofulvin resistance, intolerance, or allergy. Itraconazole is given for 4-6 wk at a dosage of 3-5 mg/kg/24 hr with food. Capsules are preferable to the syrup, which may cause diarrhea. Itraconazole is not approved by the FDA for treatment of dermatophyte infections in the pediatric population. Topical therapy alone is ineffective, but it may be an important adjunct because it may decrease the shedding of spores, and should be recommended in all patients. Asymptomatic dermatophyte carriage in family members is common. Because 1 in 3 families have at least 1 member who is a carrier, treatment of both patient and potential carriers with a sporicidal shampoo may hasten clinical resolution. Vigorous shampooing with a 2.5% selenium sulfide, zinc pyrithione, or ketoconazole shampoo is helpful. It is not necessary to shave the scalp.

Tinea Corporis

Clinical Manifestations

Tinea corporis, defined as infection of the glabrous skin, excluding the palms, soles, and groin, can be caused by most of the dermatophyte species, although *T. rubrum* and *Trichophyton mentagrophytes* are the most prevalent etiologic organisms. In children, infections with *M. canis* are also common. Tinea corporis can be acquired by direct contact with infected persons or by contact with infected scales or hairs deposited on environmental surfaces. *M. canis* infections are usually acquired from infected pets.

The most typical clinical lesion begins as a dry, mildly erythematous, elevated, scaly papule or plaque that spreads centrifugally and clears centrally to form the characteristic annular lesion responsible for the designation ringworm (Fig. 666-7). At times, plaques with advancing borders may spread over large areas. Grouped pustules are another variant. Most lesions clear spontaneously within several months, but some may become chronic. Central clearing does not always occur (Fig. 666-8), and differences in host response may result in wide variability in the clinical appearance—for example, granulomatous lesions called **Majocchi granuloma,** which are caused by penetration of organisms along the hair follicle to the level of the dermis, produce a fungal folliculitis and perifolliculitis (Fig. 666-9), and the kerion-like lesions referred to as tinea profunda. Majocchi granuloma is more

Figure 666-7 Annular plaque of tinea corporis with central clearing.

Figure 666-8 Minimal central clearing with tinea corporis.

Figure 666-9 Follicular papule and pustule in Majocchi granuloma after use of a superpotent topical steroid.

common after inappropriate treatment with topical corticosteroids, especially the superpotent class.

Differential Diagnosis

Many skin lesions, both infectious and noninfectious, must be differentiated from the lesions of tinea corporis. Those most frequently confused are granuloma annulare, nummular eczema, pityriasis rosea, psoriasis, seborrheic dermatitis, erythema chronicum migrans, and tinea versicolor. Microscopic examination of KOH wet mount preparations and cultures should always be performed when fungal infection is considered. Tinea corporis usually does not fluoresce with a Wood lamp.

Treatment

Tinea corporis usually responds to treatment with one of the topical antifungal agents (e.g., imidazoles, terbinafine, naftifine) twice daily for 2-4 wk. In unusually severe or extensive disease, a course of therapy with oral griseofulvin microcrystalline may be required for 4 wk. Itraconazole has produced excellent results in many cases with a 1-2 wk course of oral therapy. Combination topical corticosteroid/antifungal preparations should not be used as it may result in worsening or persistent infection.

Tinea Cruris

Clinical Manifestations

Tinea cruris, or infection of the groin, occurs most often in adolescent males and is usually caused by the anthropophilic species *Epidermophyton floccosum* or *T. rubrum,* but occasionally by the zoophilic species *T. mentagrophytes.*

The initial clinical lesion is a small, raised, scaly, erythematous patch on the inner aspect of the thigh. This spreads peripherally, often developing numerous tiny vesicles at the advancing margin. It eventually forms bilateral, irregular, sharply bordered patches with hyperpigmented scaly centers. In some cases, particularly in infections with *T. mentagrophytes,* the inflammatory reaction is more intense and the infection may spread beyond the crural region. The scrotum and labia are usually not involved in the infection, an important distinction from candidosis. Pruritus may be severe initially but abates as the inflammatory reaction subsides. Bacterial superinfection may alter the clinical appearance, and erythrasma or candidosis may coexist. Tinea cruris is more prevalent in obese persons and in persons who perspire excessively and wear tight-fitting clothing.

Differential Diagnosis

The diagnosis of tinea cruris is confirmed by culture and by demonstration of septate hyphae on a KOH preparation of epidermal scrapings. The disorder must be differentiated from intertrigo, allergic contact dermatitis, candidosis, and erythrasma. Bacterial superinfection must be precluded when there is a severe inflammatory reaction.

Treatment

Patients should be advised to wear loose cotton underwear. **Topical treatment** with an imidazole twice a day for 3-4 wk is recommended for severe infection, especially because these agents are effective in mixed candidal-dermatophytic infections.

Tinea Pedis

Clinical Manifestations

Tinea pedis (athlete's foot), infection of the toe webs and soles of the feet, is uncommon in young children but occurs with some frequency in preadolescent and adolescent males. The usual etiologic agents are *T. rubrum, T. mentagrophytes,* and *E. floccosum.*

Most commonly, the lateral toe webs (3rd to 4th and 4th to 5th interdigital spaces) and the subdigital crevice are fissured, with maceration and peeling of the surrounding skin (Fig. 666-10). Severe tenderness, itching, and a persistent foul odor are characteristic. These lesions may become chronic. This type of infection may involve overgrowth by bacterial flora, including *Kytococcus sedentarius, Brevibacterium epidermidis,* and Gram-negative organisms. Less commonly, a chronic diffuse hyperkeratosis of the sole of the foot occurs with only mild erythema (Fig. 666-11). In many cases, 2 feet and 1 hand are involved. This type of infection is more refractory to treatment and tends to recur. An inflammatory vesicular type of reaction may occur with *T. mentagrophytes* infection. This type is most common in young children. The lesions involve any area of the foot, including the dorsal surface, and are usually circumscribed. The initial papules progress to

Figure 666-10 Interdigital tinea pedis.

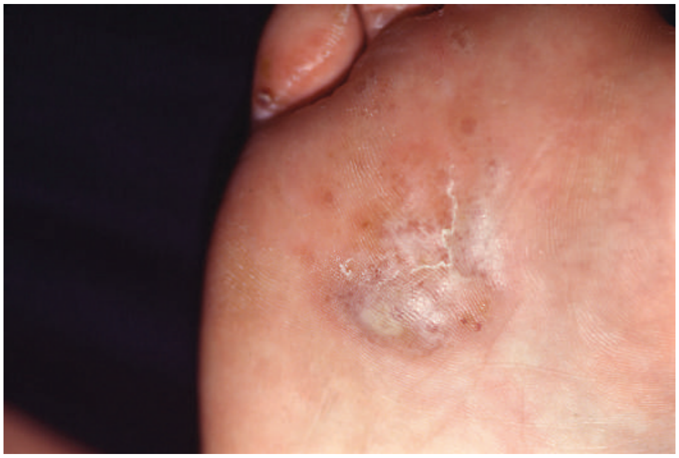

Figure 666-12 Vesicobullous tinea pedis.

Figure 666-11 Diffuse, minimally erythematous tinea pedis.

Figure 666-13 Hyperkeratotic nail in onychomycosis.

vesicles and bullae that may become pustular (Fig. 666-12). A number of factors, such as occlusive footwear and warm, humid weather, predispose to infection. Tinea pedis may be transmitted in shower facilities and swimming pool areas.

Differential Diagnosis

Tinea pedis must be differentiated from simple maceration and peeling of the interdigital spaces, which is common in children. Infection with *Candida albicans* and various bacterial organisms (erythrasma) may cause confusion or may coexist with primary tinea pedis. Contact dermatitis, vesicular foot dermatitis, atopic dermatitis, and juvenile plantar dermatitis also simulate tinea pedis. Fungal mycelia can be seen on microscopic examination of a KOH preparation or by culture.

Treatment

Treatment for mild infections includes simple measures such as avoidance of occlusive footwear, careful drying between the toes after bathing, and the use of an absorbent antifungal powder such as zinc undecylenate. Topical therapy with an imidazole is curative in most cases. Each of these agents is also effective against candidal infection. Several weeks of therapy may be necessary, and low-grade, chronic infections, particularly those caused by *T. rubrum*, may be refractory. In refractory cases, oral griseofulvin therapy may effect a cure, but recurrences are common.

Tinea Unguium

Clinical Manifestations

Tinea unguium (onychomycosis) is a dermatophyte infection of the nail plate. It occurs most often in patients with tinea pedis, but it may occur as a primary infection. It can be caused by a number of dermatophytes, of which *T. rubrum* and *T. mentagrophytes* are the most common.

The most superficial form of tinea unguium (i.e., white superficial onychomycosis) is caused by *T. mentagrophytes.* It manifests as irregular single or numerous white patches on the surface of the nail unassociated with paronychial inflammation or deep infection. *T. rubrum* generally causes a more invasive, subungual infection that is initiated at the lateral distal margins of the nail and is often preceded by mild paronychia. The middle and ventral layers of the nail plate, and perhaps the nail bed, are the sites of infection. The nail initially develops a yellowish discoloration and slowly becomes thickened, brittle, and loosened from the nail bed (Fig. 666-13). In advanced infection, the nail may turn dark brown to black and may crack or break off.

Differential Diagnosis

Tinea unguium must be differentiated from various dystrophic nail disorders. Changes as a result of trauma, psoriasis, lichen planus, eczema, and trachyonychia can all be confused with tinea unguium. Nails infected with *C. albicans* have several distinguishing features; most prominently, a pronounced paronychial swelling. Thin shavings taken from the infected nail, preferably from the deeper areas, should be examined microscopically with KOH and cultured. Repeated attempts may be required to demonstrate the fungus. Histologic evaluation of nail clippings with special stains for dermatophytes can be diagnostic.

The long half-life of itraconazole in the nail has led to promising trials of intermittent short courses of therapy (double the normal dose for 1 wk of each mo for 3-4 mo). Oral terbinafine is also used for the

treatment of onychomycosis. Terbinafine once daily for 12 wk is more effective than itraconazole pulse therapy. Griseofulvin and application of topical fungistatic agents to the nail bed are often ineffective and are not recommended.

Tinea Nigra Palmaris

Tinea nigra palmaris is a rare but distinctive superficial fungal infection that occurs principally in children and adolescents. It is caused by the dimorphic fungus *Phaeoannellomyces werneckii,* which imparts a gray-black color to the affected palm. The characteristic lesion is a well-defined hyperpigmented macule. Scaling and erythema are rare, and the lesions are asymptomatic. Tinea nigra is often mistaken for a junctional nevus, melanoma, or staining of the skin by contactants. Treatment is with an imidazole antifungal. *Keratolytic agents, such as salicylic acid, once to twice daily* can also be used.

CANDIDAL INFECTIONS (CANDIDOSIS, CANDIDIASIS, AND MONILIASIS)

See Chapter 234.

The dimorphic yeasts of the genus *Candida* are ubiquitous in the environment, but *C. albicans* usually causes candidosis in children. This yeast is not part of the indigenous skin flora, but it is a frequent transient on skin and may colonize the human alimentary tract and the vagina as a saprophytic organism. Certain environmental conditions, notably elevated temperature and humidity, are associated with an increased frequency of isolation of *C. albicans* from the skin. Many bacterial species inhibit the growth of *C. albicans,* and alteration of normal flora by the use of antibiotics may promote overgrowth of the yeast.

Chronic mucocutaneous candidiasis is associated with a diverse group of primary immunodeficiency diseases (Table 666-1). Chronic

Table 666-1 Primary Immunodeficiencies Underlying Fungal Infections

DISEASE	ASSOCIATED INFECTIONS	IMMUNOLOGIC PHENOTYPE	GENE, TRANSMISSION
CMC			
SCID	Bacteria, viruses, fungi, mycobacteria	No T cells, with or without B and/or NK cell lymphopenia	>30 genes: *IL2RG,* X-linked; *JAK3,* autosomal recessive; RAG1, autosomal recessive; *RAG2,* autosomal recessive; *ARTEMIS,* autosomal recessive; *ADA,* autosomal recessive; *CD3,* autosomal recessive, etc.
CID		T-cell defect	
CD25 deficiency	Viruses and bacteria		*IL2RA,* autosomal recessive
NEMO or iκBγ deficiency	Pyogenic bacteria, mycobacteria, viruses		*NEMO* or *IKBG* X-linked
IκBα GOF mutation			*IKBA,* autosomal dominant
DOCK8 deficiency	Viruses, bacteria and fungi		*DOCK8,* autosomal recessive
TCR-α deficiency	Viruses and bacteria		*TCRA,* autosomal recessive
CRACM1 deficiency	Viruses, mycobacteria, bacteria and fungi		*CRACM1,* autosomal recessive
MST1/STK4 deficiency	Viruses and bacteria		*MST1/STK4,* autosomal recessive
MHC class II deficiency	Viruses, bacteria and fungi		*CIITA, RFXANK, RFXC, RFXAP,* all autosomal recessive
Idiopathic CD4 lymphopenia	*Pneumocystis, Cryptococcus,* virus	CD4 T cells <300 cells/mm^3	*UNC119,* autosomal dominant, *MAGT1* X-linked, *RAG1,* autosomal recessive
SYNDROMIC CMC			
Interleukin-12Rβ1 and interleukin-12p40 deficiencies	*Mycobacteria, Salmonella*	Deficit of interleukin-17–producing T cells	*IL12RB1,* autosomal recessive, *IL12B,* autosomal recessive
STAT3 deficiency (autosomal dominant-HIES)	*Staphylococcus aureus, Aspergillus*	Hyperimmunoglobulin E, deficit of interleukin-17–producing T cells	*STAT3,* autosomal dominant
APECED/APS-1	No	Neutralizing anti–interleukin-17A, anti–interleukin-17F, and/or anti–interleukin-22 autoantibodies	*AIRE,* autosomal recessive
CARD9 deficiency	Dermatophytes, *Candida,* brain abscess	Deficit of interleukin-17–producing T cells	*CARD9,* autosomal recessive
CMCD			
Complete interleukin-17RA deficiency	*S. aureus*	No interleukin-17 response	*IL17RA,* autosomal recessive
Partial interleukin-17F deficiency	*S. aureus*	Impaired interleukin-17F, interleukin-17A/F function	*IL17F,* autosomal dominant
STAT1 GOF mutations	Bacteria, viruses, fungi, mycobacteria	Low interleukin-17–producing T cells	*STAT1,* autosomal dominant

From Lanternier F, Cypowyj S, Picard, C, et al: Primary immunodeficiencies underlying fungal infections. Curr Opin Pediatr *25:736–747, 2013.*

mucocutaneous candidiasis is characterized by chronic or recurrent *Candida* infections of the oral cavity, esophagus, genitals, nails, and skin. Chronic mucocutaneous candidiasis may also be seen as an acquired infection in patients with HIV infection, and during immunosuppressive treatments.

Oral Candidosis (Thrush)

See Chapter 234.

Vaginal Candidosis

See Chapters 120 and 234.

C. albicans is an inhabitant of the vagina in 5-10% of women, and vaginal candidosis is not uncommon in adolescent girls. A number of factors can predispose to this infection, including antibiotic therapy, corticosteroid therapy, diabetes mellitus, pregnancy, and the use of oral contraceptives. The infection manifests as cheesy white plaques on an erythematous vaginal mucosa and a thick white-yellow discharge. The disease may be relatively mild or may produce pronounced inflammation and scaling of the external genitals and surrounding skin with progression to vesiculation and ulceration. Patients often complain of severe itching and burning in the vaginal area. Before treatment is initiated, the diagnosis should be confirmed by microscopic examination and/or culture. The infection may be eradicated by insertion of nystatin or imidazole vaginal tablets, suppositories, creams, or foam. If these products are ineffective, the addition of one dose of fluconazole (150 mg) is effective.

Congenital Cutaneous Candidosis

See Chapter 234.

Candidal Diaper Dermatitis

Candidal diaper dermatitis is a ubiquitous problem in infants and, although relatively benign, is often frustrating because of its tendency to recur. Predisposed infants usually carry *C. albicans* in their intestinal tracts, and the warm, moist, occluded skin of the diaper area provides an optimal environment for its growth. A seborrheic, atopic, or primary irritant contact dermatitis usually provides a portal of entry for the yeast.

The primary clinical manifestation consists of an intensely erythematous, confluent plaque with a scalloped border and a sharply demarcated edge. It is formed by the confluence of numerous papules and vesicular pustules. Satellite pustules, those that stud the contiguous skin, are a hallmark of localized candidal infections. The perianal skin, inguinal folds, perineum, and lower abdomen are usually involved (Fig. 666-14). In males, the entire scrotum and penis may be involved, with an erosive balanitis of the perimeatal skin. In females, the lesions may be found on the vaginal mucosa and labia. In some infants, the process is generalized, with erythematous lesions distant from the diaper area. In some cases, the generalized process may represent a fungal id (hypersensitivity) reaction.

The **differential diagnosis** of candidal diaper dermatitis includes other eruptions of the diaper area that may coexist with candidal infection. For this reason, it is important to establish a diagnosis by means of KOH preparation or culture.

Treatment consists of applications of an imidazole cream 2 times daily. The combination of a corticosteroid and an antifungal agent may be justified if inflammation is severe but may confuse the situation if the diagnosis is not firmly established. Corticosteroid should not be continued for more than a few days. Protection of the diaper area by an application of thick zinc oxide paste overlying the anticandidal preparation may be helpful. The paste is more easily removed with mineral oil than with soap and water. Fungal id reactions gradually abate with successful treatment of the diaper dermatitis or may be treated with a mild corticosteroid preparation. When recurrences of diaper candidosis are frequent, it may be helpful to prescribe a course of oral anticandidal therapy to decrease the yeast population in the gastrointestinal tract. Some infants seem to be receptive hosts for *C. albicans* and may reacquire the organism from a colonized adult.

Intertriginous Candidosis

Intertriginous candidosis occurs most often in the axillae and groin, on the neck (Fig. 666-15) under the breasts, under pendulous abdominal fat folds, in the umbilicus, and in the gluteal cleft. Typical lesions are large, confluent areas of moist, denuded, erythematous skin with an irregular, macerated, scaly border. Satellite lesions are characteristic and consist of small vesicles or pustules on an erythematous base. With time, intertriginous candidal lesions may become lichenified, dry, scaly plaques. The lesions develop on skin subjected to irritation and maceration. Candidal superinfection is more likely to occur under conditions that lead to excessive perspiration, especially in obese children and in children with underlying disorders, such as diabetes mellitus. A similar condition, interdigital candidosis, commonly occurs in individuals whose hands are constantly immersed in water. Fissures occur between the fingers and have red denuded centers, with an overhanging white epithelial fringe. Similar lesions between the toes may be secondary to occlusive footwear. Treatment is the same as for other candidal infections.

Perianal Candidosis

Perianal dermatitis develops at sites of skin irritation as a result of occlusion, constant moisture, poor hygiene, anal fissures, and pruritus from pinworm infestation. It may become superinfected with *C. albicans,* especially in children who are receiving oral antibiotic or corticosteroid medication. The involved skin becomes erythematous, macerated, and excoriated, and the lesions are identical to those of candidal intertrigo or candidal diaper rash. Application of a topical

Figure 666-14 Erythematous confluent plaque caused by candidal infection.

Figure 666-15 Intertriginous candidosis of the neck.

antifungal agent in conjunction with improved hygiene is usually effective. Underlying disorders such as pinworm infection must also be treated (see Chapter 293).

Candidal Paronychia and Onychia

See Chapter 663.

Candidal Granuloma

Candidal granuloma is a rare response to an invasive candidal infection of skin. The lesions appear as crusted, verrucous plaques and hornlike projections on the scalp, face, and distal limbs. Affected patients may have single or numerous defects in immune mechanisms, and the granulomas are often refractory to topical therapy. A systemic anticandidal agent may be required for palliation or eradication of the infection.

Chapter 667
Cutaneous Viral Infections

Anna M. Juern and Beth A. Drolet

WART (VERRUCA)

Etiology

Human papillomaviruses (HPVs) cause a spectrum of disease from warts (verrucae vulgaris) to squamous cell carcinoma of the skin and mucous membranes, including the larynx (see Chapter 390.2). The HPVs are classified by genus, species, and type. More than 200 types are known, and the entire genomes of approximately 100 are completely sequenced. The incidence of all types of warts is highest in children and adolescents. HPV is spread by direct contact and autoinoculation; transmission within families and by fomites occurs. The clinical manifestations of infection develop 1 mo or longer after inoculation and depend on the HPV type, the size of the inoculum, the immune status of the host, and the anatomic site.

Clinical Manifestations

Cutaneous warts develop in 5-10% of children. **Common warts** (verruca vulgaris), caused most commonly by HPV types 2 and 4, occur most frequently on the fingers, dorsum of the hands (Fig. 667-1), paronychial areas, face, knees, and elbows. They are well-circumscribed papules with an irregular, roughened, keratotic surface. When the surface is pared away, many black dots representing thrombosed dermal capillary loops are often visible. **Periungual warts** are often painful and may spread beneath the nail plate, separating it from the nail bed (Fig. 667-2). **Plantar warts (verruca plantaris),** although similar to the common wart, are caused by HPV type 1 and are usually flush with the surface of the sole because of the constant pressure from weight bearing. When plantar warts become hyperkeratotic (Fig. 667-3), they may be painful. Similar lesions (palmar–verruca palmaris) can also occur on the palms. They are sharply demarcated, often with a ring of thick callus. The surface keratotic material must sometimes be removed before the boundaries of the wart can be appreciated. Several contiguous warts (HPV type 4) may fuse to form a large plaque, the so-called mosaic wart. Flat warts (verruca plana), caused by HPV types 3 and 10, are slightly elevated, minimally hyperkeratotic papules that usually remain <3 mm in diameter and vary in color from pink to brown. They may occur in profusion on the face, arms, dorsum of the hands, and knees. The distribution of several lesions along a line of cutaneous trauma is a helpful diagnostic feature (Fig. 667-4). Lesions may be disseminated in the beard area and on the legs by shaving and from the hairline onto the scalp by combing the hair. **Epidermodysplasia verruciformis** (*EVER1, EVER2* genes), caused primarily by HPV types 5 and 8 (β-papillomaviruses, species 1), manifests as many diffuse verrucous papules. Wart types 9, 12, 14, 15, 17, 25, 36, 38, 47,

Figure 667-2 Periungual wart with disruption of nail growth.

Figure 667-3 Hyperkeratotic plantar wart.

Figure 667-4 Multiple flat warts on the face with lesions in line of trauma.

Figure 667-5 Condylomata acuminata in the perianal area of a toddler.

and 50 may also be involved. Inheritance is thought to be primarily autosomal recessive, but an X-linked recessive form also has been postulated. Warts progress to **squamous cell carcinoma** in 10% of patients with epidermodysplasia verruciformis.

Genital HPV infection occurs in sexually active adolescents, most commonly as a result of infection with HPV types 6 and 11. **Condylomata acuminata** (mucous membrane warts) are moist, fleshy, papillomatous lesions that occur on the perianal mucosa (Fig. 667-5), labia, vaginal introitus, and perineal raphe, and on the shaft, corona, and glans penis. Occasionally, they obstruct the urethral meatus or the vaginal introitus. Because they are located in intertriginous areas, they may become moist and friable. When untreated, condylomata proliferate and become confluent, at times forming large cauliflower-like masses. Lesions can also occur on the lips, gingivae, tongue, and conjunctivae. Genital warts in children may occur after inoculation during birth through an infected birth canal, as a consequence of sexual abuse, or from incidental spread from cutaneous warts. A significant proportion of genital warts in children contain HPV types that are usually isolated from cutaneous warts. HPV infection of the cervix is a major risk factor for development of carcinoma, particularly if the infection is caused by HPV type 16, 18, 31, 33, 35, 39, 45, 52, 59, 67, 68, or 70. Immunization against types 6, 11, 16, and 18 is now available. Laryngeal (respiratory) papillomas contain the same HPV types as in anogenital papillomas. Transmission is believed to occur from mothers with genital HPV infection to neonates who aspirate infectious virus during birth and may develop laryngeal papillomatosis.

Histology

The various types of warts share the basic changes of hyperplasia of the epidermal cells and vacuolation of the spinous keratinocytes, which may contain basophilic intranuclear inclusions (viral particles). Warts are confined to the epidermis and do not have "roots." Individuals with impaired cell-mediated immunity are particularly susceptible to HPV infection. Antibodies occur in response to infection but appear to have little protective effect.

Differential Diagnosis

Common warts are most often confused with molluscum contagiosum. Plantar and palmar warts may be difficult to distinguish from punctate keratoses, corns, and calluses. In contrast to calluses, warts obliterate normal skin markings. Juvenile flat warts mimic lichen planus, lichen nitidus, angiofibromas, syringomas, milia, and acne. Condylomata acuminata may resemble condylomata lata of secondary syphilis.

Treatment

Various therapeutic measures are effective in the treatment of warts. More than 65% of warts disappear spontaneously within 2 yr. Warts are epidermal lesions and do not produce scarring unless they are managed surgically or treated in an overly aggressive fashion. Hyperkeratotic lesions (common, plantar, and palmar warts) are more responsive to therapy if the excess keratotic debris is gently pared with a scalpel until thrombosed capillaries are apparent; further paring induces bleeding. Treatment is most successful when performed regularly and frequently (every 2-4 wk).

Common warts can be destroyed by applications of liquid nitrogen or by pulsed dye laser. Daily application of salicylic acid in flexible collodion or as a stick is a slow but painless method of removal that is effective in some patients. Plantar and palmar warts may be treated with 40% salicylic acid plasters. These should be applied for 5 days at a time with a 2-day rest period between applications. Following removal of the plaster and prolonged soaking in hot water, keratotic debris can be removed with an emery board or pumice stone. Condylomata respond best to weekly applications of 25% podophyllin in tincture of benzoin. The medication should be left on the warts for 4-6 hr and then removed by bathing. Keratinized warts near the genitalia (buttocks) do not respond to podophyllin. Imiquimod (5% cream) applied 3 times weekly is also beneficial. Imiquimod is indicated for genital warts but has also been used successfully to treat warts in other locations. For nongenital warts, imiquimod should be applied daily. Cimetidine 30-40 mg/kg/day has been used in children with multiple warts unresponsive to other treatments. Immunotherapy with intralesional candida or trichophyton antigen may also be employed especially when lesions are numerous or resistant to other tried therapies. Immunotherapy is performed in clinic and multiple treatments every month (at least 3-4) are usually required. With all types of therapy, care should be taken to protect the surrounding normal skin from irritation.

MOLLUSCUM CONTAGIOSUM

Etiology

The poxvirus that causes molluscum contagiosum is a large double-stranded DNA virus that replicates in the cytoplasm of host epithelial cells. The 3 types cannot be differentiated on the basis of clinical appearance, location of lesions, or a patient's age or sex. Type 1 virus causes most infections. The disease is acquired by direct contact with an infected person or from fomites and is spread by autoinoculation. Children age 2-6 yr who are otherwise well and individuals who are immunosuppressed are affected most commonly. The incubation period is estimated to be 2 wk or longer.

Clinical Manifestations

Discrete, pearly, skin-colored, smooth, dome-shaped, papules vary in size from 1-5 mm. They typically have a central umbilication from which a plug of cheesy material can be expressed. The papules may occur anywhere on the body, but the face, eyelids, neck, axillae, and thighs are sites of predilection (Fig. 667-6). They may be found in

Figure 667-6 Grouped molluscum.

Figure 667-7 Molluscum with surrounding dermatitis.

clusters on the genitals or in the groin of adolescents and may be associated with other venereal diseases in sexually active individuals. Lesions commonly involve the genital area in children but are not acquired by sexual transmission in most cases. Mild surrounding erythema or an eczematous dermatitis may accompany the papules (Fig. 667-7). Lesions on patients with AIDS tend to be large and numerous, particularly on the face. Exuberant lesions may also be found in children with leukemia and other immunodeficiencies. Children with atopic dermatitis are susceptible to widespread involvement in areas of dermatitis. A pustular eruption at the site of individual molluscum lesions is seen (Fig. 667-8). It is not a secondary bacterial infection, but an immunologic reaction to the molluscum virus and it should not be treated with antibiotics. Atrophic scars are often seen after this type of reaction.

Differential Diagnosis

Differential diagnosis of molluscum contagiosum includes trichoepithelioma, basal cell carcinoma, ectopic sebaceous glands, syringoma, hidrocystoma, keratoacanthoma, and warty dyskeratoma. In individuals with AIDS, cryptococcosis may be indistinguishable clinically from molluscum contagiosum. Rarely, coccidioidomycosis, histoplasmosis, or *Penicillium marneffei* infection masquerades as molluscum-like lesions in an immunocompromised host.

Histology

The epidermis is hyperplastic and hypertrophied, extending into the underlying dermis and projecting above the skin surface. The central plug of material, which is composed of virus-laden cells, may be shelled out from a lesion and examined under the microscope. The rounded, cup-shaped mass of homogeneous cells, often with identifiable lobules,

Figure 667-8 Inflamed molluscum. Crusted papule at site of previous molluscum.

is diagnostic. Specific antibody against molluscum contagiosum virus is detectable in most infected individuals but is of uncertain immunologic significance. Cell-mediated immunity is thought to be important in host defense.

Treatment

Molluscum contagiosum is a self-limited disease. The average attack lasts 6-9 mo. However, lesions can persist for years, can spread to distant sites, and may be transmitted to others. Affected patients should be advised to avoid shared baths and towels until the infection is clear. Infection may spread rapidly and produce hundreds of lesions in children with atopic dermatitis or immunodeficiency. Immunotherapy with either candida or trichophyton antigen, is now the most commonly used therapy. This is repeated every 4 wk until resolution. If lesions are limited in number, then depending on the age of the patient, individual lesions can be treated with liquid nitrogen cryotherapy. For younger children, cantharidin may be applied to the lesions and covered with adhesive bandages to prevent unwanted spread of the blistering agent. A blister forms at the site of application, and the molluscum is removed with the blister. Cantharidin should not be used on the face. Cantharidin however, is now very limited or completely unavailable in the United States. Facial molluscum is more cosmetically upsetting to children and parents; imiquimod applied topically is beneficial if not excessively irritating. Molluscum is an epidermal disease and should not be overtreated such that scarring results.

Chapter 668
Arthropod Bites and Infestations

668.1 Arthropod Bites

Anna M. Juern and Beth A. Drolet

Arthropod bites are a common affliction of children and occasionally pose a problem in diagnosis. A patient may be unaware of the source of the lesions or may deny being bitten, making interpretation of the

eruption difficult. In these cases, knowledge of the habits, life cycle, and clinical signs of the more common arthropod pests of humans may help lead to a correct diagnosis (Table 668-1).

CLINICAL MANIFESTATIONS

The type of reaction that occurs after an arthropod bite depends on the species of insect and the age group and reactivity of the human host. Arthropods may cause injury to a host by various mechanisms, including mechanical trauma, such as the lacerating bite of a tsetse fly; invasion of host tissues, as in myiasis; contact dermatitis, as seen with repeated exposure to cockroach antigens; granulomatous reaction to retained mouthparts; transmission of systemic disease; injection of irritant cytotoxic or pharmacologically active substances, such as hyaluronidase, proteases, peptidases, and phospholipases in sting venom; and induction of anaphylaxis. Most reactions to arthropod bites depend on antibody formation to antigenic substances in saliva or venom. The type of reaction is determined primarily by the degree of previous exposure to the same or a related species of arthropod. When someone is bitten for the first time, no reaction develops. An immediate petechial reaction is occasionally seen. After repeated bites, sensitivity develops, producing a pruritic papule (Fig. 668-1) approximately 24 hr after the bite. This is the most common reaction seen in young children. With prolonged, repeated exposure, a wheal develops within minutes after a bite, followed 24 hr later by papule, vesicle, or bullae formation. By adolescence or adulthood, only a wheal may form, unaccompanied by the delayed papular reaction. Thus, adults in the same household as affected children may be unaffected. Ultimately, as a person becomes insensitive to the bite, no reaction occurs at all. This stage of nonreactivity is maintained only as long as the individual continues to be bitten regularly. Individuals in whom papular urticaria develops are in the transitional phase between development of primarily a delayed papular reaction and development of an immediate urticarial reaction.

Arthropod bites may occur as solitary, numerous, or profuse lesions, depending on the feeding habits of the perpetrator. Fleas tend to sample their host several times within a small localized area, whereas mosquitoes tend to attack a host as more randomly scattered sites. Delayed hypersensitivity reactions to insect bites, the predominant lesions in the young and uninitiated, are characterized by firm, persistent papules that may become hyperpigmented and are often excoriated and crusted. Pruritus may be mild or severe, transient or persistent. A central punctum is usually visible but may disappear as the lesion ages or is scratched. The immediate hypersensitivity reaction is characterized by an evanescent, erythematous wheal. If edema is marked, a tiny vesicle may surmount the wheal. Certain beetles produce bullous lesions through the action of cantharidin, and various insects, including beetles and spiders, may cause hemorrhagic nodules and ulcers. Bites on the lower extremities are more likely to be severe or persistent or to become bullous than those located elsewhere. Complications of arthropod bites include development of impetigo, folliculitis, cellulitis, lymphangitis, and severe anaphylactic hypersensitivity reactions, particularly after the bite of certain hymenopterans. The histopathologic changes are variable, depending on the arthropod, the age of the lesion, and the reactivity of the host. Acute urticarial lesions tend to show central vesiculation in which eosinophils are numerous. Papules most commonly show dermal edema and a mixed superficial and deep

Figure 668-1 Pruritic papules after bedbug bites.

Table 668-1 Bed Bugs vs Other Arthropod Bites: Main Clinical and Epidemiologic Features*

ARTHROPOD	CLINICAL FEATURES ON EXAMINATION	LOCATION	TIMING OF PRURITUS	CONTEXT
Bed bugs	3-4 Bites in a line or curve	Uncovered areas	Morning	Travelling
Fleas	3-4 Bites in a line or curve	Legs and buttocks	Daytime	Pet owners or rural living
Mosquitoes	Nonspecific urticarial papules	Potentially anywhere	*Anopheles* spp. night; *Culex* spp. night; *Aedes* spp. day	Worldwide distribution
Head lice	Live lice on the head associated with itchy, scratched lesions	Scalp, ears, and neck	Any	Children, parents, or contact with children
Body lice	Excoriated papules and hyperpigmentation; live lice inside clothes	Back	Any	Homeless people, developing countries
Sarcoptes scabiei mites (scabies)	Vesicles, burrows, nodules, and nonspecific secondary lesions	Interdigital spaces, forearms, breasts, genitalia	Night	Sexually transmitted, households or institutions
Ticks	Erythema migrans or ulcer	Potentially anywhere	Asymptomatic	Pet owners or hikers
Pyemotes X ventricosus	Comet sign, a linear erythematous macular tract	Under clothes	Any time when inside habitat	People exposed to woodworm contaminated furniture (*Pediculoides ventricosus* is a woodworm parasite)
Spiders	Necrosis (uncommon)	Face and arms	Immediate pain, no itching	Rural living

*It is difficult to diagnose a bite. Diagnosis relies on an array of arguments, none of which is specific by itself; it is the association of elements that is suggestive. Any arthropod bite can be totally asymptomatic.

From Bernardeschi C, Le Cleach L, Delaunay P, Chosidow O: Bed bug infestation. BMJ *346:f138, 2013.*

Figure 668-2 Red-brown papules in papular urticaria.

perivascular inflammatory infiltrate, often including a number of eosinophils. At times, however, the dermal cellular infiltrate is so dense that a lymphoma is suspected. Many young children demonstrate extensive dermal but nonerythematous, nontender edema and which responds to oral antihistamines in response to mosquito bites ("skeeter" syndrome), and must be distinguished from cellulitis, which tends to be painful, tender, and red. Retained mouthparts may stimulate a foreign body type of granulomatous reaction.

Papular urticaria occurs principally in the 1st decade of life. It may occur at any time of the year. The most common culprits are species of fleas, mites, bedbugs, gnats, mosquitoes, chiggers, and animal lice. Individuals with papular urticaria have predominantly transitional lesions in various stages of evolution between delayed-onset papules and immediate-onset wheals. The most characteristic lesion is an edematous, red-brown papule (Fig. 668-2). An individual lesion frequently starts as a wheal that, in turn, is replaced by a papule. A given bite may incite an id reaction at distant sites of quiescent bites in the form of erythematous macules, papules, or urticarial plaques. After a season or two, the reaction progresses from a transitional to a primarily immediate hypersensitivity urticarial reaction.

One of the most commonly encountered arthropod bites is that resulting from human, cat, or dog fleas (family *Pulicidae*). Eggs, which are generally laid in dusty areas and cracks between floorboards, give rise to larvae that then form cocoons. The cocoon stage can persist for up to 1 yr, and the flea emerges in response to vibrations from footsteps, accounting for the assaults that frequently befall the new owners of a recently reopened dwelling. Adult dog fleas can live without a blood meal for approximately 60 days. Attacks from fleas are more likely to occur when the fleas do not have access to their usual host; cat or dog fleas are more voracious and problematic when one visits an area frequented by the pet than when the pet is encountered directly. Flea bites tend to be grouped in lines or irregular clusters on the lower extremities. Fleas are often not seen on the body of a pet. Diagnosis of flea bites is aided by examination of debris from the animal's bedding material. The debris is collected by shaking the bedding into a plastic bag and examining the contents for fleas or their eggs, larvae, or feces.

TREATMENT

Treatment is directed at alleviation of pruritus by oral antihistamines and cool compresses. Potent topical corticosteroids are helpful. Topical antihistamines are potent immunologic sensitizers and have no role in the treatment of insect bite reactions. A short course of systemic steroids may be helpful if many severe reactions occur, particularly around the eyes. Insect repellents containing *N,N*-diethyl-3-methylbenzamide (DEET) may afford moderate protection against mosquitoes, fleas, flies, chiggers, and ticks, but are relatively ineffective against wasps, bees, and hornets. DEET must be applied to exposed skin and clothing to be effective. The most effective protection against mosquitoes, the human body louse, and other blood-feeding arthropods is use of DEET and permethrin-impregnated clothing. These measures are not effective, however, against the phlebotomine sand fly, which transmits leishmaniasis. Because of the potential for toxicity, the lowest effective DEET dose should be selected. Additional insect repellents include picaridin (flies, mosquitoes, chiggers, ticks), IR3535 (mosquitoes), oil of lemon, eucalyptus (mosquitoes), and citronella (mosquitoes). Table 668-2 lists methods to eliminate bed bugs.

An effort should be made to identify and eradicate the etiologic agent. Pets should be carefully inspected. Crawl spaces, eaves, and other sites of the house or outbuildings frequented by animals and birds should be decontaminated, and baseboard crevices, mattresses, rugs, furniture, and animal sleeping quarters should be decontaminated. Agents that are effective for ridding the home of fleas include lindane, pyrethroids, and organic thiocyanates. Flea-infested pets may be treated with powders containing rotenone, pyrethroids, Malathion, or methoxychlor. Lufenuron, an agent that prevents fleas from reproducing, is effective for animals in oral and injectable formulations. Fipronil is effective as a topical agent for the prevention of flea infestation.

Table 668-2 Patient Education to Eliminate Bed Bugs
Detection
• Look for brown insects no bigger than apple seeds on the mattress, sofa, and curtains and in darker places in the room (especially cracks in the walls, crevices in box springs, and furniture)
• Look for black spots on the mattress or blood traces on the sheets
Elimination
• Contact a pest management company
• Wash clothes at 60°C (140°F) or freeze delicate clothing, vacuum, and clean your home before the pest manager visits
• Collaborate with professionals who are used to dealing with bed bug infestation to increase eradication efficacy
Prevention
• Carefully examine secondhand furniture to assure the absence of bed bugs before purchase so as not to contaminate your home
• When sleeping in a hotel, even an upmarket establishment, lift mattresses to look for bed bugs or black spots
• Do not leave luggage in dark places, near furniture, or close to your bed. Before going to bed, close suitcases and put them in the bathroom—in the bathtub or shower stall

668.2 Scabies

Anna M. Juern and Beth A. Drolet

Scabies is caused by burrowing and release of toxic or antigenic substances by the female mite *Sarcoptes scabiei* var. *hominis*. The most important factor that determines spread of scabies is the extent and duration of physical contact with an affected individual. The children and sexual partner of an affected individual are most at risk. Scabies is transmitted only rarely by fomites because the isolated mite dies within 2-3 days.

ETIOLOGY AND PATHOGENESIS

An adult female mite measures approximately 0.4 mm in length, has 4 sets of legs, and has a hemispheric body marked by transverse corrugations, brown spines, and bristles on the dorsal surface. A male mite is approximately half her size and is similar in configuration. After impregnation on the skin surface, a gravid female exudes a keratolytic substance and burrows into the stratum corneum, often forming a shallow well within 30 min. She gradually extends this tract by

0.5-5.0 mm/24 hr along the boundary with the stratum granulosum. She deposits 10-25 oval eggs and numerous brown fecal pellets (scybala) daily. When egg laying is completed, in 4-5 wk, she dies within the burrow. The eggs hatch in 3-5 days, releasing larvae that move to the skin surface to molt into nymphs. Maturity is achieved in approximately 2-3 wk. Mating occurs, and the gravid female invades the skin to complete the life cycle.

CLINICAL MANIFESTATIONS

In an immunocompetent host, scabies is frequently heralded by intense pruritus, particularly at night. The first sign of the infestation often consists of 1-2 mm red papules, some of which are excoriated, crusted, or scaling. Threadlike burrows are the classic lesion of scabies (Fig. 668-3) but may not be seen in infants. In infants, bullae and pustules are relatively common. The eruption may also include wheals, papules, vesicles, and a superimposed eczematous dermatitis (Fig. 668-4). The palms, soles, and scalp are often affected. In older children and adolescents, the clinical pattern is similar to that in adults, in whom preferred sites are the interdigital spaces, wrist flexors, anterior axillary folds, ankles, buttocks, umbilicus and belt line, groin, genitals in men, and areolas in women. The head, neck, palms, and soles are generally spared. Infants will often have a diffuse eczematous eruption that will involve the scalp, neck, and face. Red-brown nodules, most often located in covered areas such as the axillae, groin, and genitals, predominate in the less common variant called nodular scabies. Additional clues include facial sparing, affected family members, poor response to topical antibiotics, and transient response to topical steroids. Untreated, scabies may lead to eczematous dermatitis, impetigo, ecthyma, folliculitis, furunculosis, cellulitis, lymphangitis, and id reaction. Glomerulonephritis has developed in children from streptococcal impetiginization of scabies lesions. In some tropical areas, scabies is the predominant underlying cause of pyoderma. A latent period of approximately 1 mo follows an initial infestation. Thus, itching may be absent and lesions may be relatively inapparent in contacts who are asymptomatic carriers. On reinfestation, however, reactions to mite antigens are noted within hours.

Figure 668-3 Classic scabies burrow.

DIFFERENTIAL DIAGNOSIS

Differential diagnosis of scabies can often be made clinically but is confirmed by microscopic identification of mites (Fig. 668-5*A*), ova, and scybala (Fig. 668-5*B*) in epithelial debris. Scrapings most often test positive when obtained from burrows or fresh papules. A reliable method is application of a drop of mineral oil on the selected lesion, scraping of it with a No. 15 blade, and transferring the oil and scrapings to a glass slide.

The differential diagnosis depends on the types of lesions present. Burrows are virtually pathognomonic for human scabies. Papulovesicular lesions are confused with papular urticaria, canine scabies, chickenpox, viral exanthems, drug eruptions, dermatitis herpetiformis, and folliculitis. Eczematous lesions may mimic atopic dermatitis and seborrheic dermatitis, and the less common bullous disorders of childhood may be suspected in infants with predominantly bullous lesions. Nodular scabies is frequently misdiagnosed as urticaria pigmentosa and Langerhans cell histiocytosis. The histopathologic appearance of nodular scabies, consisting of a deep, dense, perivascular infiltrate of lymphocytes, histiocytes, plasma cells, and atypical mononuclear cells, may mimic malignant lymphoid neoplasms.

Figure 668-4 A, Diffuse scabies on an infant. The face is clear. The lesions are most numerous around the axillae, chest, and abdomen. **B,** Scabies. Infestation of the palms and soles is common in infants. The vesicular lesions have all ruptured. *(From Habif TP, editor:* Clinical dermatology*, ed 4, Philadelphia, 2004, Mosby, Figs. 15-8 and 15-9.)*

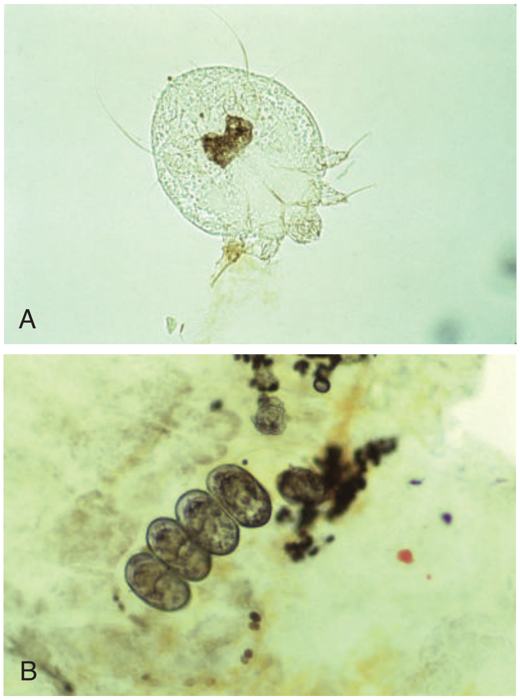

Figure 668-5 **A,** Human scabies mite obtained from scraping. **B,** Scabies ova and scybala.

TREATMENT

The treatment of choice for scabies is permethrin 5% cream (Elimite) applied to the entire body from the neck down, with particular attention to intensely involved areas, which is also standard therapy. Scabies is frequently found above the neck in infants (younger than 2 yr old), necessitating treatment of the scalp. The medication is left on the skin for 8-12 hr and should be reapplied in 1 wk for another 8-12 hr period. Additional therapies may include lindane 1% lotion or cream, sulfur ointment 5-10%, and crotamiton 10% lotion or cream. For severe infestations and in immunocompromised patients oral ivermectin 200 µg/kg per dose given orally for 2 doses, 2 wk apart can be used (off-label use). Single dose ivermectin (200 µg/kg) has also been effective in immunocompetent patients with improvement (cure) noted in 60% at 2 wk and 89% at 4 wk after treatment.

Transmission of mites is unlikely more than 24 hr after treatment. Pruritus, which is a result of hypersensitivity to mite antigens, may persist for a number of days to weeks, and may be alleviated by a topical corticosteroid preparation. If pruritus persists for >2 wk after treatment and new lesions are occurring, the patient should be reexamined for mites. Nodules are extremely resistant to treatment and may take several months to resolve. The entire family should be treated, as should caretakers of the infested child. Clothing, bed linens, and towels should be washed in hot water and dried using high heat. Clothing or other items (e.g., stuffed animals) that cannot be washed may be dry cleaned or stored in bags for 3 days to 1 wk, as the mite will die when separated from the human host.

NORWEGIAN SCABIES

The Norwegian variant of human scabies is highly contagious and occurs mainly in individuals who are cognitively and physically debilitated, particularly those who are institutionalized and those with Down syndrome; in patients with poor cutaneous sensation (leprosy, spina bifida); in patients who have severe systemic illness (leukemia, diabetes); and in immunosuppressed patients (HIV infection). Affected individuals are infested by myriad mites that inhabit the crusts and exfoliating scales of the skin and scalp. The nails may become thickened and dystrophic. The subungual debris is densely populated by mites. The infestation is often accompanied by generalized lymphadenopathy and eosinophilia. There is massive orthokeratosis and parakeratosis with numerous interspersed mites, psoriasiform epidermal hyperplasia, foci of spongiosis, and neutrophilic abscesses. Norwegian scabies is thought to represent a deficient host immune response to the organism. Management is difficult, requiring scrupulous isolation measures, removal of the thick scales, and repeated but careful applications of permethrin 5% cream. Ivermectin (200-250 µg/kg) has been used successfully as single-dose therapy in refractory cases, particularly in HIV-infected patients. A second dose may be needed a week later. The FDA has not approved this agent for treatment of scabies.

CANINE SCABIES

Canine scabies is caused by *S. scabiei* var. *canis,* the dog mite that is associated with mange. The eruption in humans, which is most frequently acquired by cuddling an infested puppy, consists of tiny papules, vesicles, wheals, and excoriated eczematous plaques. Burrows are not present because the mite infrequently inhabits human stratum corneum. The rash is pruritic and has a predilection for the arms, chest, and abdomen, the usual sites of contact with dogs. Onset is sudden and usually follows exposure by 1-10 days, possibly resulting from development of a hypersensitivity reaction to mite antigens. Recovery of mites or ova from scrapings of human skin is rare. The disease is self-limited because humans are not a suitable host. Bathing and changing clothes are generally sufficient. Removal or treatment of the infested animal is necessary. Symptomatic therapy for itching is helpful. In rare cases in which mites are demonstrated in scrapings from an affected child, they can be eradicated by the same measures applicable to human scabies.

OTHER TYPES OF SCABIES

Other mites that occasionally bite humans include the chigger or harvest mite *(Eutrombicula alfreddugesi),* which prefers to live on grass, shrubs, vines, and stems of grain. Larvae have hooked mouthparts, which allow the chigger to attach to the skin, but not to burrow, to obtain a blood meal, most commonly on the lower legs. Avian mites may affect those who come into close contact with chickens or pet gerbils. Humans may occasionally be assaulted by avian mites that have infested a nest outside a window, an attic, heating vents, or an air conditioner. The dermatitis is variable, including grouped papules, wheals, and vesicular lesions on the wrists, neck, breasts, umbilicus, and anterior axillary folds. A prolonged investigation is often undertaken before the cause and source of the dermatitis are discovered.

Bibliography is available at Expert Consult.

668.3 Pediculosis

Anna M. Juern and Beth A. Drolet

Three types of lice are obligate parasites of the human host: body or clothing lice *(Pediculus humanus corporis),* head lice *(Pediculus humanus capitis),* and pubic or crab lice *(Phthirus pubis).* Only the body louse serves as a vector of human disease (typhus, trench fever, relapsing fever). Body and head lice have similar physical characteristics. They are approximately 2-4 mm in length. Pubic lice are only 1-2 mm in length and are greater in width than length, giving them a crab-like appearance. Female lice live for approximately 1 mo and deposit 3-10 eggs daily on the human host. Body lice, however, generally lay eggs in or near the seams of clothing. The ova or nits are glued to hairs or fibers of clothing but not directly on the body. Ova hatch in 1-2 wk and require another week to mature. Once the eggs hatch, the nits remain attached to the hair as empty sacs of chitin. Freshly hatched larvae die unless a meal is obtained within 24 hr and every few days thereafter. Both nymphs and adult lice feed on human blood, injecting their salivary juices into the host and depositing their fecal matter on the skin. Symptoms of infestation do not appear immediately but develop as an individual becomes sensitized. The hallmark of all types of pediculosis is pruritus.

Pediculosis corporis is rare in children except under conditions of poor hygiene, especially in colder climates when the opportunity to change clothes on a regular basis is lacking. The parasite is transmitted mainly on contaminated clothing or bedding. The primary lesion is a small, intensely pruritic, red macule or papule with a central hemorrhagic punctum, located on the shoulders, trunk, or buttocks. Additional lesions include excoriations, wheals, and eczematous, secondarily infected plaques. Massive infestation may be associated with constitutional symptoms of fever, malaise, and headache. Chronic infestation may lead to "vagabond's skin," which manifests as lichenified, scaling, hyperpigmented plaques, most commonly on the trunk. Lice are found on the skin only transiently when they are feeding. At other times, they inhabit the seams of clothing. Nits are attached firmly to fibers in the cloth and may remain viable for up to 1 mo. Nits hatch when they encounter warmth from the host's body when the clothes are worn again. Therapy consists of improved hygiene and hot water laundering of all infested clothing and bedding. A uniform temperature of 65°C (149°F), wet or dry, for 15-30 min kills all eggs and lice. Alternatively, eggs hatch and nymphs starve if clothing is stored for 2 wk at 23.9-29.4°C (75-85°F).

Pediculosis capitis is an intensely pruritic infestation of lice in the scalp hair. It is the most common form of lice to affect children, in particular those between the ages of 3 and 12 yr. Fomites and head-to-head contact are important modes of transmission. In summer months in many areas of the United States and in the tropics at all times of the year, shared combs, brushes, or towels have a more important role in louse transmission. Translucent 0.5 mm eggs are laid near the proximal portion of the hair shaft and become adherent to 1 side of the shaft (Fig. 668-6). A nit cannot be moved along or knocked off the hair shaft with the fingers. Secondary pyoderma, after trauma from scratching, may result in matting together of the hair and cervical and occipital lymphadenopathy. Hair loss does not result from pediculosis but may accompany the secondary pyoderma. Head lice are a major cause of numerous pyodermas of the scalp, particularly in tropical environments. Lice are not always visible, but nits are detectable on the hairs, most commonly in the occipital region and above the ears, rarely on beard or pubic hair. Dermatitis may also be noted on the neck and pinnae. An id reaction, consisting of erythematous patches and plaques, may develop, particularly on the trunk. Head lice rarely infest African-Americans and this is possibly related to the diameter, shape or twisted nature of their hair shafts (which makes grasping of the shaft more difficult for the louse).

Figure 668-6 Intact nits on human hairs.

Because of resistance of head lice to pyrethroids, malathion 0.5% in isopropanol is the treatment of choice for head lice and should be applied to dry hair until hair and scalp are wet, and left on for 12 hr. A second application 7-9 days after initial treatment may be necessary. This product is flammable, so care should be taken to avoid open flames. Malathion, like lindane shampoo, is not indicated for use in neonates and infants. Additional approved therapies include spinosad (if >4 yr old), benzyl alcohol lotion (if >6 mo), and ivermectin for difficult-to-treat head lice (Table 668-3). All household members should be treated at the same time. Nits can be removed with a fine-toothed comb after application of a damp towel to the scalp for 30 min. Clothing and bed linens should be laundered in very hot water or dry-cleaned; brushes and combs should be discarded or coated with a pediculicide for 15 min and then thoroughly cleaned in boiling water. Children may return to school after the initial treatment.

Pediculosis pubis is transmitted by skin-to-skin or sexual contact with an infested individual; the chance of acquiring the lice with 1 sexual exposure is 95%. The infestation is usually encountered in adolescents, although small children may occasionally acquire pubic lice on the eyelashes. Patients experience moderate to severe pruritus and may develop a secondary pyoderma from scratching. Excoriations tend to be shallower, and the incidence of secondary infection is lower than in pediculosis corporis. Maculae ceruleae are steel-gray spots, usually <1 cm in diameter, which may appear in the pubic area and on the chest, abdomen, and thighs. Oval translucent nits, which are firmly attached to the hair shafts, may be visible to the naked eye or may be readily identified by a hand lens or by microscopic examination (see Fig. 668-6). Grittiness, as a result of adherent nits, may sometimes be detected when the fingers are run through infested hair. Adult lice are difficult to detect than head or body lice because of their lower level of activity and smaller, translucent bodies. Because pubic lice occasionally may wander or may be transferred to other sites on fomites, terminal hair on the trunk, thighs, axillary region, beard area, and eyelashes should be examined for nits. The coexistence of other venereal diseases should be considered. Treatment with a 10-min application of a pyrethrin preparation is usually effective. Retreatment may be required in 7-10 days. The shampoo form of lindane, which requires a 10 min application time, is an alternative choice, but lindane cream and lotion are no longer recommended for treatment of pubic lice. Infestation of eyelashes is eradicated by petrolatum applied 3-5 times per 24 hr for 8-10 days. Clothing, towels, and bed linens may be contaminated with nit-bearing hairs and should be thoroughly laundered or dry-cleaned.

Bibliography is available at Expert Consult.

668.4 Seabather's Eruption

Anna M. Juern and Beth A. Drolet

Seabather's eruption is a severely pruritic dermatosis of inflammatory papules that develops within ≈12 hr of bathing in saltwater, primarily on body sites that were covered by a bathing suit. The eruption has been described primarily in connection with bathing in the waters of Florida and the Caribbean. Lesions, which may include pustules, vesicles, and urticarial plaques, are more numerous in individuals who keep their bathing suits on for an extended period after leaving the water. The eruption may be accompanied by systemic symptoms of fatigue, malaise, fever, chills, nausea, and headache; in 1 large series, ≈40% of children younger than 16 yr of age had fever. Duration of the pruritus and skin eruption is 1-2 wk. Lesions consist of a superficial and deep perivascular and interstitial infiltrate of lymphocytes, eosinophils, and neutrophils. The eruption appears to be due to an allergic hypersensitivity reaction to venom from larvae of the thimble jellyfish *(Linuche unguiculata)*. Treatment is largely symptomatic. Potent topical corticosteroids have been shown to provide relief to some patients.

Chapter 669
Acne
Sheila S. Galbraith

ACNE VULGARIS

Acne, particularly the comedonal form, occurs in 80% of adolescents.

Pathogenesis

Lesions of acne vulgaris develop in sebaceous follicles, which consist of large, multilobular sebaceous glands that drain their products into the follicular canals. The initial lesion of acne is a microcomedone, which progresses to a comedone. A comedone is a dilated epithelium-lined follicular sac filled with lamellated keratinous material, lipid, and bacteria. An open comedone, known as a **blackhead,** has a patulous pilosebaceous orifice that permits visualization of the plug. An open comedone becomes inflammatory less commonly than does a closed comedone or whitehead, which has only a pinpoint opening. An inflammatory papule or nodule develops from a comedone that has ruptured and extruded its follicular contents into the subadjacent dermis, inducing a neutrophilic inflammatory response. If the inflammatory reaction is close to the surface, a papule or pustule develops. If the inflammatory infiltrate develops deeper in the dermis, a nodule forms. Suppuration and an occasional giant cell reaction to the keratin and hair are the cause of nodulocystic lesions. These are not true cysts but liquefied masses of inflammatory debris.

The primary pathogenetic alterations in acne are (1) abnormal keratinization of the follicular epithelium, resulting in impaction of keratinized cells within the follicular lumen; (2) increased sebaceous gland production of sebum; (3) proliferation of *Propionibacterium acnes* within the follicle; and (4) inflammation. Comedonal acne (Fig. 669-1), particularly of the central face, is frequently the first sign of pubertal maturation. At puberty, the sebaceus gland enlarges and sebum production increases in response to the increased activities of androgens of primarily adrenal origin. Most patients with acne do not have endocrine abnormalities. Hyperresponsiveness of the sebocyte to androgens is likely involved in determining the severity of acne in a given individual. Sebocytes and follicular keratinocytes contain 5α-reductase and 3β- and 17β-hydroxyl-steroid dehydrogenase, which are capable of metabolizing androgens. A significant number of women with acne (25-50%), particularly those with

Figure 669-1 Primarily comedonal acne in a 7 yr old girl.

relatively mild papulopustular acne, note that their acne flares about 1 wk before menstruation.

Freshly formed sebum consists of a mixture of triglycerides, wax esters, squalene, and sterol esters. Normal follicular bacteria produce lipases that hydrolyze sebum triglycerides to free fatty acids. Those of medium-chain length (C8-C14) may be provocative factors in initiating an inflammatory reaction. Sebum also provides a favorable substrate for proliferation of bacteria. *P. acnes* appears to be largely responsible for the formation of free fatty acids. Skin surface *P. acnes* counts do not correlate with the severity of acne. There is a correlation between reduction of *P. acnes* count and improvement in acne vulgaris. It is probable that bacterial proteases, hyaluronidases, and hydrolytic enzymes produce biologically active extracellular materials that increase the permeability of the follicular epithelium. Chemotactic factors released by the intrafollicular bacteria attract neutrophils and monocytes. Lysosomal enzymes from the neutrophils, released in the process of phagocytizing the bacteria, further disrupt the integrity of the follicular wall and intensify the inflammatory reaction.

Clinical Manifestations

Acne vulgaris is characterized by 4 basic types of lesions: open and closed comedones, papules, pustules (Fig. 669-2), and nodulocystic lesions (Fig. 669-3 and Table 669-1). One or more types of lesions may predominate. In its mildest form, which is often seen early in adolescence, lesions are limited to comedones on the central area of the face. Lesions may also involve the chest, upper back, and deltoid areas. A predominance of lesions on the forehead, particularly closed comedones, is often attributable to prolonged use of greasy hair preparations (pomade acne) (Fig. 669-4). Marked involvement on the trunk is most often seen in males. Lesions often heal with temporary postinflammatory erythema and hyperpigmentation. Pitted, atrophic, or hypertrophic scars may be interspersed, depending on the severity, depth, and chronicity of the process. Diagnosis of acne is rarely difficult, although flat warts, folliculitis, and other types of acne (drug induced: glucocorticoid agents, anabolic steroids, gold, dactinomycin, isoniazid, lithium, phenytoin, progestins) may be confused with acne vulgaris. The differential diagnosis includes sarcoidosis, angiofibromas, keratosis pilaris, chloracne, rosacea, and fibrofolliculomas.

Treatment

No evidence shows that early treatment, with the exception of isotretinoin, alters the course of acne. Acne can be controlled and severe scarring prevented by judicious maintenance therapy that is continued until the disease process has abated spontaneously. Therapy must be individualized and aimed at preventing microcomedone formation through reduction of follicular hyperkeratosis, sebum production, the *P. acnes* population in follicular orifices, and free fatty acid production. Initial control takes at least 6-8 wk, depending on the severity of the acne (Table 669-2 and Fig. 669-5). It is also important to address the potentially severe emotional impact of acne on adolescents.

Figure 669-2 Inflammatory papules and pustules.

Table 669-1 Classification of Acne

SEVERITY	DESCRIPTION
Mild	Comedones (noninflammatory lesions) are the main lesions. Papules and pustules may be present but are small and few in number (generally <10).
Moderate	Moderate numbers of papules and pustules (10-40) and comedones (10-40) are present. Mild disease of the trunk may also be present.
Moderately severe	Numerous papules and pustules are present (40-100), usually with many comedones (40-100) and occasional larger, deeper nodular inflamed lesions (up to 5). Widespread affected areas usually involve the face, chest, and back.
Severe	Nodulocystic acne and acne conglobata, with many large, painful nodular or pustular lesions, are present, along with many smaller papules, pustules, and comedones.

From James WD: Clinical practice: acne, N Engl J Med *352:1463–1472, 2005.*

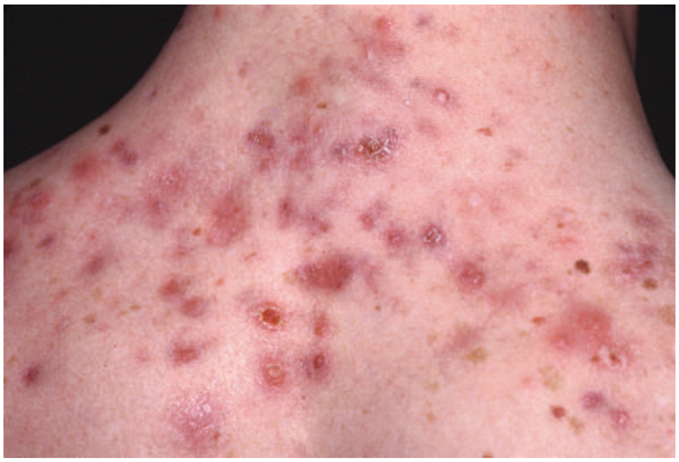

Figure 669-3 Severe nodulocystic acne.

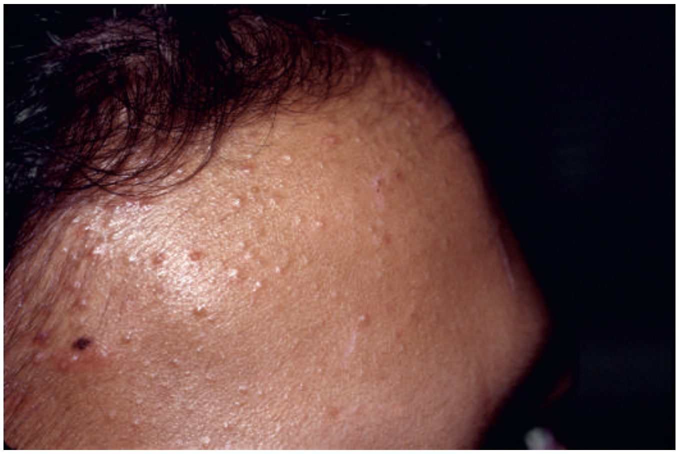

Figure 669-4 Pomade acne along the hairline.

The pediatrician must be aware of the frequently poor correlation between acne severity and psychosocial impact, particularly in adolescents. As adolescents become preoccupied with their appearance, offering treatment even to the youngster whose acne is mild may enhance self-image.

Diet

Little evidence shows that ingestion of particular foods can trigger acne flares. When a patient is convinced that certain dietary items exacerbate acne, it is prudent for the patient to omit those foods.

Climate

Climate appears to influence acne, in that improvement frequently occurs in summer and flares are more common in winter. Remission in summer may relate, in part, to the relative absence of stress. Emotional tension and fatigue seem to exacerbate acne in many individuals; the mechanism is unclear but has been proposed to relate to an increased adrenocortical response.

Table 669-2 Typical Treatment Regimens for Acne
COMEDONAL ACNE Topical retinoid *or* Azelaic acid *or* Salicylic acid
MILD PAPULOPUSTULAR ACNE Topical retinoid *plus* Benzoyl peroxide *or* Benzoyl peroxide/topical antibiotic *or* Benzoyl peroxide/oral antibiotic
SEVERE PAPULOPUSTULAR OR NODULAR ACNE Topical retinoid *plus* Benzoyl peroxide and oral antibiotic *or* Isotretinoin 1 mg/kg/day

Cleansing

Cleansing with soap and water removes surface lipid and renders the skin less oily in appearance, but no evidence shows that surface lipid has a role in generating acne lesions. Only superficial drying and peeling are achieved by cleansing, and almost any mild soap or astringent is adequate. Repetitive cleansing can be harmful because it irritates and chaps the skin. Cleansing agents that contain abrasives and keratolytic agents, such as sulfur, resorcinol, and salicylic acid, may temporarily remove sebum from the skin surface. They exert a mild drying and peeling effect and suppress lesions to a limited degree. They do not prevent microcomedones from forming. No evidence shows that preparations containing alcohol or hexachlorophene decrease acne because surface bacteria are not involved in the pathogenesis. Greasy cosmetic and hair preparations must be discontinued because they exacerbate preexisting acne and cause further plugging of follicular pores. Manipulation and squeezing of facial lesions only ruptures intact lesions and provokes a localized inflammatory reaction.

Topical Therapy

All topical preparations must be used for 6-8 wk before their effectiveness can be assessed. Retinoids may be used alone for mild acne, but combination therapy is frequently more effective. A popular and effective combination is use of benzoyl peroxide gel in the morning and a retinoid at night.

Retinoids. A topical retinoid should be the **primary treatment** for acne vulgaris. Topical retinoids have multiple actions, including inhibition of the formation and number of microcomedones, reduction of mature comedones, reduction of inflammatory lesions, and production of normal desquamation of the follicular epithelium. Retinoids should be applied daily to all the affected areas. The main side effects of retinoids are irritation and dryness. Not all patients initially

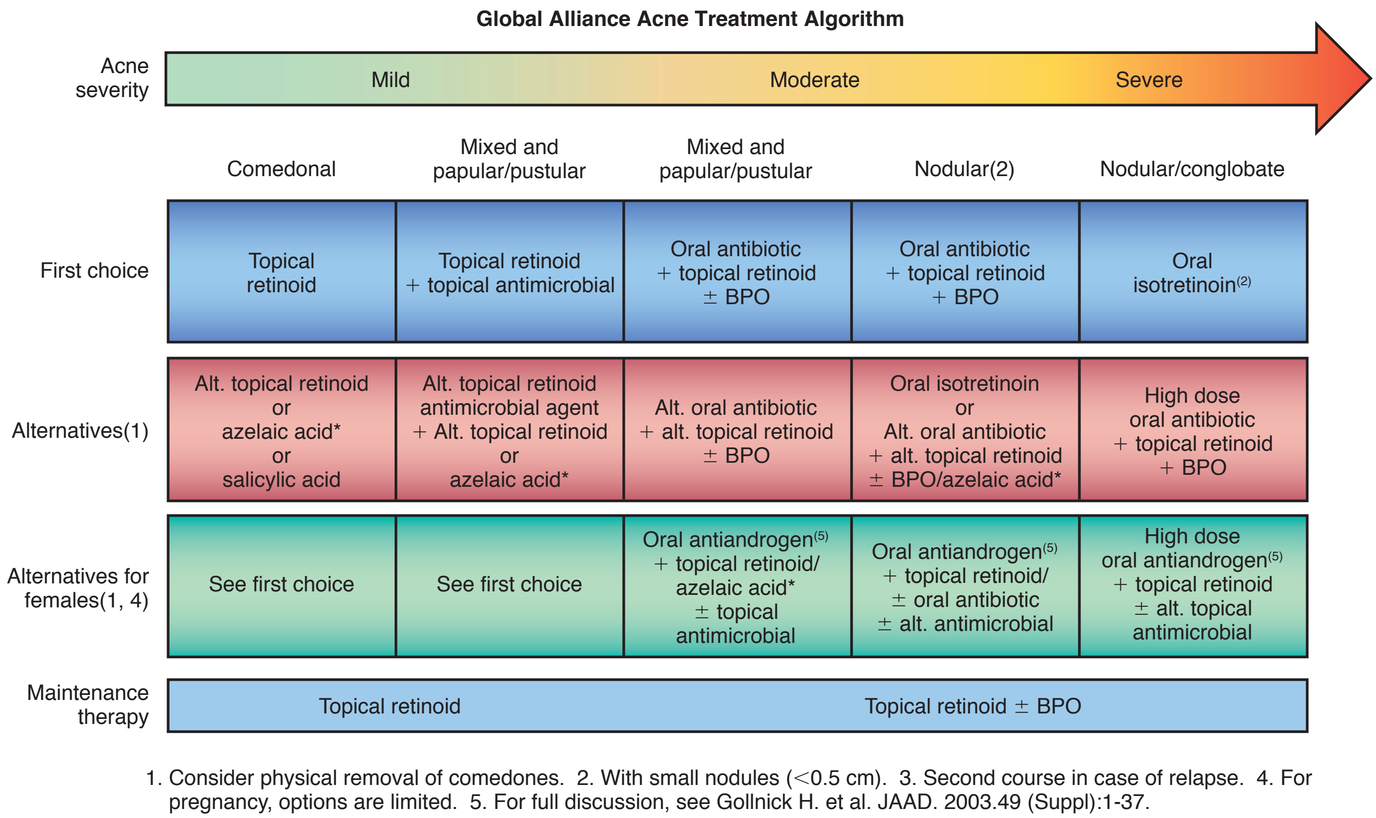

Figure 669-5 Acne treatment algorithm. BPO, benzoyl peroxide. *(From Thiboutot D, Gollnick H; Global Alliance to Improve Acne, et al: New insights into the management of acne: an update from the global alliance to improve outcomes in acne,* J Am Acad Dermatol *60:S1–S50, 2009.)*

tolerate daily use of a retinoid. It is prudent to begin therapy every other or every 3rd day and slowly increase the frequency of application as tolerated. Tretinoin, adapalene, and tazarotene (Table 669-3) are the available retinoids. They vary in strength and efficacy, although adapalene tends to be less irritating and tazarotene is more irritating but may be more effective.

Benzoyl Peroxide. Benzoyl peroxide is primarily an antimicrobial agent. It has an advantage over topical antibiotics in that it does not enhance antimicrobial resistance. It is available in multiple formulations and concentrations. The gel formulations are preferred, owing to better stability and more consistent release of the active ingredient. Washes and cleansers are useful for covering large surface areas such as the chest and back. As with retinoids, the main side effects are irritation and drying. Benzoyl peroxide can also bleach clothing.

Topical Antibiotics. Topical antibiotics are indicated for the treatment of inflammatory acne. Clindamycin is the most commonly used. It is not as effective as oral antibiotics. It should not be used as monotherapy because it does not inhibit microcomedone formation and it has the potential to induce antimicrobial resistance. Irritation and dryness are generally less than with retinoids or benzoyl peroxide. Topical antibiotics are best used as combination products. The most common is benzoyl peroxide/clindamycin. A combination tretinoin/clindamycin product may also be used.

Table 669-3 Medications for the Treatment of Acne

DRUG	DOSE	SIDE EFFECT(S)	OTHER CONSIDERATIONS
TOPICAL AGENTS			
Retinoids			
Tretinoin	Applied once nightly; strengths of 0.025-0.1% available**	Irritation (redness and scaling)	Generics available
Adapalene	Applied once daily, at night or in the morning; 0.01% and 0.3%**	Minimal irritation	0.1% generic available
Tazarotene*	Applied once nightly; 0.05% and 0.1%**	Irritation	Limited data suggest tazarotene more effective than alternatives
Antimicrobials			
Benzoyl peroxide, alone or with zinc, 2.5-10%	Applied once or twice daily	Benzoyl peroxide can bleach clothing and bedding	Available over the counter; 2.5-5% concentrations as effective as and less drying than 10% concentration
Clindamycin, erythromycin†	Applied once or twice daily	Propensity to resistance	Most effective for inflammatory lesions (rather than comedones); resistance a concern when used alone
Combination benzoyl peroxide and clindamycin or erythromycin Combination tretinoin and clindamycin	Applied once or twice daily		Combination more effective than topical antibiotics alone; limits development of resistance; use of individual products in combination less expensive and appears similarly effective
Other Topical Agents			
Azelaic acid, sodium sulfacetamide-sulfur, salicylic acid†	Applied once or twice daily	Well tolerated	Good adjunctive or alternative treatments
ORAL ANTIBIOTICS‡			
Tetracycline§	250-500 mg once or twice daily	Gastrointestinal upset, pseudomotor cerebri	Inexpensive; dosing limited by need to take on empty stomach
Doxycycline§	50-100 mg once or twice daily	Phototoxicity, pseudomotor cerebri, pill esophagitis, gastrointestinal upset	20 mg dose antiinflammatory only; limited data on efficacy
Minocycline§	50-100 mg once or twice daily	Hyperpigmentation of teeth, oral mucosa, and skin; lupus-like reactions with long-term treatment, pseudomotor cerebri, DRESS	
Trimethoprim-sulfamethoxazole	One dose (160 mg trimethoprim, 800 mg sulfamethoxazole) twice daily	Toxic epidermal necrolysis and allergic eruptions	Trimethoprim may be used alone in 300 mg dose twice daily; limited data available
Erythromycin†	250-500 mg twice daily	Gastrointestinal upset	Resistance problematic; consensus is that efficacy is limited
HORMONAL AGENTS¶			
Spironolactone§	50-200 mg in divided doses	Menstrual irregularities, breast tenderness	Higher doses more effective but cause more side effects; best given in combination with oral contraceptives
Estrogen-containing oral contraceptives	Daily	Potential side effects include thromboembolism	

Continued

Table 669-3 Medications for the Treatment of Acne—cont'd

DRUG	DOSE	SIDE EFFECT(S)	OTHER CONSIDERATIONS
ORAL RETINOID			
Isotretinoin[‖] (Accutane)	0.5-1.0 mg/kg/day in divided doses	Birth defects; adherence to pregnancy prevention program outlined by drug manufacturer, including 2 initial negative pregnancy tests, is essential; hypertriglyceridemia, elevated results on liver function tests, abnormal night vision, benign intracranial hypertension, dryness of the lips, ocular, nasal, and oral mucosa and skin, secondary staphylococcal infections, arthralgias, and mood disturbances are possible common or important side effects; laboratory testing of lipid profiles and liver function tests monthly should be performed monthly until dose is stabilized	Relapse rate higher if patient is younger than age 16 yr at initial treatment, if acne is of high severity and involves the trunk, or if drug is used in adult women
Absorica (isotretinoin agent)	0.5-1 mg/kg/day bid	Same as Accutane	Same as Accutane

*Tazarotene is in pregnancy category X: contraindicated in pregnancy.
[†]Clindamycin, erythromycin, and azelaic acid are in pregnancy category B: no evidence of risk in humans.
[‡]Oral antibiotics are indicated for moderate to severe disease; for the treatment of acne on the chest, back, or shoulders; and in patients with inflammatory disease in whom topical combinations have failed or are not tolerated.
[§]This drug is in pregnancy category D: positive evidence of risk in humans.
[¶]Hormonal agents are for use in women only.
[‖]Isotretinoin is in pregnancy category X: contraindicated in pregnancy. It should be used only in patients with severe acne that does not clear with combined oral and topical therapy.
**As cream or gel.
DRESS, drug rash with eosinophilia and systemic symptoms.
Modified from James WD: Clinical practice: acne, N Engl J Med *352:1463–1472, 2005.*

Azelaic Acid. Azelaic acid (20% cream) has mild antimicrobial and keratolytic properties. It can also help expedite resolution of postinflammatory hyperpigmentation.

Systemic Therapy

Antibiotics, especially tetracycline and its derivatives (see Table 669-3), are indicated for treatment of patients whose acne has not responded to topical medications, who have moderate to severe inflammatory papulopustular and nodulocystic acne, and who have a propensity for scarring. Tetracycline and its derivatives act by reducing the growth and metabolism of *P. acnes.* They also have antiinflammatory properties. For most adolescent patients, therapy may be initiated twice daily, for at least 6-8 wk, followed by a gradual decrease to the minimal effective dose. The drugs should always be administered in combination with a topical retinoid and topical benzoyl peroxide, but not topical antibiotics. Tetracycline absorption is inhibited by food, milk, iron supplements,, and calcium-magnesium salts. It should be taken on an empty stomach 1 hr before or 2 hr after meals. Minocycline and doxycycline may be taken with food. Side effects of tetracycline and derivatives are rare. Side effects of tetracycline include vaginal candidosis, particularly in those who take tetracycline concurrently with oral contraceptives; gastrointestinal irritation; phototoxic reactions, including onycholysis and brown discoloration of nails; esophageal ulceration; inhibition of fetal skeletal growth; and staining of growing teeth, precluding its use during pregnancy and in those younger than age 8 yr. Doxycycline is the most photosensitizing of the tetracycline derivatives and is also more likely to cause pill esophagitis. Rarely, minocycline causes dizziness, intracranial hypertension, bluish discoloration of the skin and mucous membranes, hepatitis, a lupus-like syndrome, and drug reaction with eosinophilia and systemic symptoms. A possible complication of prolonged systemic antibiotic use is proliferation of Gram-negative organisms, particularly *Enterobacter, Klebsiella, Escherichia coli,* and *Pseudomonas aeruginosa,* producing severe, refractory folliculitis.

Women who have acne and hormonal abnormalities, whose acne is unresponsive to antibiotic therapy, or who are not candidates for isotretinoin therapy should be considered for a trial of hormonal therapy. Combined oral contraceptive pills are the primary form of hormonal therapy. Spironolactone has also shown effectiveness.

Isotretinoin (13-*cis*-retinoic acid; Accutane) is indicated for severe nodulocystic acne and moderate to severe acne that has not responded to conventional therapy. The recommended dosage is 0.5-1.0 mg/kg/day. A standard course in the United States lasts 16-20 wk. At the end of 1 course of isotretinoin, 70-80% of patients are cured, 10-20% need conventional topical and/or oral medications to maintain adequate control, and 10-20% have relapses and need an additional course of isotretinoin. Dosages <0.5 mg/kg/day, or a cumulative dose of <120 mg/kg, are associated with a significantly higher rate of treatment failure and relapse. If the disease process is not in remission 2 mo after the first course of isotretinoin, a second course should be considered. Isotretinoin reduces size and secretion of sebaceous glands, normalizes follicular keratinization, prevents new microcomedone formation, decreases the population of *P. acnes,* and exerts an antiinflammatory effect.

Isotretinoin use has many side effects. It is highly **teratogenic** and is **absolutely contraindicated** in pregnancy. Pregnancy should be avoided for 6 wk after discontinuation of therapy. Two forms of birth control are required, as are monthly pregnancy tests. *Concerns over cases of pregnancy despite warnings have prompted a manufacturer registration program, iPLEDGE (www.ipledgeprogram.com), which requires physician enrollment and careful patient pregnancy screening to prescribe isotretinoin.* Many patients also experience cheilitis, xerosis, periodic epistaxis, and blepharoconjunctivitis. Increased serum triglyceride and cholesterol levels are also common. It is important to rule out

Icepick (V)	Rolling (U)	Boxcar (M)	Keloids	Hypertrophic
Punch excision (deep bases) Elevation and grafting Laser resurfacing/ dermabrasion (many scars close together) Spot TCA peel	**Combined therapy** Micrograft and subcision + ± filler Resurfacing microdermabrasion Deep-spot TCA peel	**Shallow** ≤3 mm diameter-laser skin resurfacing >3 mm diameter-laser skin resurfacing ± punch elevation **Deep** ≤3 mm diameter-punch excision >3 mm diameter-punch excision or punch elevation Fractional thermolysis (deep or shallow) Dermabrasion CO_2 laser resurfacing	Intralesional corticosteroids Intralesional 5-FU Intralesional bleomycin Compression Imiquimod after intralesional excision Cryotherapy Pulsed-dye laser Excision + electrotherapy	Intralesional steroids Intralesional 5-FU Vascular laser Intralesional bleomycin Compression Imiquimod after intralesional excision
Adjunctive treatment: Topical retinoids 2 weeks prior to and following treatment, sunscreens, moisturizers				

Non-ablative lasers for mild disease; ablative and fractional lasers for moderate scarring

Figure 669-6 Treatment options for acne scars. CO_2, carbon dioxide; FU, fluorouracil; TCA, trichloroacetic acid. *(From Thiboutot D, Gollnick H; Global Alliance to Improve Acne, et al: New insights into the management of acne: an update from the global alliance to improve outcomes in acne,* J Am Acad Dermatol *60:S1–S50, 2009.)*

preexisting liver disease and hyperlipidemia before initiating therapy and to recheck laboratory values 4 wk after commencement of therapy. Less common but significant side effects include arthralgias, myalgias, temporary thinning of the hair, paronychia, increased susceptibility to sunburn, formation of pyogenic granulomas, and colonization of the skin with *Staphylococcus aureus,* leading to impetigo, secondarily infected dermatitis, and scalp folliculitis. Rarely, hyperostotic lesions of the spine develop after more than 1 course of isotretinoin. Concomitant use of tetracycline and isotretinoin is contraindicated because either drug, but particularly when they are used together, can cause benign intracranial hypertension. Although no cause-and-effect relationship has been established, drug-induced mood changes and depression and/or suicide have mandated close attention to psychiatric well-being before and during isotretinoin prescription.

Surgical Therapy

Intralesional injection of low-dose (3-5 mg/mL) mid-potency glucocorticoids (e.g., triamcinolone) with a 30-gauge needle on a tuberculin syringe may hasten the healing of individual, painful nodulocystic lesions. Dermabrasion or laser peel to minimize scarring should be considered only after the active process is quiescent. Figure 669-6 describes the management of scarring.

The role of pulsed-dye laser in the treatment of inflammatory acne is controversial and inconclusive.

DRUG-INDUCED ACNE

Pubertal and postpubertal patients who are receiving systemic corticosteroid therapy are predisposed to steroid-induced acne. This monomorphous folliculitis occurs primarily on the face, neck, chest (Fig. 669-7), shoulders, upper back, arms, and, rarely, on the scalp. Onset follows the initiation of steroid therapy by approximately 2 wk. The lesions are small, erythematous papules or pustules that may erupt in profusion and are all in the same stage of development. Comedones may occur subsequently, but nodulocystic lesions and scarring are rare. Pruritus is occasional. Although steroid acne is relatively refractory if the medication is continued, the eruption may respond to use of tretinoin and a benzoyl peroxide gel.

Figure 669-7 Monomorphous papular eruption of steroid acne.

Other **drugs** that can induce **acneiform lesions** in susceptible individuals include isoniazid, phenytoin, phenobarbital, trimethadione, lithium carbonate, androgens (anabolic steroids), and vitamin B_{12}.

HALOGEN ACNE

Administration of medications containing iodides or bromides or, rarely, ingestion of massive amounts of vitamin–mineral preparations or iodine-containing "health foods" such as kelp may induce halogen acne. The lesions are often very inflammatory. Discontinuation of the provocative agent and appropriate topical preparations usually achieve reasonable therapeutic results.

CHLORACNE

Chloracne is a result of external contact with, inhalation of, or ingestion of halogenated aromatic hydrocarbons, including polyhalogenated biphenyls, polyhalogenated naphthalenes, and dioxins. Lesions are primarily comedonal. Inflammatory lesions are infrequent but may include papules, pustules, nodules, and cysts. Healing occurs with atrophic or hypertrophic scarring. The face, postauricular regions, neck, axillae, genitals, and chest are most commonly involved. The nose is often spared. In cases of severe exposure, associated findings may include hepatitis, production of porphyrins, bulla formation on sun-exposed skin, hyperpigmentation, hypertrichosis, and palmar and plantar hyperhidrosis. Topical or oral retinoids may be effective; benzoyl peroxide and antibiotics are generally ineffective.

NEONATAL ACNE

Approximately 20% of normal neonates demonstrate acne in the 1st mo of life. Small inflammatory papules and pustules predominate on the cheeks and forehead (Fig. 669-8); comedones are absent. The cause of neonatal acne is unknown but it has been theorized that it may be an inflammatory reaction to *Pityrosporum* species rather than true acne; therefore, the term neonatal cephalic pustulosis has been proposed. Other theories include placental transfer of maternal androgens, hyperactive neonatal adrenal glands, and a hypersensitive neonatal end-organ response to androgenic hormones. The eruption involutes spontaneously over a few months. **Treatment** is usually unnecessary. If desired, the lesions can be treated effectively with topical antifungals, and/or benzoyl peroxide.

INFANTILE ACNE

Infantile acne usually manifests between 3 mo and 2 yr of age, more commonly in boys than in girls. Acne lesions are more numerous, pleomorphic, severe, and persistent than in neonatal acne (Fig. 669-9). Open and closed comedones predominate on the face. Papules and pustules occur frequently, but only occasionally do nodulocystic lesions develop. Pitted scarring is seen in 10-15%. The course may be relatively brief, or the lesions may persist for many months or years, although the eruption generally resolves by age 4 yr. Use of topical benzoyl peroxide gel and tretinoin usually clears the eruption within a few weeks. Oral erythromycin is occasionally necessary. A child with refractory acne warrants a search for an abnormal source of androgens, such as a virilizing tumor or congenital adrenal hyperplasia.

TROPICAL ACNE

A severe form of acne occurs in tropical climates and is believed to be caused by the intense heat and humidity. Hydration of the pilosebaceous duct pore may accentuate blockage of the duct. Affected individuals tend to have an antecedent history of adolescent acne that is quiescent at the time of the eruption. Lesions occur mainly on the entire back, chest, buttocks, and thighs, with a predominance of suppurating papules and nodules. Secondary infection with *S. aureus* may be a complication. The eruption is refractory to acne therapy if the environmental factors are not eliminated.

ACNE CONGLOBATA

Acne conglobata is a chronic progressive inflammatory disease that occurs mainly in men, and more commonly in white than in black individuals, but it may begin during adolescence. Patients usually have a history of preexisting acne vulgaris. The principal lesion is the nodule, although there is often a mixture of comedones with multiple pores, papules, pustules, nodules, cysts, abscesses, and subcutaneous dissection with formation of multichanneled sinus tracts. Severe scarring is characteristic. The face is relatively spared, but in addition to the back and chest, the buttocks, abdomen, arms, and thighs may be involved. Constitutional symptoms and anemia may accompany the inflammatory process. Coagulase-positive staphylococci and β-hemolytic streptococci are frequently cultured from lesions but do not appear to be primarily involved in the pathogenesis. Acne conglobata occasionally occurs in association with hidradenitis suppurativa and dissecting cellulitis of the scalp (as the follicular occlusion triad) and may be complicated by erosive arthritis and ankylosing spondyloarthritis. Endocrinologic studies are not revealing. Routine acne therapy is generally ineffective. Systemic therapy with a corticosteroid may be required to suppress the intense inflammatory activity. Isotretinoin is the most effective form of therapy for some patients but may produce a flare after its initiation.

ACNE FULMINANS (ACUTE FEBRILE ULCERATIVE ACNE)

Acne fulminans is characterized by abrupt onset of extensive inflammatory, tender ulcerative acneiform lesions on the back and chest of male teenagers. The distinctive feature is the tendency for large nodules to form exudative, necrotic, ulcerated, crusted plaques. Lesions often spare the face and heal with scarring. A preceding history of mild papulopustular or nodular acne is noted in most patients. Constitutional symptoms and signs are common, including fever, debilitation, arthralgias, myalgias, weight loss, and leukocytosis. Blood cultures are sterile. Lesions of **erythema nodosum** sometimes develop on the shins. **Osteolytic bone** lesions may develop in the clavicle, sternum, and epiphyseal growth plates; affected bones appear normal or have slight sclerosis or thickening on healing. Salicylates may be helpful for the myalgias, arthralgias, and fever. Corticosteroids (1 mg/kg of

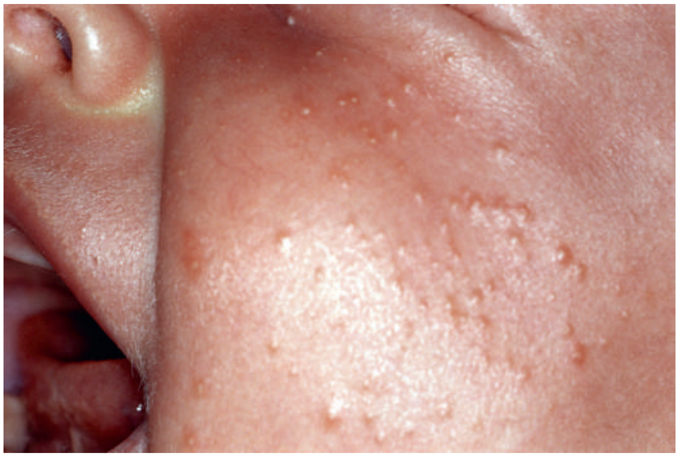

Figure 669-8 Comedonal acne in a neonate.

Figure 669-9 Inflammatory infantile acne.

prednisone) are started first. Then 1 wk later, isotretinoin (0.5-1.0 mg/kg) is added. Dapsone may be effective if isotretinoin cannot be used. The corticosteroid dosage is tapered over approximately 6 wk. Antibiotics are not indicated unless there is evidence of secondary infection. Compared with acne conglobata, acne fulminans occurs in younger patients, is more explosive in onset, more commonly has associated constitutional symptoms and ulcerated crusted lesions, and less commonly has multiheaded comedones or involves the face.

EPIDERMAL INCLUSION CYST (EPIDERMOID CYST)

Epidermoid cysts are the nodules most commonly seen in children. Such a cyst is a sharply circumscribed, dome-shaped, firm, freely movable, skin-colored nodule (Fig. 670-1) often with a central dimple or punctum that is a plugged, dilated pore of a pilosebaceous follicle. Epidermoid cysts form most frequently on the face, neck, chest, or upper back and may periodically become inflamed and infected secondarily, particularly in association with acne vulgaris. The cyst wall may also rupture and induce an inflammatory reaction in the dermis. The wall of the cyst is derived from the follicular infundibulum. A mass of layered keratinized material that may have a cheesy consistency fills the cavity. Epidermoid cysts may arise from occlusion of pilosebaceous follicles, from implantation of epidermal cells into the dermis as a result of an injury that penetrates the epidermis, and from rests of epidermal cells. Multiple epidermoid cysts may be present in Gardner syndrome and the nevoid basal cell carcinoma syndrome. Excision of the cysts with removal of the entire sac and its contents is indicated, particularly if the cyst becomes recurrently infected. A fluctuant, infected cyst should be treated with antibiotics or intralesional corticosteroids. After the inflammation subsides, the cyst should be removed.

MILIUM

Milium is a 1-2 mm, firm, pearly white or yellowish, subepidermal keratin cyst. Milia in newborns is discussed in Chapter 647. Secondary milia occur in association with subepidermal blistering diseases, after dermabrasion or other injury to the skin. They are retention cysts caused by hyperproliferation of injured epithelium and are indistinguishable histopathologically from primary milia. Those that develop after blistering usually arise from the eccrine sweat duct, but they may develop from the hair follicle, sebaceous duct, or epidermis. A milium body differs from an epidermoid cyst only in its small size and superficial location.

FIBROFOLLICULOMAS

These lesions usually appear in late adolescents or in young adults and are characterized by multiple dome-shaped clear-white papules appearing on the nose, cheeks, and neck, and at times the trunk or ears (Fig. 670-2). They are associated with the familial cancer syndrome of Birt-Hogg-Dubé, an autosomal dominant disorder that results from a mutation in the folliculin *(FLCN)* gene. Associated features include pulmonary cysts, pneumothorax, renal cell carcinoma, and other benign or malignant tumors.

PILAR CYST (TRICHILEMMAL CYST)

Pilar cyst may be clinically indistinguishable from an epidermoid cyst. It manifests as a smooth, firm, mobile nodule, predominantly on the scalp (Fig. 670-3). Pilar cysts occasionally develop on the face, neck, or trunk. A cyst may become inflamed and may occasionally suppurate and ulcerate. The cyst wall is composed of epithelial cells with indistinct intercellular bridges. The peripheral cell layer of the wall shows a palisade arrangement, which is not seen in an epidermoid cyst. No granular layer is present. The cyst cavity contains homogeneous eosinophilic keratinous material, and foci of calcification are seen in 25% of cases. The propensity for development of pilar cysts may be inherited in an autosomal dominant manner. More than one cyst generally develops in a patient. Numerous pilar and epidermoid cysts, desmoid tumors, fibromas, lipomas, or osteomas may be associated with colonic polyposis or adenocarcinoma in Gardner syndrome. Pilar cysts shell out easily from the dermis.

PILOMATRICOMA

The second most common nodule seen in children, pilomatricoma is a benign tumor that manifests as a 3-30 mm, firm, solitary, deep dermal or subcutaneous tumor on the head, neck, or upper extremities. The overlying epidermis is usually normal. The tumor may occasionally be located more superficially, however, tinting the overlying skin

Figure 670-1 Flesh-colored cyst on the forehead.

Figure 670-2 Multiple, dome-shaped, whitish papules on the nose and cheeks in a 31 yr old carrier of an *FLCN* mutation. *(From Menko FH, van Steensel MAM, Giraud S, et al: Birt-Hogg-Dubé syndrome: diagnosis and management.* Lancet *10:1199–1206, 2009, Fig. 1.)*

blue-red (Fig. 670-4). Multiple pilomatricomas are seen in myotonic dystrophy, Gardner syndrome, Rubinstein-Taybi syndrome, and Turner syndrome. In general, however, pilomatricomas are not hereditary. Histopathologically, irregularly shaped islands of epithelial cells are embedded in a cellular stroma. Calcium deposits are found in 75% of tumors. Pilomatricomas are caused by mutations in β-catenin.

TRICHOEPITHELIOMA

A 2-8 mm, smooth, round, firm, skin-colored papule, trichoepithelioma is derived from an immature hair follicle. Trichoepitheliomas generally occur singly on the face in childhood or early adulthood. Multiple trichoepitheliomas are inherited autosomal dominantly (type 1: *CYLD* gene; type 2: 9p21 gene currently unidentified), appear in childhood or at puberty, and gradually increase in number on the nasofacial folds, nose, forehead, and upper lip and, occasionally, on the scalp, neck, and upper trunk. Microscopically, these benign tumors are characterized by horn cysts composed of a fully keratinized center surrounded by basophilic cells in an adenoid network. Topical imiquimod therapy may be beneficial. Surgical excision is the only other therapy.

ERUPTIVE VELLUS HAIR CYSTS

Eruptive vellus hair cysts are 1-3 mm, asymptomatic, soft, skin-colored follicular papules on the central chest (Fig. 670-5). They may become crusted or umbilicated. Abnormal vellus hair follicles become occluded at the level of the infundibulum, resulting in retention of hairs within an epithelium-lined cystic dilation of the proximal part of the follicle. Most cases are chronic, but spontaneous regression has been reported.

Figure 670-3 Pilar cyst of the anterior scalp.

Figure 670-4 Pilomatricoma. Firm tumor with overlying bluish discoloration of the skin.

STEATOCYSTOMA MULTIPLEX

An autosomal dominant (*KRT17* gene) condition, steatocystoma multiplex usually manifests in adolescence or early adulthood as numerous soft to firm cystic nodules that are adherent to the underlying skin and are 3 mm to 3 cm in diameter. When punctured, the cysts may drain oily or cheesy material. Sites of predilection include the sternal region, axillae, arms, and scrotal skin. The multiply folded cyst wall is lined on the luminal side with a thick, homogeneous, eosinophilic horny layer and lacks a granular layer. Flattened sebaceous gland lobules are often visible in the cyst wall, and lanugo hairs may be present in the cystic cavity.

SYRINGOMA

The benign tumors known as syringomas are soft, small, skin-colored or yellowish brown papules that develop on the face, particularly in the periorbital regions (Fig. 670-6). Other sites of predilection include the axillae and umbilical and pubic areas. They often develop during puberty and are more frequent in females. Eruptive syringomas develop in crops over the anterior trunk during childhood or adolescence. A

Figure 670-5 Eruptive vellus hair cysts. Multiple papules on the chest.

Figure 670-6 Syringomas. Multiple yellow papules near the eye.

syringoma is derived from an intraepidermal sweat gland duct. Syringomas are of cosmetic significance only. Sparse lesions may be excised, but they are often too numerous to remove.

INFANTILE DIGITAL FIBROMA

Infantile digital fibroma is a smooth, firm, erythematous or skin-colored nodule on the dorsal or lateral surface of a distal phalanx of a finger or toe. More than 80% of tumors occur in infancy. They may be present at birth. Lesions may be solitary or multiple and may manifest as "kissing" tumors on opposing digits. They are usually asymptomatic, but flexion deformity of the digits may occur. Clinically, the lesion resembles a fibroma, leiomyoma, angiofibroma, acquired digital fibrokeratoma, accessory digit, or mucous cyst. The diagnosis is confirmed by the finding of numerous spindle-shaped fibroblasts that contain small, round, dense, eosinophilic cytoplasmic inclusion bodies composed of collections of actin microfilaments. Local recurrence after simple excision of this tumor has been reported in 75% of patients. Because the tumor does not metastasize and may regress spontaneously in 2-3 yr, a course of expectant observation is advised. If functional impairment or flexion deformity of the digit becomes apparent, prompt full excision of the tumor is indicated.

DERMATOFIBROMA (HISTIOCYTOMA)

A benign dermal tumor, dermatofibroma may be pedunculated, nodular (Fig. 670-7), or flat and is usually well circumscribed and firm but occasionally feels soft on palpation. The overlying skin is usually hyperpigmented, may be shiny or keratotic, and dimples when the tumor is pinched. Dermatofibromas range in size from 0.5-10.0 mm, arise most frequently on the limbs, and are usually asymptomatic but may occasionally be pruritic. They are composed of fibroblasts, young and mature collagen, capillaries, and histiocytes in varying proportions, forming a nodule in the dermis that has poorly defined edges. The cause of these tumors is unknown, but trauma such as an insect bite or folliculitis appears to induce reactive fibroplasia. The differential diagnosis includes epidermal inclusion cyst, juvenile xanthogranuloma, hypertrophic scar, and neurofibroma. Dermatofibromas may be excised or left intact, according to the patient's preference. They usually persist indefinitely.

JUVENILE XANTHOGRANULOMA

A firm, dome-shaped, yellow, pink, or orange papule or nodule (Fig. 670-8), juvenile xanthogranuloma varies from 5 mm to approximately 4 cm in diameter. The average age at onset is 2 yr. These nodules are 10 times more common in white than in African-American individuals. Sites of predilection are the scalp, face, and upper trunk, where they may erupt in profusion or remain as solitary lesions. Nodular lesions may appear on the oral mucosa. Mature lesions are characterized histopathologically by a dermal infiltrate of lipid-laden histiocytes, admixed inflammatory cells, and Touton giant cells. The lesions may clinically resemble papulonodular urticaria pigmentosa, dermatofibromas, or xanthomas of hyperlipoproteinemia, but can be distinguished from these entities histopathologically.

Affected infants are nearly always otherwise normal, and blood lipid values are not elevated. Café-au-lait macules are found on 20% of patients with juvenile xanthogranuloma. Xanthogranulomatous infiltrates occur occasionally in ocular tissues. This process may result in glaucoma, hyphema, uveitis, heterochromia iridis, iritis, or sudden proptosis. Age less than 2 yr, multiple lesions, and periocular location may heighten concerns for intraocular involvement. There appears to be an association among juvenile xanthogranuloma, neurofibromatosis, and childhood leukemia, most frequently juvenile chronic myelogenous leukemia. There is no need to remove the benign lesions of juvenile xanthogranuloma because most of them regress spontaneously in the 1st few yr. Residual pigmentation and atrophy may result.

LIPOMA

A benign collection of fatty tissue, lipoma appears on the trunk, neck, or proximal portions of the limbs. Lipomas are soft, compressible, lobulated, subcutaneous masses. Multiple lesions may occur occasionally, as in Gardner syndrome. Atrophy, calcification, liquefaction, or xanthomatous change may sometimes complicate their course. A lipoma is composed of normal fat cells surrounded by a thin connective tissue capsule. Lipomas represent a cosmetic defect and may be surgically excised. Multiple lipomas, identical to those that occur singly, are inherited in an autosomal dominant fashion and often appear by the 3rd decade in patients with familial multiple lipomatosis. Lipomas may appear intraabdominally, intramuscularly, and subcutaneously. Congenital lipomatosis manifests in the 1st few mo of life as large subcutaneous fatty masses on the chest, with extension into skeletal muscle. Congenital lipomatosis can also be a manifestation of Proteus syndrome (overgrowth/hyperplasia skin, connective tissue, mutation in *AKT1*). Angiolipomas usually manifest as numerous painful subcutaneous nodules on the arms and trunk.

CLOVES syndrome (congenital lipomatous overgrowth, vascular malformations, epidermal nevi, and scoliosis/skeletal-spinal anomalies) is usually a sporadic disorder with an asymmetric truncal lipomatous mass present at birth. Additional features include macrodactyly, vascular malformations (low flow), linear epidermal nevus and renal anomalies. The differential diagnosis includes Proteus, Klippel-Trenaunay, and Bannayan-Riley-Ruvalcaba syndrome.

BASAL CELL CARCINOMA

Basal cell carcinoma is very rare in children in the absence of a predisposing condition, such as nevoid basal cell carcinoma syndrome, xeroderma pigmentosum, nevus sebaceus of Jadassohn, arsenic intake, or exposure to irradiation. The lesions are smooth, pearly, pink, telangiectatic papules that enlarge slowly and may bleed or ulcerate. Sites of predilection are the face, scalp, and upper back. The differential

Figure 670-7 Dermatofibroma. Red-brown nodular variant.

Figure 670-8 Juvenile xanthogranuloma. Solitary orange papule.

diagnosis includes pyogenic granuloma, nevocellular nevus, epidermal inclusion cyst, closed comedo, dermatofibroma, and adnexal tumor. Depending on the site of occurrence and associated disease of the host, electrodesiccation and curettage or simple excision of basal cell epithelioma is usually curative. When the tumor is recurrent, >2 cm in diameter, located on problematic anatomic areas such as the midface or ears, or is an aggressive histopathologic type, Mohs microscopically controlled surgery may be the most appropriate treatment.

NEVOID BASAL CELL CARCINOMA SYNDROME (BASAL CELL NEVUS SYNDROME, GORLIN SYNDROME)

The autosomal dominant entity known as nevoid basal cell carcinoma syndrome is caused by mutations in the *PTCH1* and *PTCH2* ("patched") genes. These tumor-suppressor genes, part of the hedgehog signaling pathway, are important in determining embryonic patterning and cell fate in a number of structures in the developing embryo. Mutations in human patched genes produce dysregulation of several genes involved in organogenesis and carcinogenesis. Consequently, the syndrome includes a wide spectrum of defects involving the skin, eyes, central nervous and endocrine systems, and bones. The predominant features are early-onset basal cell carcinomas and mandibular cysts. Approximately 20% of those in whom a basal cell carcinoma develops before age 19 yr have this syndrome. Basal cell carcinomas appear between puberty and age 35 yr, erupting in crops of tumors that vary in size, color, and number, and may be difficult to distinguish from other types of skin lesions. Sites of predilection are the periorbital skin, nose, malar areas, and upper lip, but the lesions can develop on the trunk and limbs and are not restricted to sun-exposed areas. Ulceration, bleeding, crusting, and local invasion can occur. Small milia, epidermal cysts, pigmented lesions, hirsutism, and palmar and plantar pits are additional cutaneous findings.

The facies of patients with this syndrome are characterized by temporoparietal bossing, prominent supraorbital ridges, a broad nasal root, ocular hypertelorism or dystopia canthorum, and prognathism. Keratinized cysts (odontogenic keratocysts) in the maxilla and mandible occur in most patients. They range in size from a few millimeters to several centimeters, may result in maldevelopment of the teeth, and cause pain, swelling of the jaw, facial deformity, bone erosion, pathologic fractures, and suppurating sinus tracts. Osseous defects such as anomalous rib development, spina bifida, kyphoscoliosis, and brachymetacarpalism occur in 60% of patients, and ocular abnormalities including cataracts, glaucoma, coloboma, strabismus, and blindness occur in approximately 25%. Some males have hypogonadism, and the testes are absent or undescended. Kidney malformations have also been reported. Neurologic manifestations include calcification of the falx, seizures, mental retardation, partial agenesis of the corpus callosum, hydrocephalus, and nerve deafness. The incidence of medulloblastoma, ameloblastoma of the oral cavity, fibrosarcoma of the jaw, teratoma, cystadenoma, cardiac fibroma, ovarian fibroma, and fetal onset rhabdomyoma is higher in patients with nevoid basal cell carcinoma syndrome.

Treatment of these patients requires the participation of various specialists according to individual clinical problems. Basal cell carcinomas should not be treated with irradiation. Most of the basal cell carcinomas have a clinically benign course, and it is often impossible to remove them all. Those with an aggressive growth pattern and those on the central areas of the face, however, should be removed promptly. Treatment options include surgery, Mohs micrographic surgery, laser ablation, cryotherapy, photodynamic therapy, topical 5% imiquimod and oral retinoids (0.5-1.0 mg/kg/day). Vismodegib, which inhibits smoothened protein in the hedgehog pathway, is a targeted therapy available for unresectable basal cell carcinomas. Genetic counseling is also indicated.

MUCOSAL NEUROMA SYNDROME (MULTIPLE ENDOCRINE NEOPLASIA TYPE IIB)

Mucosal neuroma syndrome, an autosomal dominant trait, is characterized by an asthenic or marfanoid habitus with scoliosis, pectus excavatum, pes cavus, and muscular hypotonia. The syndrome is caused by mutations in the tyrosine kinase domain of the *RET* gene. Patients have thick, patulous lips and soft-tissue prognathism simulating acromegaly. Multiple mucosal neuromas or neurofibromas appear as pink, pedunculated or sessile nodules on the anterior third of the tongue, at the commissures of the lips, and on the buccal mucosa and palpebral conjunctiva. Various ophthalmologic defects and intestinal ganglioneuromatosis with recurrent diarrhea are additional common findings. There is a high incidence of medullary thyroid carcinoma in association with high calcitonin levels, pheochromocytoma, and hyperparathyroidism in patients with this syndrome. Periodic screening tests for the associated malignant tumors are mandatory.

Chapter 671

Nutritional Dermatoses

Joel C. Joyce

ACRODERMATITIS ENTEROPATHICA

Acrodermatitis enteropathica is a rare autosomal recessive disorder caused by an inability to absorb sufficient zinc from the diet. The genetic defect is in the intestinal zinc-specific transporter gene *SLC39A4*. Initial signs and symptoms usually occur in the 1st few mo of life, often after weaning from breast milk to cow's milk. The cutaneous eruption consists of vesiculobullous, eczematous, dry, scaly, or psoriasiform skin lesions symmetrically distributed in the perioral, acral, and perineal areas (Fig. 671-1) and on the cheeks, knees, and elbows (Fig. 671-2). The hair often has a peculiar, reddish tint, and alopecia of some degree is characteristic. Ocular manifestations include photophobia, conjunctivitis, blepharitis, and corneal dystrophy detectable by slit-lamp examination. Associated manifestations include chronic diarrhea, stomatitis, glossitis, paronychia, nail dystrophy, growth retardation, irritability, delayed wound healing, intercurrent bacterial infections, and superinfection with *Candida albicans*. Lymphocyte function and free radical scavenging are impaired. Without treatment, the course is chronic and intermittent but often relentlessly progressive. When the disease is less severe, only growth retardation and delayed development may be apparent.

The **diagnosis** is established by the constellation of clinical findings and detection of a low plasma zinc concentration. A serum zinc level less than 50 µg/dL is suggestive, but not diagnostic, of acrodermatitis enteropathica. Levels of alkaline phosphatase, a zinc-dependent enzyme, may also be decreased. Histopathologic changes in the skin are nonspecific and include parakeratosis and pallor of the upper epidermis. The variety of manifestations of the syndrome may be because zinc has a role in numerous metabolic pathways, including those of copper, protein, essential fatty acids, and prostaglandins, and that zinc is incorporated into many zinc metalloenzymes.

Oral **therapy** with zinc compounds is the treatment of choice. Replacement for individuals with inherited acrodermatitis enteropathica is with 3 mg/kg/24 hr of elemental zinc found in zinc sulfate, gluconate, or acetate (i.e., 220 mg of zinc sulfate contains 50 mg of elemental zinc). Zinc gluconate carries less risk of gastrointestinal distress. Plasma zinc levels should be monitored every 3-6 mo, however, to individualize the dosage. Zinc therapy rapidly abolishes the manifestations of the disease. A syndrome resembling acrodermatitis enteropathica has been observed in patients with secondary zinc deficiency resulting from long-term total parenteral nutrition without

Figure 671-1 **A,** Periorificial eruption. **B,** Diaper rash. The skin findings are typical of zinc deficiency, in this case caused by low levels of zinc in breast milk. *(From Eichenfield LF, Frieden IJ, Esterly NB:* Textbook of neonatal dermatology, *Philadelphia, 2001, WB Saunders, Fig. 14-14.)*

supplemental zinc or to chronic malabsorption syndromes. A rash similar to that of acrodermatitis enteropathica has also been reported in infants fed breast milk that is low in zinc and in those with maple syrup urine disease, organic aciduria, methylmalonic acidemia, biotinidase deficiency, essential fatty acid deficiency, severe protein malnutrition (kwashiorkor), and cystic fibrosis. For those individuals with acquired zinc deficiency, oral replacement with 0.5-1.0 mg/kg/24 hr of elemental zinc should be undertaken and the cause of underlying malnutrition should be addressed.

ESSENTIAL FATTY ACID DEFICIENCY

Essential fatty acid deficiency causes a generalized, scaly dermatitis composed of thickened, erythematous, desquamating plaques. Individuals may also show failure-to-thrive, growth retardation, alopecia, thrombocytopenia, and poor wound healing. The eruption has been induced experimentally in animals fed a fat-free diet and has been observed in patients with chronic severe malabsorption, such as in short-gut syndrome, and in those sustained on a fat-free diet or fat-free parenteral alimentation. Linoleic acid (18 : 2 n-6) and arachidonic acid (20 : 4 n-6) are deficient, and an abnormal metabolite, 5,8,11-eicosatrienoic acid (20 : 3 n-9), is present in the plasma. Alterations in the triene : tetraene ratio are diagnostic (arachidonic acid : eicosatrienoic acid ratio greater than 0.4 or linoleic acid : arachidonic acid ratio greater than 2.3). The horny layer of the skin contains microscopic cracks, the barrier function of the skin is disturbed, and transepidermal water loss is increased. Topical application of linoleic acid, which is present in sunflower seed and safflower oils, may ameliorate the clinical and biochemical skin manifestations. Oral and/or parenteral therapy can also be considered. Appropriate nutrition should be provided.

KWASHIORKOR

Severe protein and essential amino acid deprivation in association with adequate caloric intake can lead to kwashiorkor, particularly at the time of weaning to a diet that consists primarily of corn, rice (or rice milk), or beans (see Chapter 46). Children can be fed such a restricted diet for cultural reasons or because of misdiagnosis on the part of the child's parents or healthcare providers of perceived food allergies. Diffuse fine reddish brown scaling (enamel/flaky paint sign) is the classic cutaneous finding. In severe cases, erosions and linear fissures

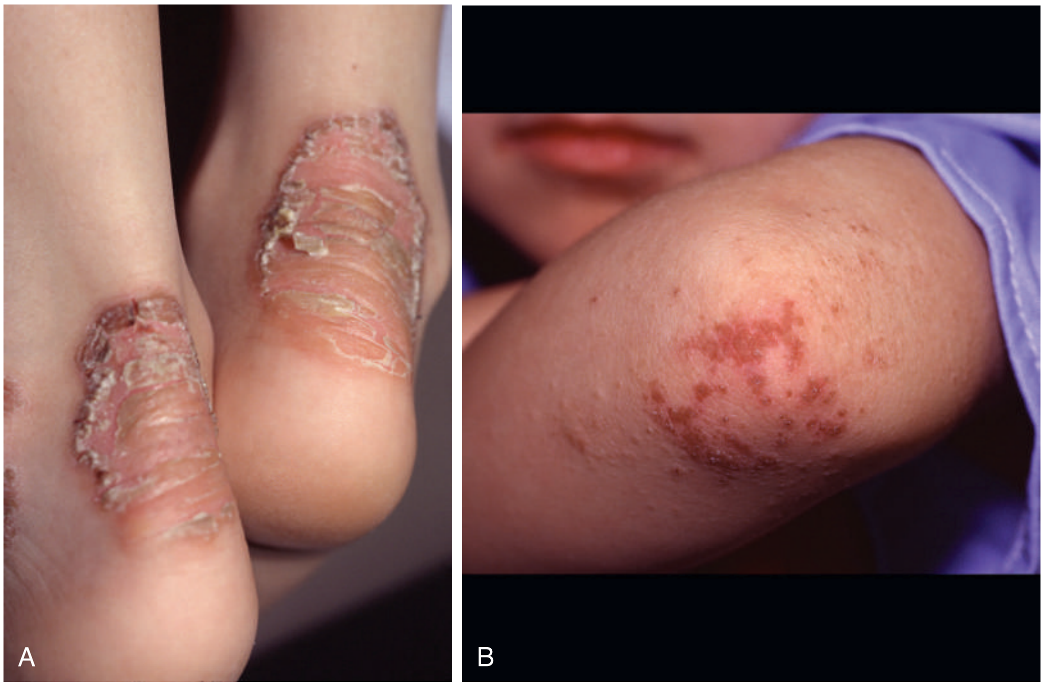

Figure 671-2 **A,** Psoriasiform lesion of zinc deficiency dermatitis on the ankles. **B,** Similar lesions on the elbows.

Figure 671-3 Erosions and scaling in kwashiorkor.

develop (Fig. 671-3). Nails are thin and soft, and hair is sparse, thin, and depigmented, sometimes displaying a "flag sign" consisting of alternating light and dark bands that reflect alternating periods of adequate and inadequate nutrition. The cutaneous manifestations may closely resemble those of acrodermatitis enteropathica, however; edema of the extremities and face ("moon facies") and a protuberant abdomen ("pot belly") are key features uniformly observed in kwashiorkor. The serum zinc level is often deficient, and in some cases, skin lesions of kwashiorkor heal more rapidly when zinc is applied topically.

CYSTIC FIBROSIS

See Chapter 403.

Protein-calorie malnutrition develops in 5-10% of patients with cystic fibrosis. Rash in infants with cystic fibrosis and malnutrition is rare but may appear by age 6 mo. The initial eruption consists of scaling, erythematous papules and progresses in 1-3 mo to extensive desquamating plaques. The rash is accentuated around the mouth and perineum and on the extremities (lower > upper). Alopecia may be present, but mucous membranes and nails are uninvolved.

PELLAGRA

See Chapter 49.

Pellagra manifests as edema, erythema, and burning of sun-exposed skin on the face, neck, and dorsal aspects of the hands, forearms, and feet. Lesions of pellagra may also be provoked by burns, pressure, friction, and inflammation. The eruption on the face frequently follows a butterfly distribution, and the dermatitis encircling the neck has been termed "Casal's necklace." Blisters and scales develop, and the skin increasingly becomes dry, rough, thickened, cracked, and hyperpigmented. Skin infections may be unusually severe. Pellagra develops in patients with insufficient dietary intake or malabsorption of niacin and/or tryptophan. Administration of isoniazid, 6-mercaptopurine, or 5-fluorouracil may also produce pellagra. Hartnup disease (see Chapter 85), caused by a mutation in *SLC6A19* that encodes a neutral amino acid transporter, is a rare autosomal recessive disorder that presents in infancy with a "pellagra-like syndrome" as a result of decreased absorption of tryptophan. Nicotinamide supplementation and sun avoidance are the mainstays of therapy in pellagra.

SCURVY (VITAMIN C OR ASCORBIC ACID DEFICIENCY)

See Chapter 50.

Scurvy manifests initially as follicular hyperkeratosis, coiling of the hair on the upper arms, back, buttocks, and lower extremities. Other features are perifollicular erythema and hemorrhage, particularly on the legs and advancing to involve large areas of hemorrhage; swollen, erythematous gums; stomatitis; and subperiosteal hematomas. In children, the most common risk factors are behavioral or psychiatric disease that results in poor nutrition. The best method of confirmation of a clinical diagnosis of scurvy is a trial of vitamin C supplementation.

VITAMIN A DEFICIENCY

See Chapter 48.1.

Vitamin A deficiency manifests initially as impairment of visual adaptation to the dark. Cutaneous changes include xerosis and hyperkeratosis and hyperplasia of the epidermis, particularly the lining of hair follicles and sebaceous glands. In severe cases, desquamation may be prominent.

Bone and Joint Disorders

PART XXXII

Section 1

Orthopedic Problems

Chapter 672
Growth and Development

Keith D. Baldwin, Lawrence Wells, and John P. Dormans

Statistically, normal is defined as 95% of a population that falls within 2 SD of the mean from any given measurement. Statistically normal should not be confused with ideal in any given person or parent's mind. Table 672-1 lists terms used to describe some common deviations from normal. Congenital anomalies can be categorized into production problems and packaging problems. Production problems include abnormalities caused by malformation, dysplasia, or disruption that will not spontaneously resolve (see Chapter 108). Packaging problems include deformations caused by mechanical causes including in utero positioning and molding, and they usually resolve with time.

IN UTERO POSITIONING

In utero positioning produces temporary joint and muscle contractures and affects the torsional alignment of the long bones, particularly those of the lower extremities. Normal full-term newborns can have up to 20-30 degree hip and knee flexion contractures. These contractures tend to resolve by 4-6 mo of age. The newborn hip externally rotates in extension up to 80-90 degrees and has limited internal rotation to approximately 0-10 degrees. The lower leg often has inward rotation (internal tibial torsion). The face may also be distorted; the spine and upper extremities are less affected by the in utero position. The effects of in utero positioning, therefore, are physiologic in origin and resolve by 3-4 mo of age.

Table 672-1 Terminologies for Deviations

TERMINOLOGY	DESCRIPTION
Congenital	Anomaly that is apparent at birth
Deformation	A normally formed structure that is pushed out of shape by mechanical forces
Deformity	A body part altered in shape from normal, outside the normal range
Developmental	A deviation that occurs over time; one that might not be present or apparent at birth
Disruption	A structure undergoing normal development that stops developing or is destroyed or removed
Dysplasia	A tissue that is abnormal or wrongly constructed
Malformation	A structure that is wrongly built; failure of embryologic development or differentiation resulting in abnormal or missing structures

GROWTH AND DEVELOPMENT

Consideration of growth and development helps to formulate treatment strategies designed to preserve or restore normal growth potential. Growth is subject to many variables including genetics, nutrition, general health, endocrine status, mechanical forces, and physiologic age. Growth also varies between 2 anatomic regions and even between 2 bones of the same region.

Bone formation or ossification occurs in 2 different ways. In **endochondral ossification**, mesenchymal cells undergo chondrogenesis to form cartilage that matures to become bone. Most bones in the axial and appendicular skeleton are formed in this manner. In **intramembranous ossification**, osteoblasts are formed by direct differentiation of mesenchymal cells into bone. Flat bones of the skull and clavicle are examples of this pattern of bone formation.

CENTERS OF OSSIFICATION

At the beginning of the fetal period the chondrocytes in the midshaft of the long bones form the **primary** centers of growth from which the bone eventually lengthens. **Secondary** centers of ossification appear in the chondroepiphysis and mostly appear postnatally. They direct the formation of bone throughout growth, particularly joint development. The ossification centers that are typically present at birth are the distal femur, proximal tibia, calcaneus, and talus.

Anatomic Locations: Descriptive Terms

Typical **long bones are divided into** the physis, epiphysis, metaphysis, diaphysis, and perichondrial ring (Fig. 672-1). The physis is the growth plate located at the end of bone. The epiphysis is typically a secondary ossification center that contributes to joint development. The metaphysis is the bone adjacent to the physis on the side away from the joint. The diaphysis is the central part or shaft of long bones. The perichondrial ring contributes to appositional growth.

The articular cartilage also contributes to the growth of the epiphysis. The perichondrial ring, which surrounds the physes, and the perichondrium around the epiphyses and periosteum, which surrounds the metaphysis and diaphyseal regions of the bone, contribute to appositional or circumferential growth. Bones without physes (pelvis, scapulae, carpals, tarsals) grow by appositional bone growth from their surrounding perichondrium and periosteum. Other bones (metacarpals, metatarsals, phalanges, spine) grow by a combination of appositional and endochondral ossification.

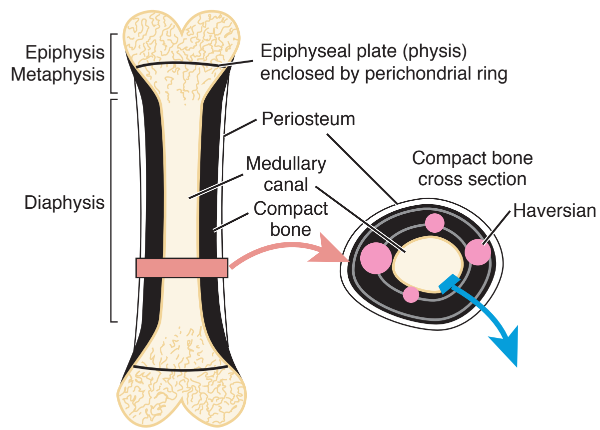

Figure 672-1 Diagram showing typical long bone divisions.

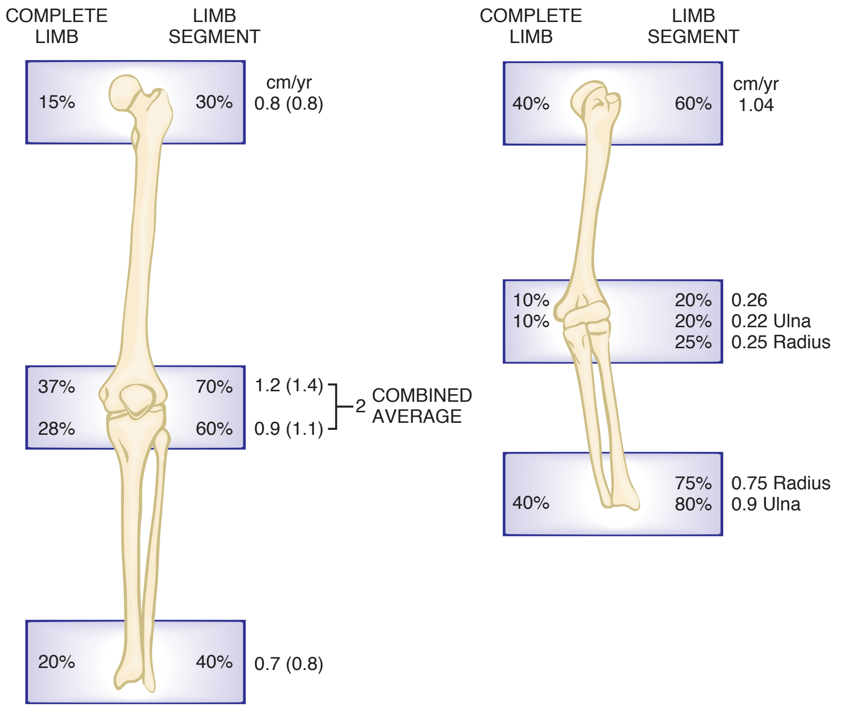

Figure 672-2 The contribution (%) of each physis to the overall length of the extremities. *(From Morrissy R, Weinstein S, editors:* Lovell and Winter's pediatric orthopedics, *ed 5, Philadelphia, 2001, Lippincott Williams & Wilkins.)*

Table 672-2	Skeletal Growth Considerations

- Abnormal stature can be assessed as "proportionate" or "disproportionate" based on comparing the ratio of sitting height with subischial height (lower limbs).
- Normally the arm span is almost equal to standing height.
- The head is disproportionately large at birth and ratio of head height to total height is approximately 1:4 at birth, which changes to 1:7.5 at skeletal maturity.
- Lower extremities account for approximately 15% of height at birth and 30% at skeletal maturity.
- The rate of height and growth increase is not constant and varies with growth spurts.
- By age 5 yr, birth height usually doubles and the child is approximately 60% of adult height. The child is approximately 80% of final height at 9 yr. During puberty, the standing height increases by approximately 1 cm/mo.
- Bone age is more important than chronologic age in determining future growth potential.

Important Growth and Developmental Milestones

Table 672-2 summarizes some important musculoskeletal growth considerations.

Growth Patterns in Upper and Lower Extremities

The upper extremity grows longitudinally, primarily from physes of the proximal humeral physis and the distal radial and ulnar physes. In the lower extremity, most of the longitudinal growth occurs around the knee, in the distal femoral and the proximal tibial physes (Fig. 672-2).

In the hip joint, the acetabulum forms with the convergence of 3 primary ossification centers: ischium, ilium, and pubis.

GAIT/FUNCTIONAL MATURATION

Functional mobility develops in infants in a predictable fashion (Table 672-3). Failure to achieve functional milestones is an indication for referral to a neurologist to determine if a central nervous system problem exists. Central nervous system maturation contributes significantly to the development of gait. In early ambulation (at 8-15 mo), the child usually has a wide-based gait with hyperflexion of hips and knees, and initial contact with the heel. By the age of 2 yr, the wide gait diminishes, reciprocal arm swing begins, and there is increased stride length and velocity. Adult fluid gait patterns usually start developing by 3 yr and mature to an adult-like pattern by age 7 yr.

Table 672-3 Functional Milestones

MILESTONE	ACHIEVED BY
Head control	3-6 months
Sitting	6-9 months
Crawling	8 months
Pulling to stand	8-12 months
Ambulating	12-18 months

Chapter 673

Evaluation of the Child

Keith D. Baldwin, Lawrence Wells, and John P. Dormans

A detailed history and thorough physical examination are critical to the evaluation of a child with an orthopedic problem. The child's family and acquaintances are important sources of information, especially in younger children and infants. Appropriate radiographic imaging and, occasionally, laboratory testing may be necessary to support the clinical diagnosis.

HISTORY

A comprehensive history should include details about the prenatal, perinatal, and postnatal periods. Prenatal history should include maternal health issues: smoking, prenatal vitamins, illicit use of drugs or narcotics, alcohol consumption, diabetes, rubella, and sexually transmitted infections. The child's prenatal and perinatal history should include information about the length of pregnancy, length of labor, type of labor (induced or spontaneous), presentation of fetus, evidence of any fetal distress at delivery, requirements of oxygen following the delivery, birth length and weight, Apgar score, muscle tone at birth, feeding history, and period of hospitalization. In older infants and young children, evaluation of developmental milestones for posture, locomotion, dexterity, social activities, and speech are important. Specific orthopedic questions should focus on joint, muscular, appendicular, or axial skeleton complaints. Information regarding pain or other symptoms in any of these areas should be appropriately elicited (Table 673-1). The family history can give clues to heritable disorders. It also can forecast expectations of the child's future development and allow appropriate interventions as necessary.

PHYSICAL EXAMINATION

The orthopedic physical examination includes a thorough examination of the musculoskeletal system along with a comprehensive neurologic examination. The musculoskeletal examination includes inspection, palpation, and evaluation of motion, stability, and gait. A basic neurologic examination includes sensory examination, motor function, and reflexes. The orthopedic physical examination requires basic knowledge of anatomy of joint range of motion, alignment, and stability. Many common musculoskeletal disorders can be diagnosed by the history and physical examination alone. One screening tool that has been useful in adults has now been adapted and evaluated for use in children, the pediatric gait, arms, legs, spine (pGALS) test, the components of which are listed in Figure 673-1.

Inspection

Initial examination of the child begins with inspection. The clinician should use the guidelines listed in Table 673-2 during inspection.

Palpation

Palpation of the involved region should include assessment of local temperature and tenderness; assessment for a swelling or mass, spasticity or contracture, and bone or joint deformity; and evaluation of anatomic axis of limb and of limb lengths.

Contractures are a loss of mobility of a joint from congenital or acquired causes and are caused by periarticular soft-tissue fibrosis or involvement of muscles crossing the joint. Congenital contractures are common in **arthrogryposis** (see Chapter 682). Spasticity is an abnormal increase in tone associated with hyperreflexia and is common in cerebral palsy.

Deformity of the bone or joint is an abnormal fixed shape or position from congenital or acquired causes. It is important to assess the type of deformity, its location, and degree of deformity upon clinical examination. It is also important to assess whether the deformity is fixed or can be passively or actively corrected and whether there is any associated muscle spasm, local tenderness, or pain on motion. Classification of the deformity depends on the plane of deformity: **varus** (away from midline) or **valgus** (apex toward midline), or **recurvatum** (backward curvature) or **flexion** deformity (sagittal plane). In the axial skeleton, especially the spine, deformity can be defined as scoliosis, kyphosis, hyperlordosis, and kyphoscoliosis.

Range of Motion

Active and passive joint motion should be assessed, recorded, and compared to the opposite side. Objective evaluation should be done with a goniometer and recorded.

Vocabulary for direction of joint motion is as follows:

Abduction: Away from the midline
Adduction: Toward the midline
Flexion: Movement of bending from the starting position
Extension: Movement from bending to the starting position
Supination: Rotating the forearm to face the palm upward
Pronation: Rotating the forearm to face the palm downward
Inversion: Turning the hindfoot inward
Eversion: Turning the hindfoot outward
Plantarflexion: Pointing the toes away from the body (toward the floor)
Dorsiflexion: Pointing the toes toward the body (toward the ceiling)
Internal rotation: Turning inward toward the axis of the body
External rotation: Turning outward away from the axis of the body

Table 673-1 Characterization of Pain and Presenting Symptom

Location: Whether pain is localized to a particular segment or involves a larger area
Intensity: Usually on a pain scale of 1-10
Quality: Tumor pain is often unrelenting, progressive, and often present during the night. Pain at night particularly suggests osteoid osteoma. Pain in inflammation and infection is usually continuous
Onset: Was it acute and related to specific trauma or was it insidious? Acute pain and history of trauma are more commonly associated with fractures.
Duration: Whether transient, only lasting for minutes, or lasting for hours or days. Pain lasting for longer than 3-4 wk suggests a serious underlying problem.
Progress: Whether static, increasing, or decreasing
Radiation: Pain radiating to upper or lower extremities or complaints of numbness, tingling, or weakness require appropriate work-up.
Aggravating factors: Relationship to any activities such as swimming or diving or any particular position
Alleviating factors: Is the pain relieved by rest, heat, and/or medication? Conditions such as spondylolysis, Scheuermann disease, inflammatory spondyloarthropathy, muscle pulls, or overuse are improved by bed rest.
Gait and posture: Disturbances associated with pain

Table 673-2 Guidelines During Inspection of a Child with Musculoskeletal Problem

- The patient should be *comfortable with adequate exposure and well-lit surroundings* (lest some important physical finding be missed). Infants or young children may be examined on their parent's lap so that they feel more secure and are more likely to be cooperative.
- It is important to inspect how the patient moves about in the room before and during the examination, as well as during various maneuvers. *Balance, posture, and gait pattern* should also be checked.
- *General examination* findings should include inspection for skin rashes, café-au-lait spots, hairy patches, dimples, cysts, tuft of hair, or evidence of spinal midline defects that can indicate serious underlying problems that need review.
- *General body habitus,* including signs of cachexia, pallor, and nutritional deficiencies, should be noted.
- Note any obvious spinal asymmetry, axial or appendicular deformities, trunk decompensation, and evidence of muscle spasm or contractures. The *forward bending test* is valuable in assessing asymmetry and movement of the spine.
- It is essential to perform and document a *thorough neurologic examination.* Motor, sensory, and reflex testing should be performed and recorded.
- Any *discrepancies in limb lengths*, as well as *muscle atrophy*, should be recorded.
- The range of motion of all joints, their stability, and any evidence of hyperlaxity, peripheral pulsations, and lymphadenopathy should also be noted in all cases.

Gait

A "Walk on your tip-toes."* Observe the child walking

B "Walk on your heels."* Observe the child walking

Arms

C "Put your hands out in front of you."

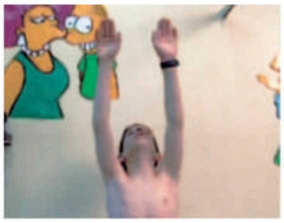
D "Turn your hands over and make a fist. Pinch your index finger and thumb together."

E "Touch the tips of your fingers with your thumb."

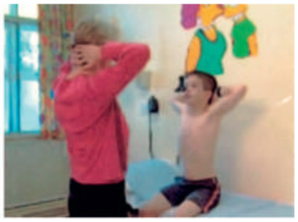
F Squeeze metacarpophalangeal joints

G "Put your hands together."*

H "Put your hands back to back."*



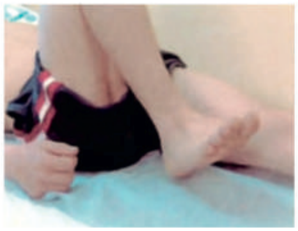
I "Reach up and touch the sky.* Look at the ceiling."



J "Put your hands behind your neck."

Legs

K Feel for effusion at the knee



L "Bend and the straighten your knee." (active movement of knees and examiner feels for crepitus)

M Passive flexion (90 degrees) with internal rotation of hip

Spine

N "Open your mouth and put 3 of your (child's own) fingers in your mouth."*

O Lateral flexion of cervical spine: "Try and touch your shoulder with your ear."

P Observe spine from behind

Q "Can you bend and touch your toes?" Observe curve of spine from side and behind

Figure 673-1 The components of pediatric gait, arms, legs, spine (pGALS) screen, with illustration of movement. Screening questions: (1) Do you have any pain or stiffness in your joints, muscles, or back? (2) Do you have any difficulty getting yourself dressed without any help? (3) Do you have any difficulty going up and down stairs? *Additions and amendments to the original adult gait, arms, legs, spine screen. *(From Foster HE, Kay LJ, Friswell M, et al: Musculoskeletal screening examination [pGALS] for school-age children based on the adult GALS screen,* Arthritis Rheum *55:709–716, 2006.)*

Gait Assessment

Children typically begin walking between 8 and 16 mo of age. Early ambulation is characterized by short stride length, a fast cadence, and slow velocity with a wide-based stance. Gait cycle is a single sequence of functions that starts with heel strike, toe off, swing, and heel strike. The 4 events describe 1 gait cycle and include 2 phases: stance and swing. The stance phase is the period during which the foot is in contact with the ground. The swing phase is the portion of the gait cycle during which a limb is being advanced forward without ground contact (see Chapter 672). Normal gait is a symmetric and smooth process. Deviation from the norm indicates potential abnormality and should trigger investigation.

Neurologic maturation is necessary for the development of gait and the normal progression of developmental milestones. A child's gait changes with neurologic maturation. Infants normally walk with greater hip and knee flexion, flexed arms, and a wider base of gait than older children. As the neurologic system continues to develop in the cephalocaudal direction, the efficiency and smoothness of gait increase. The gait characteristics of a 7 yr old child are similar to those of an adult. When the neurologic system is abnormal (cerebral palsy), gait can be disturbed, exhibiting pathologic reflexes and abnormal movements.

Deviations from normal gait occur in a variety of orthopedic conditions. Disorders that result in muscle weakness (e.g., spina bifida, muscular dystrophy), spasticity (e.g., cerebral palsy), or contractures (e.g., arthrogryposis) lead to abnormalities in gait. Other causes of gait disturbances include limp, pain, torsional variations (in-toeing and out-toeing), toe walking, joint abnormalities, and leg-length discrepancy (Table 673-3).

LIMPING

A thorough history and clinical examination are the first steps toward early identification of the underlying problem causing a limp. Limping can be considered as either **painful (antalgic)** or painless, with the differential diagnosis ranging from benign to serious causes (septic hip, tumor). In a painful gait, the stance phase is shortened as the child decreases the time spent on the painful extremity. In a painless gait, which indicates underlying proximal muscle weakness or hip instability, the stance phase is equal between the involved and uninvolved sides, but the child leans or shifts the center of gravity over the involved extremity for balance. A bilateral disorder produces a waddling gait. Trendelenburg gait is produced by weak abnormal hip abductors. In single leg stance, a Trendelenburg sign can often be elicited when abductors are weak.

Disorders most commonly responsible for an abnormal gait generally vary based on the age of the patient. The differential diagnosis of limping varies based on age group (Table 673-4) or mechanism (Table 673-5). Neurologic disorders, especially spinal cord or peripheral nerve disorders, can also produce limping and difficult walking. Antalgic gait is predominantly a result of trauma, infection, or pathologic fracture. Trendelenburg gait is generally caused by congenital, developmental, or muscular disorders. In some cases, limping also may be caused by nonskeletal causes such as testicular torsion, inguinal hernia, and appendicitis.

BACK PAIN

Children frequently have a specific skeletal pathology as the cause of back pain. The most common causes of back pain in children are trauma, spondylolysis, spondylolisthesis, and infection (see Table 679-2). Tumor and tumor-like lesions that cause back pain in children are likely to be missed unless a thorough clinical assessment and adequate work-up are performed when required. Nonorthopedic causes of back pain include urinary tract infections, nephrolithiasis, and pneumonia.

NEUROLOGIC EVALUATION

A careful neurologic evaluation is a part of every pediatric musculoskeletal examination (see Chapter 590). The assessment should include evaluation of developmental milestones, muscle strength, sensory assessment, muscle tone, and deep tendon reflexes. The neurologic evaluation should also assess the spine and identify any deformity, such as scoliosis and kyphosis, or abnormal spinal mobility. The hips and feet should also be examined specifically, along with torsional abnormalities of the lower extremity, which are vastly more common in the neurologically involved population. Specific peripheral nerve examinations may be necessary.

As the nervous system matures, the developing cerebral cortex normally inhibits rudimentary reflexes that are often present at birth (see Chapter 590). Therefore, persistence of these reflexes can indicate neurologic abnormality. The most commonly performed deep tendon reflex tests include biceps, triceps, quadriceps, and gastrocnemius and soleus tendons. Upper motor neuron signs should also be noted. The

Table 673-6 Ashworth Scale of Spasticity

0	No increase in muscle tone
1	Slight increase in muscle tone, usually a catch or minimal resistance at end range of motion
2	Moderate tone throughout range of motion
3	Considerable increase in tone; passive range of motion difficult
4	Rigid in flexion or extension

Table 673-7 Clinical Scale of Upper-Extremity Motor Control

GRADE	DEFINITION
Grade 1	Hypotonic, no volitional motion
Grade 2	Hypertonic, no volitional motion
Grade 3	Mass flexion or extension in response to a stimulus
Grade 4	Patient can initiate movement but results in mass flexion or extension
Grade 5	Slow volitional movement; stress or rapid movement results in mass action
Grade 6	Volitional control of specific joints/muscles

Ashworth scale is often used to grade spasticity (Table 673-6). Upper-extremity motor control is often graded, and these grades are useful both diagnostically and prognostically. Passive range of motion should be assessed to determine contractures (Table 673-7). Localized or diffuse weakness must be determined and documented. A thorough assessment and grading of muscle strength is mandatory in all cases of neuromuscular disorders.

RADIOGRAPHIC ASSESSMENT

Plain radiographs are the first step in evaluation of most musculoskeletal disorders. Advanced imaging includes special procedures such as nuclear bone scans, ultrasonography, MRI, CT, and positron emission tomography.

Plain Radiographs

Routine radiographs are the first step and consist of anteroposterior and lateral views of the involved area with 1 joint above and below. Comparison views of the opposite side, if uninvolved, may be helpful in difficult situations but are not always necessary. It is important for the clinician to be aware of normal radiographic variants of the immature skeleton. Several synchondroses may be mistaken for fractures. A patient with "normal" plain radiographic appearance but having persistent pain or symptoms might need to be evaluated further with additional imaging studies.

Nuclear Medicine Imaging

A bone scan displays physiologic information rather than pure anatomy and relies on the emission of energy from the nucleotide injected into the patient. Indications include early septic arthritis, osteomyelitis, avascular necrosis, tumors (osteoid osteoma), metastatic lesions, occult and stress fractures, and cases of child abuse.

Total-body radionuclide scan (technetium-99) is useful to identify bony lesions, inflammatory tumors, and stress fractures. Tumor vascularity can also be inferred from the flow phase and the blood pool images. Gallium or indium scans have high sensitivity for local infections. Thallium-201 chloride scintiscans have >90% sensitivity and between 80% and 90% accuracy in detecting malignant bone or soft-tissue tumors.

Ultrasonography

Ultrasonography is useful to evaluate suspected fluid-filled lesions such as popliteal cyst and hip joint effusions. Major indications for ultrasonography are fetal studies of the extremities and spine, including detection of congenital anomalies like spondylocostal dysostosis, fractures suggesting osteogenesis imperfecta, developmental dysplasia of the hip, joint effusions, occult *neonatal* spinal dysraphism, foreign bodies in soft tissues, and popliteal cysts of the knee.

Magnetic Resonance Imaging

MRI is the **imaging modality of choice** for defining the exact anatomic extent of most musculoskeletal lesions (particularly if the structure is soft tissue). MRI avoids ionizing radiation and doing does not produce any known harmful effects. It produces excellent anatomic images of the musculoskeletal system, including the soft tissue, bone marrow cavity, spinal cord, and brain. It is especially useful for defining the extent of soft-tissue lesions, infections, and injuries. Tissue planes are well delineated, allowing more accurate assessment tumor invasion into adjacent structures. Cartilage structures can be visualized (articular cartilage of the knee can be distinguished from the fibrocartilage of the meniscus). MRI is also helpful in visualizing unossified joints in the pediatric population including the shoulders, elbows, and hips of young infants.

Magnetic Resonance Angiography

Magnetic resonance angiography has largely replaced routine angiography in the preoperative assessment of vascular lesions and bone tumors. Magnetic resonance angiography provides good visualization of peripheral vascular branches and tumor neovascularity in patients with primary bone tumors.

Computed Tomography

CT has enhanced the evaluation of multiple musculoskeletal disorders. Coronal, sagittal, and axial imaging is possible with CT including 3-dimensional reconstructions that can be beneficial in evaluating complex lesions of the axial and appendicular skeleton. It allows visualization of the detailed bone anatomy and the relationship of bones to contiguous structures. CT is useful to readily evaluate tarsal coalition, accessory navicular bone, infection, growth plate arrest, osteoid osteoma, pseudoarthrosis, bone and soft tissue tumors, spondylolysis, and spondylolisthesis. CT is superior to MRI for assessing bone involvement and cortical destruction (even subtle changes), including calcification or ossification and fracture (particularly if displacement of an articular fracture is suspected.

LABORATORY STUDIES

Laboratory tests are occasionally necessary in the evaluation of a child with musculoskeletal disorder. These may include a complete blood cell count; erythrocyte sedimentation rate; C-reactive protein assay; Lyme titers; and blood, wound, joint, periosteum, or bone cultures for infectious conditions such as septic arthritis or osteomyelitis. Rheumatoid factor, antinuclear antibodies, and human leukocyte antigen B27 may be necessary for children with suspected rheumatologic disorders. Creatine kinase, aldolase, aspartate aminotransferase, and dystrophin testing are indicated in children with suspected disorders of striated muscle such as Duchenne muscular dystrophy.

Chapter 674
The Foot and Toes
Jennifer J. Winell and Richard S. Davidson

Abnormalities affecting the osseous and articular structures of the foot may be congenital, developmental, neuromuscular, inflammatory, or acquired. Problems with the foot and/or toes may be associated with a host of connective tissue diseases and syndromes; overuse syndromes are commonly observed in young athletes. Symptoms may include pain and abnormal shoe wear; cosmetic concerns are common. The foot may be divided into the **forefoot** (toes and metatarsals), the **midfoot** (cuneiforms, navicular, cuboid), and the **hindfoot** (talus and calcaneus). While the tibiotalar joint (ankle) provides plantarflexion and dorsiflexion, the subtalar joint (between the talus and calcaneus) is oriented obliquely, providing inversion and eversion. Inversion represents a combination of plantarflexion and varus, while eversion involves dorsiflexion and valgus. The subtalar joint is especially important for walking on uneven surfaces. Inversion of the transverse tarsal (Chopart) joint locks the midfoot to provide a stable base on which to perform toe off during the gait cycle. Eversion of the transverse tarsal joint unlocks the **hindfoot** to provide accommodation during heel strike of the of the gait cycle. The talonavicular and calcaneocuboid joints connect the midfoot with the hindfoot.

674.1 Metatarsus Adductus
Jennifer J. Winell and Richard S. Davidson

Metatarsus adductus involves adduction of the forefoot relative to the hindfoot. When the forefoot is supinated and adducted, the deformity is termed *metatarsus varus* (Fig. 674-1). The disorder is common in newborns, most frequently caused by intrauterine molding; the deformity is bilateral in 50% of cases. As with other intrauterine positional foot deformities, a careful hip and neck examination should always be performed to look for other abnormalities associated with intrauterine positioning.

CLINICAL MANIFESTATIONS
The forefoot is adducted (occasionally supinated), whereas the midfoot and hindfoot are normal. The lateral border of the foot is convex, and the base of the 5th metatarsal appears prominent. Range of motion at the ankle and subtalar joints is normal. Both the magnitude and the degree of flexibility should be documented. When the foot is viewed from the plantar surface, a line through the midpoint of (and parallel to) the heel should normally extend through the 2nd toe. Flexibility is assessed by stabilizing the hindfoot and midfoot in a neutral position with 1 hand and applying pressure over the 1st metatarsal head with the other. Correction with little pressure is indicative of a more flexible deformity. In the walking child with an uncorrected metatarsus adductus deformity, an in-toe gait and abnormal shoe wear may occur. A subset of patients will also have a dynamic adduction deformity of the great toe (hallux varus), which is often most noticeable during ambulation. This usually improves spontaneously and does not require treatment.

RADIOGRAPHIC EVALUATION
Radiographs are not performed routinely in infants. Older children with residual deformity should have anteroposterior (AP) and lateral weight-bearing or simulated weight-bearing radiographs. The AP radiographs demonstrate adduction of the metatarsals at the tarsometatarsal articulation and an increased intermetatarsal angle between the 1st and 2nd metatarsals.

TREATMENT
The treatment of metatarsus adductus is based on the rigidity of the deformity; most children respond to nonoperative treatment. Deformities that are flexible and overcorrect into abduction with passive manipulation may be observed. Those feet that correct just to a neutral position may benefit from stretching exercises which can be demonstrated to the parents in the office. In a walking child, the parents can try reversing the shoes as well. If this is not effective, reverse-last shoes to maintain the abducted position of foot can be prescribed. These are worn full time (22 hr/day), and the condition is reevaluated in 4-6 wk.

Figure 674-1 Clinical picture of metatarsus adductus with a normal foot on opposite side.

If improvement occurs, treatment can be continued. If there is no improvement, serial plaster casts should be considered. When stretching a foot with metatarsus adductus, care should be taken to maintain the hindfoot in neutral to slight varus alignment to avoid creating hindfoot valgus. Feet that cannot be corrected to a neutral position may benefit from serial casting; the best results are obtained when treatment is started before 8 mo of age. In addition to stretching the soft tissues, the goal is to alter physeal growth and stimulate remodeling, resulting in permanent correction. Once flexibility and alignment are restored, orthoses or corrective shoes are generally recommended for an additional period. A dynamic hallux varus usually improves spontaneously, and no active treatment is required.

Surgical treatment may be considered in the small subset of patients with symptomatic residual deformities that have not responded to previous treatment. Surgery is generally delayed until children are 4-6 yr of age. Cosmesis is often a concern, and pain and/or the inability to wear certain types of shoes may occasionally lead patients to consider surgery. Options for surgical treatment include either soft-tissue releases or osteotomies. An osteotomy (midfoot or multiple metatarsals) is most likely to result in permanent restoration of alignment.

Bibliography is available at Expert Consult.

674.2 Calcaneovalgus Feet

Jennifer J. Winell and Richard S. Davidson

A common finding in the newborn, the calcaneovalgus foot is secondary to in utero positioning. Excessive dorsiflexion and eversion are observed in the hindfoot, and the forefoot may be abducted. There may be an associated external tibial torsion (see Chapter 675).

CLINICAL MANIFESTATIONS

The infant typically presents with the foot dorsiflexed and everted, and occasionally the dorsum of the foot or toes, will be in contact with the anterolateral surface of the lower leg (Fig. 674-2). Dimpling may be indicative of reduced subcutaneous fat at the dorsolateral ankle. Plantarflexion and inversion are often restricted. As with other intrauterine positional deformities, a careful hip examination should be performed; if there is any concern, hip ultrasonography should be considered. When comparing risk for developmental hip dysplasia (DDH) with other congenital foot deformities, congenital calcaneovalgus has the highest association with 19.4% of patients having coexisting DDH. The calcaneovalgus foot may be confused with a congenital vertical talus and may rarely be associated with a posteromedial bow of the tibia. A calcaneovalgus deformity may also be seen in older patients, typically those with a neuromuscular imbalance involving weakness or paralysis of the gastrocsoleus muscle (polio, myelomeningocele).

RADIOGRAPHIC EVALUATION

Radiographs are usually not required but should be ordered if the deformity fails to correct spontaneously or with early treatment. AP and lateral radiographs along with a lateral radiograph of the foot in maximal plantarflexion may help distinguish calcaneovalgus from a congenital vertical talus or congenital oblique talus. Evaluation of the position of the talus in relation to the navicular in both the lateral and maximally plantarflexed lateral view confirm congenital vertical or oblique talus. If a posteromedial bow of the tibia is suspected, AP and lateral radiographs of the tibia and fibula are necessary. In posteromedial bowing of the tibia, the deformity is located in the tibia with the apex of deformity positioned posterior and medial. All three conditions may be confused clinically with calcaneovalgus feet.

TREATMENT

Mild cases of calcaneovalgus foot, in which full passive range of motion is present at birth, require no active treatment. These usually resolve within the 1st few wk of life. A gentle stretching program, focusing on plantarflexion and inversion, is recommended for cases with some restriction in motion. For cases with a greater restriction in mobility, serial casts may be considered to restore motion and alignment. Casting is rarely required in the treatment of calcaneovalgus feet. The management for those cases associated with a posteromedial bow of the tibia is similar.

674.3 Talipes Equinovarus (Clubfoot)

Jennifer J. Winell and Richard S. Davidson

Clubfoot or congenital talipes equinovarus (CTEV) is the term used to describe a deformity involving malalignment of the calcaneotalar-navicular complex. Components of this deformity may be best understood using the mnemonic **CAVE** (cavus, adductus, varus, equinus). Although this is predominantly a hindfoot deformity, there are plantarflexion (cavus) of the first ray and adduction of the forefoot/midfoot on the hindfoot. The hindfoot is in varus and equinus. The clubfoot deformity may be positional, congenital, associated with a variety of underlying diagnoses (neuromuscular or syndromic) or a focal dysplasia of musculoskeletal tissue distal to the knee.

The **positional (or postural) clubfoot** is a normal foot that has been held in a deformed position in utero and is found to be flexible on examination in the newborn nursery. The **congenital clubfoot** can either be idiopathic or syndromic. There is a spectrum of severity, but clubfoot associated with neuromuscular diagnoses or syndromes is

typically rigid and more difficult to treat. Clubfoot is also extremely common in patients with myelodysplasia, arthrogryposis, and other chromosomal syndromes such as trisomy 18 and chromosome 22q11 deletion syndrome (see Chapter 81).

Congenital clubfoot is seen in approximately 1 in 1,000 births and most likely results from a complex multifactorial polygenic inheritance. The risk is approximately 1 in 4 when both a parent and 1 sibling have clubfeet. It occurs more commonly in males (2 : 1) and is bilateral in 50% of cases. The pathoanatomy involves both abnormal tarsal morphology (plantar and medial deviation of the head and neck of the talus) and abnormal relationships between the tarsal bones in all 3 planes, as well as associated contracture of the soft tissues on the plantar and medial aspects of the foot.

CLINICAL MANIFESTATIONS

A complete physical examination should be performed to rule out coexisting musculoskeletal and neuromuscular problems. The spine should be inspected for signs of occult dysraphism. Examination of the infant clubfoot demonstrates forefoot cavus and adductus and hindfoot varus and equinus (Fig. 674-3). The degree of flexibility varies, and all patients will exhibit calf atrophy. Internal tibial torsion, foot length shortening and leg-length discrepancy (shortening of the ipsilateral extremity) will be observed in a subset of cases. Although classically not associated with DDH (see Chapter 678), there is a higher association of CTEV and DDH than in the general population.

RADIOGRAPHIC EVALUATION

Anteroposterior and lateral radiographs are not recommended for idiopathic clubfoot. For arthrogrypotic or syndromic feet, x-rays may be helpful but must be performed, with the foot held in the maximally corrected position. Multiple radiographic measurements can be made to describe malalignment between the tarsal bones. The navicular bone does not ossify until 3-6 yr of age, so the focus of radiographic interpretation is the relationships between segments of the foot, forefoot to hindfoot. A common radiographic finding is "parallelism" between lines drawn through the axis of the talus and the calcaneus on the lateral radiograph, indicating hindfoot varus. X-ray may be particularly useful for older children with persistent or recurrent deformities that are difficult to assess.

TREATMENT

Nonoperative treatment is initiated in all infants and should be started as soon as possible following birth. Techniques have included taping and strapping, manipulation and serial casting, and functional treatment. Historically, a significant percentage of patients treated by manipulation and casting required a surgical release, which was usually performed between 3 and 12 mo of age. Although many feet remain well aligned after surgical releases, a significant percentage of patients have required additional surgery for recurrent or residual deformities. Stiffness remains a concern at long-term follow-up. While pain is uncommon in childhood and adolescence, symptoms may appear during adulthood. These concerns have led to considerable interest in less-invasive methods for treating the deformity. The Ponseti method of clubfoot treatment, which has now become the standard of initial treatment, involves a specific technique for manipulation and serial casting and may be best described as minimally invasive rather than nonoperative. The order of correction follows the mnemonic **CAVE**. Weekly cast changes are performed; 5-10 casts are typically required. The most difficult deformity to correct is the hindfoot equinus, and approximately 90% of patients will require a percutaneous tenotomy of the heel cord as an outpatient. Following the tenotomy, a long leg cast with the foot in maximal abduction (up to 70 degrees) and dorsiflexion is worn for 3-4 wk; the patient then begins a bracing program. An abduction brace is worn full time for 3 mo and then at nighttime for 3-5 yr. A small subset of patients (up to 20%) with recurrent, dynamic supination deformity will require transfer of the tibialis anterior tendon to the middle cuneiform for recurrence. Although most patients require some form of surgery, the procedures are minimal in comparison with extensive surgical release, which requires lengthening and/or release of muscles and tendons about the ankle and capsulotomy of the major joints to reposition the foot. The results of the Ponseti method are excellent at up to 40 yr of follow-up. Despite casting, children do not have much dysfunction or delay in achieving normal motor milestones. Compliance with the splinting program is essential; recurrence is common if the brace is not worn as recommended. Functional treatment, or the "French method," involves daily manipulations (supervised by a physical therapist) and splinting with elastic tape, as well as continuous passive motion (machine required) while the baby sleeps. While results are promising, it is usually performed in the

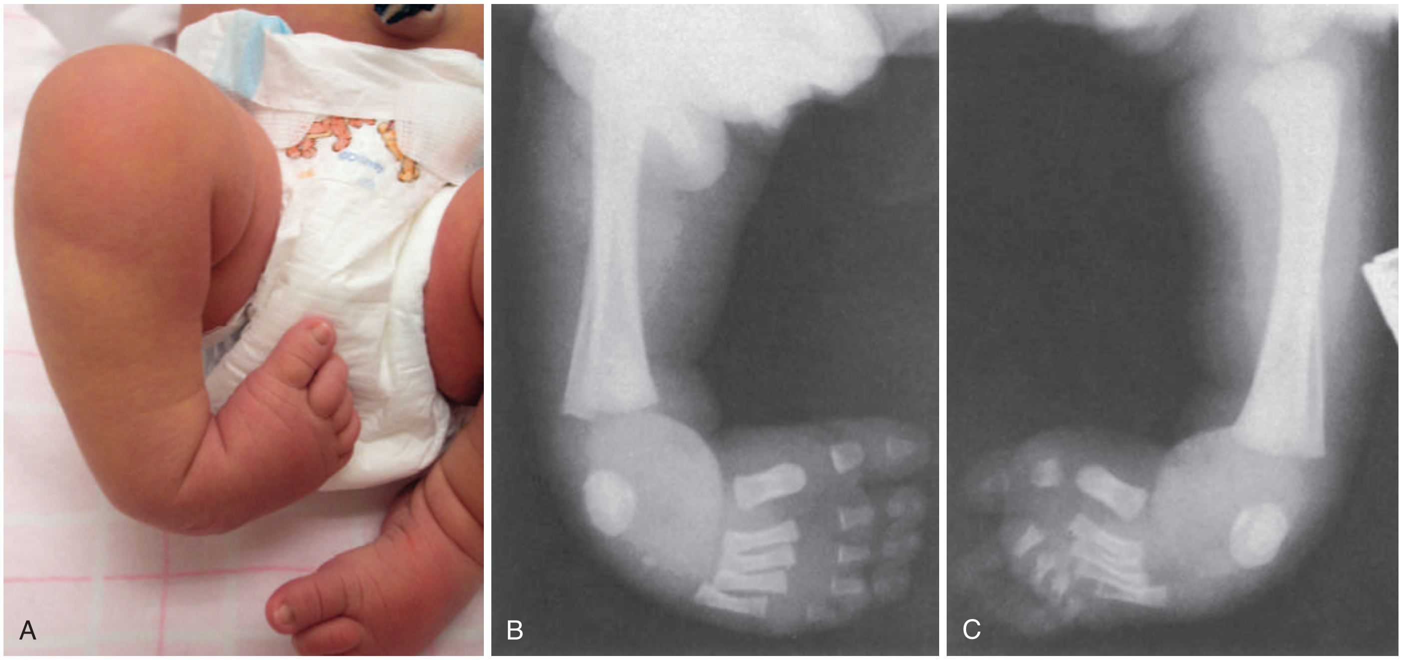

Figure 674-3 Talipes equinovarus in a newborn. **A,** Clinical appearance of an untreated clubfoot. **B** and **C,** Initial radiographic appearance of bilateral untreated clubfeet. *(From Herring JA:* Tachdjian's pediatric orthopaedics, *ed 5, Philadelphia, 2014, WB Saunders, Fig. 23-42, p. 791.)*

inpatient setting as the method is labor intensive. Implementation on an outpatient basis may be challenging, although just as successful. It remains unclear whether the technique will gain popularity in the United States. These minimally invasive methods are most successful when treatment is begun at birth or during the 1st few mo of life and with good compliance with postmanipulation bracing. As there are varying degrees of severity for idiopathic CTEV, grading systems have been proposed based on rigidity and magnitude of deformity.

Aggressive surgical realignment has a definite role in the management of clubfeet, especially in the minority of congenital clubfeet that have failed nonoperative or minimally invasive methods, and for the rigid neuromuscular and syndromic clubfeet. In such cases, nonoperative methods such as the Ponseti technique may potentially be of value in decreasing the magnitude of surgery required. Common surgical approaches include a release of the involved joints (realignment of the tarsal bones), a lengthening of the shortened posteromedial musculotendinous units, and usually pinning of the foot in the corrected position. The “a la carte” method allows the surgeon to apply the principles to be tailored to the unique characteristics of each deformity. For older children with untreated clubfeet or those in whom a recurrence or residual deformity is observed, bony procedures (osteotomies) may be required in addition to soft-tissue surgery. Triple arthrodesis is reserved as salvage for painful, deformed feet in adolescents and adults.

Bibliography is available at Expert Consult.

674.4 Congenital Vertical Talus

Jennifer J. Winell and Richard S. Davidson

Congenital vertical talus is an uncommon foot deformity in which the midfoot is dorsally dislocated on the hindfoot and the ankle is in fixed equinus. There is nearly an even split between idiopathic cases and cases with an underlying neuromuscular condition or a syndrome. Neurologic causes include myelodysplasia, tethered cord, and sacral agenesis. Other associated conditions include arthrogryposis, Larsen syndrome, multiple pterygium syndrome, and chromosomal abnormalities (trisomy 13-15, 19: see Chapter 81). Depending on the age at diagnosis, the differential diagnosis may include a calcaneovalgus foot, oblique talus (talonavicular joint reduces passively), flexible flatfoot with a tight Achilles tendon, and tarsal coalition. Genetic studies are ongoing regarding abnormal muscle morphology on biopsy.

CLINICAL MANIFESTATIONS

Congenital vertical talus has also been described as a **rocker-bottom foot** (Fig. 674-4) or a Persian slipper foot. The plantar surface of the foot is convex, and the talar head is prominent along the medial border of the midfoot. The fore part of the foot is dorsiflexed (dorsally dislocated on the hindfoot) and abducted relative to the hindfoot, and the hindfoot is in equinus and valgus. There is an associated contracture of the anterolateral (tibialis anterior, toe extensors) and the posterior (Achilles tendon, peroneals) soft tissues. The deformity is typically rigid. A thorough physical examination is required to identify any coexisting neurologic and/or musculoskeletal abnormalities.

RADIOGRAPHIC EVALUATION

AP, lateral, and maximal plantarflexion and dorsiflexion lateral radiographs should be obtained when the diagnosis is suspected. The plantarflexion view helps to determine whether the dorsal subluxation or dislocation of the midfoot on the hindfoot can be reduced passively. The dorsiflexion lateral view confirms the equinus contracture of the ankle. Although the navicular does not ossify until 3-6 yr of age, the relationship between the talus and the 1st metatarsal may be evaluated.

TREATMENT

The initial management consists of serial manipulation and casting, which is started shortly after birth. A “reverse” Ponseti method of casting is particularly useful in stretching out the dorsiflexion and valgus deformities. Open reduction and pin fixation can then stabilize the midfoot allowing simultaneous heel cord tenotomy and dorsiflexion with casting to correct the ankle equinus.

In recalcitrant cases the competing deformities of the midfoot and the hindfoot make conservative treatment difficult. Initially, an attempt is made to reduce the dorsal dislocation of the forefoot/midfoot on the hindfoot. Once this has been achieved, attention can be directed toward stretching the hindfoot contracture. These deformities are typically rigid, and surgical intervention is required in the majority of cases. In such cases, casting helps to stretch out the contracted soft tissues. Surgery is generally performed between 6 and 12 mo of age; a soft-tissue release is performed as a 1 or 2 stage procedure. One component involves release/lengthening of the contracted anterior soft tissues in concert with an open reduction of the talonavicular joint, while the other involves a posterior release with lengthening of the contracted musculotendinous units. Fixation with Kirschner wires is commonly performed to maintain alignment. Postoperatively, casting is employed for a variable period of time; patients often require the use of an orthosis for extended periods, depending on the underlying diagnosis. Salvage options for recurrent or residual deformities in older children include a subtalar or triple arthrodesis.

Bibliography is available at Expert Consult.

674.5 Hypermobile Pes Planus (Flexible Flatfeet)

Jennifer J. Winell and Richard S. Davidson

Flatfoot is a common diagnosis; it has been estimated that up to 23% of the public may be affected, depending on the diagnostic criteria. Three types of flatfeet may be identified: a flexible flatfoot, a flexible flatfoot with a tendo-Achilles contracture, and a rigid flatfoot. Flatfoot describes a change in foot shape, and there are several abnormalities in alignment between the tarsal bones. There is eversion of the subtalar complex. The hindfoot is aligned in valgus. There is midfoot sag at the naviculocuneiform and/or the talonavicular joints. The forefoot is abducted relative to the hindfoot, and the head of the talus is uncovered and prominent along the plantar and medial border of the midfoot/hindfoot. Although hypermobile or flexible pes planus represents a common source of concern for parents, these children are rarely symptomatic. Flatfeet are common in neonates and toddlers and are associated with physiologic ligamentous laxity. Improvement may be seen when the longitudinal arch develops between 5 and 10 yr of age. Flatfoot is less common in societies where shoes are not worn during infancy and childhood. In general, comfortable flexible-soled shoes are recommended for children. Flexible flatfeet persisting into adolescence and adulthood are usually associated with **familial ligamentous laxity** and can often be identified in other family members.

CLINICAL MANIFESTATIONS

Patients typically have a normal longitudinal arch when examined in a non–weightbearing position or standing on the toes, but the arch disappears when standing flat. The hindfoot collapses into valgus, and the midfoot sag becomes evident. Generalized ligamentous laxity is commonly observed. Range of motion should be assessed at both the subtalar and the ankle joints and will be normal in patients with a flexible flatfoot. When assessing range of motion at the ankle, the foot should always be inverted while testing dorsiflexion. If the foot is neutral or everted, spurious dorsiflexion may occur through the midfoot, masking a tendo-Achilles contracture. If subtalar motion is restricted, then the flatfoot is not hypermobile/flexible, and other diagnoses, such as tarsal coalition and juvenile rheumatoid arthritis, must be considered. On occasion, there may be tenderness and/or callus formation under the talar head medially. The shoes should be assessed as well and may have evidence of excessive wear along the medial border.

RADIOGRAPHIC EVALUATION

Routine radiographs of asymptomatic flexible flatfeet are usually not indicated. If obtained for diagnostic reasons, weightbearing radiographs (AP and lateral) are required to assess the deformity. On the AP radiograph, there is widening of the angle between the longitudinal axis of the talus and the calcaneus, indicating excessive heel valgus. The lateral view shows distortion of the normal straight-line relationship between the long axis of the talus and the 1st metatarsal with sag either of the talonavicular or naviculocuneiform joint, resulting in flattening of the normal medial longitudinal arch (Fig. 674-5).

Figure 674-5 Lateral weightbearing radiograph demonstrating features of flatfoot.

TREATMENT

Although the natural history of the flexible flatfoot remains unknown, there is little evidence to suggest that this condition results in long-term problems or disability. As such, treatment is reserved for the small

subset of patients who develop symptoms. Patients may complain of hindfoot pain, abnormal shoe wear or fatigue after long walking. These patients may benefit from an nonprescription orthosis, such as a medial arch support. Severe cases, often associated with an underlying connective tissue disorder such as Ehlers-Danlos syndrome (see Chapter 659) or Down syndrome (see Chapter 81), may benefit from a custom orthosis such as the UCBL (University of California Biomechanics Laboratory) orthosis to better control the hindfoot and prevent collapse of the arch. Although an orthosis may relieve symptoms, there is no evidence to suggest any permanent change in the shape of the foot or alignment of the tarsal bones. Patients with a flexible flatfoot and a tight tendo-Achilles should be treated with stretching exercises. Many times patients are referred to physical therapy to ensure that the patients are stretching appropriately. On occasion, the muscle will need to be lengthened surgically. For the few patients with persistent pain, surgical treatment can be considered. There has been considerable interest in a lateral column lengthening, which addresses all components of the deformity. The procedure involves an osteotomy of the calcaneus, with placement of a trapezoidal bone graft. A lengthening of the tendo-Achilles is required, often with a plantarflexion osteotomy of the medial cuneiform. This procedure preserves the mobility of the hindfoot joints, in contrast to a subtalar or triple arthrodesis. While a hindfoot arthrodesis may correct the deformity adequately, the stress transfer to neighboring joints may result in late-onset, painful degenerative changes.

Bibliography is available at Expert Consult.

674.6 Tarsal Coalition

Jennifer J. Winell and Richard S. Davidson

Tarsal coalition, also known as **peroneal spastic flatfoot**, is characterized by a painful, rigid flatfoot deformity and peroneal (lateral calf) muscle spasm but without true spasticity. It represents a congenital fusion or failure of segmentation between 2 or more tarsal bones. Any condition that alters the normal gliding and rotatory motion of the subtalar joint may produce the clinical appearance of a tarsal coalition. Thus, congenital malformations, arthritis or inflammatory disorders, infection, neoplasms, and trauma can be possible causes.

The most common tarsal coalitions occur at the medial talocalcaneal (subtalar) facet and between the calcaneus and navicular (calcaneonavicular). Coalitions can be fibrous, cartilaginous, or osseous. Tarsal coalition occurs in approximately 1% of the general population and appears to be inherited as an autosomal dominant trait with nearly full penetrance. Approximately 60% of calcaneonavicular and 50% of the medial facet talocalcaneal coalitions are bilateral.

CLINICAL MANIFESTATIONS

Approximately 25% of patients will become symptomatic, typically during the 2nd decade of life. Although the flatfoot and a decrease in subtalar motion may have been present since early childhood, the onset of symptoms may correlate with the additional restriction in motion that occurs as a cartilaginous bar ossifies. Recurrent “ankle sprains” often accompany the presenting symptoms. The timing of ossification varies between the talonavicular (3-5 yr of age), the calcaneonavicular (8-12 yr of age), and the talocalcaneal (12-16 yr of age) coalitions. Hindfoot pain is commonly observed, especially in the region of the sinus tarsi and also under the head of the talus. Symptoms are activity related and are often increased with running or prolonged walking, especially on uneven surfaces. There may be tenderness over the site of the coalition and/or pain with testing of subtalar motion. The clinical appearance of a flatfoot is seen in both the weightbearing and non–weightbearing positions. There is a restriction in subtalar motion.

RADIOGRAPHIC EVALUATION

AP and lateral weightbearing radiographs and an oblique radiograph of the foot should be obtained (Table 674-1). A calcaneonavicular coalition is seen best on the oblique radiograph (Fig. 674-6). On the lateral radiograph, there may be elongation of the anterior process of the calcaneus, known as the “anteater sign.” A talocalcaneal coalition may be seen on a Harris (axial) view of the heel. On the lateral radiograph, there may be narrowing of the posterior facet of the subtalar joint, or a C-shaped line along the medial outline of the talar dome and the inferior outline of the sustentaculum tali (“C sign”). This “C sign” is made up of the sustentaculum talus of the calcaneus in continuity with the coalition. Beaking of the anterior aspect of the talus on the lateral view is seen with some frequency, and results from an alteration in the distribution of stress. This finding does not imply the presence of degenerative arthritis. Irregularity in the subchondral bony surfaces may be seen in patients with a cartilaginous coalition, in contrast to a well-formed bony bridge in those with an osseous coalition. A fibrous coalition may require additional imaging studies to diagnose. While plain films may be diagnostic, a CT scan is the *imaging modality of choice* when a coalition is suspected (Fig. 674-7). In addition to securing the diagnosis, this study helps to define the degree of joint involvement in patients with a talocalcaneal coalition. Although uncommon, more than one tarsal coalition may be observed in the same patient. Only in young children, MRI may be more effective in identifying either the coalition or a differential diagnosis for the foot pain. MRI offers less radiation exposure but requires more time and may necessitate sedation.

TREATMENT

The treatment of symptomatic tarsal coalitions varies according to the type and extent of coalition, the age of the patient, and the presence and magnitude of symptoms. Treatment is required only for symptomatic coalitions, and the initial management consists of activity

Table 674-1	Radiographic Secondary Signs Associated with Tarsal Conditions

restriction and nonsteroidal antiinflammatory medications, with or without a shoe insert. Immobilization in a short leg walking cast for 4-6 wk may be required in patients with more pronounced symptoms. For patients with chronic pain despite an adequate trial of nonoperative therapy, surgical treatment should be considered, and options include resection of the coalition, osteotomy, or arthrodesis. For the calcaneonavicular coalition, resection and interposition of the extensor digitorum brevis muscle have been successful. Often, concomitant hindfoot valgus and contracture of the gastrocnemius-soleus is present. In these patients, more reliable pain relief can be obtained with resection of the coalition, correction of the hindfoot valgus by calcaneal lengthening osteotomy with bank bone graft and lengthening of the gastrocnemius-soleus. For those with extensive involvement of the joint and/or degenerative changes, a triple arthrodesis may be the best option; however, this is rarely needed in adolescents.

Bibliography is available at Expert Consult.

674.7 Cavus Feet

Jennifer J. Winell and Richard S. Davidson

Cavus is a deformity involving plantarflexion of the forefoot or midfoot on the hindfoot and may involve the entire forepart of the foot or just the medial column. The result is an elevation of the medial longitudinal arch (Fig. 674-8). A deformity of the hindfoot will often develop to compensate for the primary forefoot abnormality. While familial cavus may occur, the majority of patients with this deformity will have an underlying neuromuscular etiology. The initial goal is to rule out (and treat) any underlying causes. These diagnoses may relate to abnormalities of the spinal cord (occult dysraphism, tethered cord, polio, myelodysplasia, etc.) and peripheral nerves (hereditary motor and sensory neuropathies [see Chapter 613] such as Charcot-Marie-Tooth [CMT] disease, Dejerine-Sottas disease, or Refsum disease). Although a unilateral cavus foot is most likely to result from an occult intraspinal anomaly, bilateral involvement usually suggests an underlying nerve or muscle disease. Cavus is commonly observed in association with a hindfoot deformity. Two-thirds of CMT patients have pes cavovarus, while 80% of pes cavovarus is most commonly seen in patients with the hereditary motor and sensory neuropathies (CMT), with 80% of CMT patients having pes cavovarus and 65% of patients with cavovarus having CMT. In patients with hereditary motor and sensory neuropathies, progressive weakness and muscle imbalance result in plantarflexion of the 1st ray/medial column. To obtain a plantigrade foot, the hindfoot must roll into varus. With equinocavus, the hindfoot is in equinus, whereas in calcaneocavus (usually seen in polio or myelodysplasia), the hindfoot is in calcaneus (excessive dorsiflexion).

Figure 674-8 Clinical picture demonstrating pes cavus.

TREATMENT

Any underlying diagnosis must be identified as this knowledge also helps to address the specific disorder and formulate the proper management strategy. With mild deformities, stretching through physical therapy or serial casting of the plantar fascia and contracted muscles with exercises to strengthen weakened muscles may help to delay progression. An ankle–foot orthosis may be necessary to stabilize the foot and improve ambulation. Surgical treatment is indicated for progressive or symptomatic deformities that have failed to respond to nonoperative measures or in the foot that is no longer braceable. The specific procedures recommended depend on the degree of deformity and the underlying diagnosis. In the case of a progressive neuromuscular condition, recurrence of deformity is commonly observed, and additional procedures may be required to maintain a plantigrade foot. Families should be counseled in detail regarding the disease process and the expected gains from the surgery. The goal of surgery is to restore motion and alignment and to improve muscle balance. For milder deformities, a soft-tissue release of the plantar fascia, often combined with a tendon transfer, may suffice. For patients with a fixed bony deformity of the forefoot, midfoot and/or the hindfoot, 1 or more osteotomies may be required for realignment. A triple arthrodesis (calcaneocuboid, talonavicular, and subtalar) may be required for severe feet (or recurrent deformities) in older patients. Long-term bracing is usually helpful in preventing recurrence.

674.8 Osteochondroses/Apophysitis

Jennifer J. Winell and Richard S. Davidson

Osteochondroses are idiopathic avascular necrosis of bones which may involve tarsal bones as well. Although rare, they may be observed in the tarsal navicular **(Köhler disease)** or the 2nd or 3rd metatarsal head **(Freiberg infraction)** (Fig. 674-9). These are generally self-limited conditions that commonly result in activity-related pain, which can at times be disabling. The treatment is based on the degree of symptoms and commonly includes restriction of activity. The diagnosis is often made by history and physical exam in conjunction with concordant radiographic findings. The navicular is particularly sensitive

as it is the last tarsal bone to ossify which may lead to compression from adjacent ossified bones. For patients with Köhler disease, nonsurgical treatment with a short leg cast for 6-8 wk may provide significant relief. Patients with Freiberg infraction may benefit from a period of casting and/or shoe modifications such as a rocker-bottom sole, a stiff-soled shoe, or a metatarsal bar. Degenerative changes and collapse of the metatarsal head will occasionally occur following the gradual healing process, and surgical intervention is required in a small subset of cases. Procedures have included joint debridement, bone grafting, redirectional osteotomy, subtotal or complete excision of the metatarsal head, and joint replacement.

Apophysitis represents inflammation at the tendinous insertion of a muscle from repetitive tensile loading and is most commonly observed during periods of rapid growth. These stresses result in microfractures at the fibrocartilaginous insertion site, associated with inflammation. Calcaneal apophysitis **(Sever disease)** is the most common cause of heel pain in children; treatment includes activity modification, nonsteroidal antiinflammatory medications, heel cord stretching exercises, and heel cushions or arch supports. **Iselin disease** represents an apophysitis at the 5th metatarsal base where the peroneus brevis attaches and is less common. Even though the mandate for imaging heel pain in all children remains controversial, radiographs should be considered when the symptoms are unilateral or with a failure to respond to treatment. A period of rest (6-8 wk) and avoidance of sports will often resolve symptoms, although recurrence is common until maturity when the apophyses close.

Bibliography is available at Expert Consult.

674.9 Puncture Wounds of the Foot

Jennifer J. Winell and Richard S. Davidson

Most puncture wound injuries to the foot may be adequately managed in the emergency department. **Treatment** involves a thorough irrigation and a tetanus booster, if appropriate; many clinicians will recommend antibiotics. Using this approach, the majority will heal without a complication. A subset of cases may develop cellulitis, most often caused by *Staphylococcus aureus*, and require intravenous antibiotics with or without surgical drainage. Persistent signs of infection should be investigated more thoroughly. Deep infection is uncommon and may be associated with septic arthritis or osteomyelitis. The most common organisms are *S. aureus* and *Pseudomonas aeruginosa*; the treatment involves a thorough surgical debridement followed by a short course (10-14 days) of systemic antibiotics. Although plain radiographs will demonstrate any metallic fragments or other radiopaque foreign bodies, ultrasonography (or advanced imaging such as CT or MRI) may be necessary to identify radiolucent objects such as glass, plastic, or wood. Routine exploration and removal of foreign bodies is not required, but may be necessary when symptoms are present, with recurrences, or when an infection is suspected. Pain and/or gait disturbance is more likely with superficial objects under the plantar surface of the foot.

A special situation occurs when a puncture wound from a nail comes through a rubber sneaker or running shoe. This situation presents a high risk of a *Pseudomonas* infection, and consideration should be given to a thorough irrigation and debridement under general anesthesia followed by systemic antibiotics for 10-14 days. Foreign-body entrapment of rubber may also occur.

Bibliography is available at Expert Consult.

674.10 Toe Deformities

Jennifer J. Winell and Richard S. Davidson

JUVENILE HALLUX VALGUS (BUNION)

Juvenile hallux valgus is most common in females (~10-fold), and while a family history is uncommon, it is typically associated with familial ligamentous laxity. The etiology is multifactorial, and important factors include genetic factors, ligamentous laxity, pes planus, wearing shoes with a narrow toe box, and occasionally spasticity (cerebral palsy).

Clinical Manifestations

There is prominence of the 1st metatarsophalangeal (MTP) joint and often erythema and callus from chronic irritation. The great toe is in valgus and is usually pronated, and there is splaying of the forefoot. Pes planus, with or without an associated heel cord contracture, is also observed commonly. Although cosmesis is perhaps the most common concern, patients may have pain in the region of the 1st MTP joint and/or difficulty with shoe wear.

Radiographic Evaluation

Weightbearing AP and lateral radiographs of the feet are obtained. On the AP view, common measurements include the angular relationships between the 1st and 2nd metatarsals (intermetatarsal angle, <10 degrees is normal) and between the 1st metatarsal and the proximal phalanx (hallux valgus angle, <25 degrees is normal). The orientation of the 1st metatarsal–medial cuneiform joint is also documented. On the lateral radiograph, the angular relationship between the talus and the 1st metatarsal helps to identify a midfoot break associated with pes planus. Radiographs are more helpful in surgical planning than in establishing the diagnosis.

Treatment

Conservative management of adolescent bunions consists primarily of shoe modifications. It is important that footwear accommodate the width of the forefoot. Patients should avoid wearing shoes with a narrow toe box and/or a high heel. Shoe modifications, such as a soft upper, bunion last, or heel cup, may also be recommended. In the presence of a pes planus, an orthotic to restore the medial longitudinal arch may be beneficial. If a tendo-Achilles contracture is present, stretching exercises are recommended. The value of night splinting remains to be determined. Surgical treatment is reserved for those patients with persistent and disabling pain who have failed a course of nonoperative therapy. Surgery is not advised purely for cosmesis. Surgery is usually delayed until skeletal maturity to decrease the risk of recurrence or overcorrection. Radiographs are essential in preoperative planning to assess both the magnitude of deformity (hallux valgus angle, intermetatarsal angle, distal metatarsal articular angle) and associated features such as obliquity of the 1st metatarsal–medial cuneiform joint. Surgical treatment often involves a soft-tissue release and or rebalancing procedure at the 1st MTP joint, and a single or double osteotomy of the 1st metatarsal to decrease foot width and realign the joints along the medial column of the forefoot. An arthrodesis of the 1st MTP joint may be indicated in patients with spasticity to prevent recurrence.

CURLY TOES

A curly toe is caused by contracture of the flexor digitorum longus, and there is flexion at the MTP and the interphalangeal (IP) joints associated with medial deviation of the toe. The toe usually lies underneath its neighbor, and the 4th and 5th toes are most commonly involved. The deformity rarely causes symptoms, and active treatment (stretching, splinting, or taping) is not required. Most cases improve over time, and a subset will resolve completely. For the rare case in which there is chronic pain or skin irritation, release of the flexor digitorum longus muscle at the distal IP joint may be considered when the child is older.

OVERLAPPING FIFTH TOE

Congenital digitus minimus varus, or varus 5th toe, involves dorsiflexion and adduction of the 5th toe. The 5th toe typically overlaps the 4th. There is also a rotatory deformity of the toe, and the nail tends to point outward. The deformity is usually bilateral and may have a genetic basis. Symptoms are frequent and involve pain over the dorsum of the toe from shoe wear. Nonoperative treatment has not been successful. For symptomatic patients, several different options for reconstruction have been described. Common features include releasing the contracted extensor tendon and the MTP joint capsule (dorsal, dorsomedial, or complete). A partial removal of the proximal phalanx and creation of a syndactyly between the 4th and 5th toes has been performed in conjunction with the release as well.

POLYDACTYLY

Polydactyly is the most common congenital toe deformity and is seen in approximately 2 in 1,000 births and is bilateral in 50% of cases. Polydactyly may be preaxial (great toe) or postaxial (5th toe), and occasionally one of the central toes is duplicated. Associated anomalies are found in approximately 10% of the preaxial and 20% of postaxial polydactyly. One-third of patients will also have polydactyly of the hand. Conditions that may be associated with polydactyly include Ellis-Van Creveld (chondroectodermal dysplasia), longitudinal deficiency of the tibia, and Down syndrome. The extra digit may be either rudimentary or well formed, and plain radiographs of the foot help to define the anatomy and evaluate any coexisting bony anomalies. Treatment is indicated for cosmesis and to allow for fitting with standard shoes. This involves surgical removal of the extra digit, and the procedure is generally performed between 9 and 12 mo of age. Rudimentary digits may be surgically excised earlier, but should not be "tied off."

SYNDACTYLY

Syndactyly involves webbing of the toes, which may be incomplete or complete (extends to the tip of the toes), and the toenails may be confluent. There is often a positive family history, and the 3rd and 4th toes are involved most commonly. Symptoms are extremely rare, and cosmetic concerns are infrequent. Treatment is only required for a subset of cases in which there is an associated polydactyly (Fig. 674-10). In such cases, the border digit is excised, and the extra skin facilitates coverage of the wound. If the syndactyly does not involve the extra toe, then it can be observed. A complex syndactyly may be seen in patients with Apert syndrome.

Figure 674-10 Clinical picture of polysyndactyly involving the great toe.

HAMMER TOE

A hammer toe involves flexion at the proximal IP (PIP) joint with or without the distal IP (DIP) joint, and the MTP joint may be hyperextended. This deformity may be distinguished from a curly toe by the absence of rotation. The 2nd toe is most commonly involved, and a painful callus may develop over the dorsum of the toe where it rubs on the shoe. Nonoperative therapy is rarely successful, and surgery is recommended for symptomatic cases. A release of the flexor tendons will suffice in the majority of cases. Some authors recommend a transfer of the flexor tendon to the extensor tendon. For severe cases with significant rigidity, especially in older patients, a partial or complete resection of the proximal phalanx and a PIP fusion may be required.

MALLET TOE

Mallet toe involves a flexion contracture at the DIP joint and results from congenital shortening of the flexor digitorum longus tendon. Patients may develop a painful callus on the plantar surface of the tuft. As nonoperative therapy is usually unsuccessful, surgery is required for patients with chronic symptoms. For flexible deformities in younger children, release of the flexor digitorum longus tendon is recommended. For stiffer deformities in older patients, resection of the head of the middle phalanx, or arthrodesis of the DIP joint, may be considered.

CLAW TOE

A claw toe deformity involves hyperextension at the MTP joint and flexion at both the PIP and DIP joints, often associated with dorsal subluxation of the MTP joint. The majority are associated with an underlying neurologic disorder such as CMT disease. The etiology is usually muscle imbalance, and the extensor tendons are recruited to substitute for weakening of the tibialis anterior muscle. If treatment is elected, then surgery is required. Transfer of the extensor digitorum (or hallucis) tendon to the metatarsal neck is commonly performed along with a dorsal capsulotomy of the MTP joint and fusion of the fusion of the PIP joint (IP joint of the great toe).

ANNULAR BANDS

Bands of amniotic tissue associated with amniotic disruption syndrome (early amniotic rupture sequence, congenital constriction band syndrome, annular band syndrome) may become entwined along the

Figure 674-11 Constriction band syndrome with congenital amputation.

Figure 674-12 Constriction band syndrome with foot involvement.

extremities, resulting in a spectrum of problems from in utero amputation (Fig. 674-11) to a constriction ring along a digit (Fig. 674-12) (see Chapter 108). These rings, if deep enough, may result in impairment of arterial or venous blood flow. Even though concerns regarding tissue viability are less common, swelling from impairment in venous return is often a great problem. The treatment of annular bands usually involves observation; however, circumferential release of the band may be required emergently if arterial inflow is obstructed or electively to relieve venous congestion.

MACRODACTYLY

Macrodactyly represents an enlargement of the toes and may occur as an isolated problem or in association with a variety of other conditions such as Proteus syndrome (Fig. 674-13), neurofibromatosis, tuberous sclerosis, and Klippel-Trenaunay-Weber syndrome. This condition results from a deregulation of growth, and there is hyperplasia of one or more of the underlying tissues (osseous, nervous, lymphatic, vascular, fibrofatty). Macrodactyly of the toes may be seen in isolation (localized gigantism) or with enlargement of the entire foot. In addition to cosmetic concerns, patients may have difficulty wearing standard shoes. The treatment is observation, if possible. This is a difficult condition to treat surgically, and complications are frequent. For involvement of a single toe, the best option may be a resection of the ray (including the metatarsal). For greater degrees of involvement, debulking of the various tissues is required. Often, a growth arrest of the underlying osseous structures is performed. Stiffness and wound problems are common. The rate of recurrence is high, and more than one

Figure 674-13 Macrodactyly of the great toe in a case of Proteus syndrome.

debulking may be required. Patients may elect to have an amputation if the process cannot be controlled by less extensive procedures.

SUBUNGUAL EXOSTOSIS

A subungual exostosis is a mass of normal bone tissue that projects out from the dorsal and medial surface of a toe, under the nail. The etiology is unknown but may relate to minor, repetitive trauma. The great toe is involved most often. Patients present with discomfort, and the toenail may be elevated. The lesion may be demonstrated on plain radiographs, and histologically involves normal bone with a fibrocartilaginous cap. The treatment for symptomatic lesions is excision, and the recurrence rate is in the range of 10%.

INGROWN TOENAIL

Ingrown toenails are relatively common in infants and young children and usually involve the medial or lateral border of the great toe. Symptoms include chronic irritation and discomfort, and recurrent infection is seen in some cases. Parents should be instructed when cutting toe nails to cut straight across the distal aspect of the nail, rather than curve inwards at the nail edges. If conservative measures including shoe modifications, warm soaks, and appropriate nail trimming fail to control the symptoms, then surgical removal of a portion of the nail should be considered.

radiographs are most helpful in establishing the diagnosis. Occasionally, more sophisticated imaging modalities such as CT or MRI will be required.

674.12 Shoes

Jennifer J. Winell and Richard S. Davidson

In toddlers and children, a well-fitting shoe with a **flexible** sole is recommended. This recommendation is in part based on studies suggesting that the development of the longitudinal arch seems to be best in societies where shoes are not worn and flatfeet are more common in shod children. Well-cushioned, shock-absorbing shoes are helpful in the child and adolescent athlete to decrease the chances of developing an overuse injury. Otherwise, shoe modifications are generally reserved for abnormalities in either alignment between segments of the foot or symptoms from an underlying condition (such as a limb-length discrepancy). Numerous modifications are available.

As a rule, shoes protect the foot from abnormal temperature as well as rough surfaces and sharp objects but have not been shown to help the normal foot develop. Poorly fitting shoes may create problems.

Chapter 675

Torsional and Angular Deformities

675.1 Normal Limb Development

Keith D. Baldwin and Lawrence Wells

Pediatricians must understand normal limb development so as to recognize pathologic conditions during routine and targeted exams. During the 7th wk of intrauterine life, the lower limb rotates medially to bring the great toe toward the midline. The hip joint forms by the 11th wk; the proximal femur and acetabulum continue to develop until physeal closure in adolescence. At birth, the femoral neck is rotated forward approximately 40 degrees. This forward rotation is referred to as anteversion (the angle between the axis of the femoral neck and the transcondylar axis). The increased anteversion increases the internal rotation of the hip. Femoral anteversion decreases to 15-20 degrees by 8-10 yr of age. Conditions such as cerebral palsy that involve spasticity of the lower extremities can result in the persistence of fetal anteversion, which results in torsional abnormalities of the lower limb and gait disturbances. The second source of limb rotation is found in the tibia. Infants can have 30 degrees of medial rotation of the tibia, and by maturity the rotation is between 5 degrees of medial rotation and 15 degrees of lateral rotation (Fig. 675-1). Excessive medial rotation of tibia is referred to as **medial tibial torsion**. This is very common, and although very concerning to parents, very rarely requires treatment. Observation is indicated for most cases of medial tibial torsion. The tibial torsion is the angular difference between the axis of the knee and the transmalleolar axis. The medial or lateral rotation beyond ±2 SDs from the mean is considered abnormal rotation. The third source of rotational (axial) abnormalities of the lower extremity comes from the foot. Metatarsus adductus can cause the toes to point inward, and can be assessed by assessing if the medial border of the foot is straight.

Torsional deformity may be simple, involving a single segment, or complex, involving multiple segments. Complex deformities may be additive (internal tibial torsion and internal femoral torsion are additive) or compensatory (external tibial torsion and internal femoral torsion are compensatory).

The normal tibiofemoral angle at birth is 10-15 degrees of physiologic varus. The alignment changes to 0 degrees by 18 mo, and physiologic valgus up to 12 degrees is reached in between 3 and 4 yr of age. The normal valgus of 7 degrees is achieved by 5-8 yr of age (Fig. 675-2). Persistence of varus beyond 2 yr of age may be pathologic and is seen in conditions such as Blount disease. Overall, 95% of developmental physiologic genu varum and genu valgum cases resolve with growth. Persistent genu valgum or valgus into adolescence is considered pathologic and deserves further evaluation.

Bibliography is available at Expert Consult.

675.2 Evaluation

Keith D. Baldwin and Lawrence Wells

In evaluation of concerns relating to the limb, the pediatrician should obtain a history of the onset, progression, functional limitations, previous treatment, evidence of neuromuscular disorder, and any significant family history.

The examination should assess the exact torsional profile and include (1) foot progression angle, (2) femoral anteversion, (3) tibial version with thigh–foot angle, and (4) assessment of foot adduction and abduction.

FOOT PROGRESSION ANGLE

Limb position during gait is expressed as the foot progression angle and represents the angular difference between the axis of the foot with the direction in which the child is walking. Its value is usually estimated by asking the child to walk in the clinic hallway (Fig. 675-3). Inward rotation of the foot is assigned a negative value, and outward rotation is designated with positive value. The normal foot progression angle in children and adolescents is 10 degrees (range: −3 to 20 degrees). The foot progression angle serves only to define whether there is an in-toeing or out-toeing gait.

FEMORAL ANTEVERSION

Measuring the hip rotation with the child in prone position, the hip in neutral flexion or extension, thighs together, and the knees flexed 90

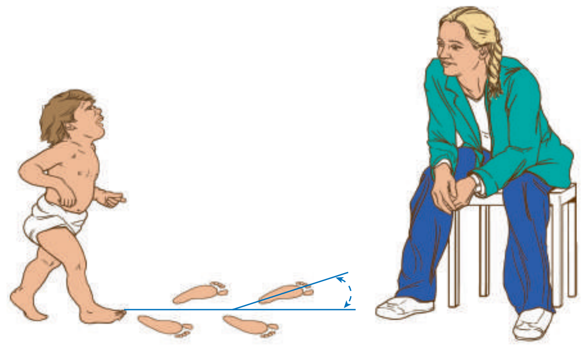

Figure 675-3 **Foot progression angle.** The long axis of the foot is compared with the direction in which the child is walking. If the long axis of the foot is directed outward, the angle is positive. If the foot is directed inward, the angle is negative and indicates in-toeing. *(From Thompson GH: Gait disturbances. In Kliegman RM, editor:* Practical strategies in pediatric diagnosis and therapy*. Philadelphia, 2004, WB Saunders.)*

Figure 675-4 Anteversion measured by medial rotation of hip **(A)** and lateral rotation of hip **(B)**.

degrees indirectly assesses the anteversion (Fig. 675-4). Both hips are assessed at the same time. As the lower leg is rotated ipsilaterally, this produces internal rotation of the hip, whereas contralateral rotation produces external rotation. Excessive anteversion increases internal rotation, and, retroversion increases the external rotation. The amount of anteversion can be roughly estimated by palpating the greater trochanter of the hip while internally rotating the limb. The point of maximal prominence of the greater trochanter corresponds to femoral anteversion.

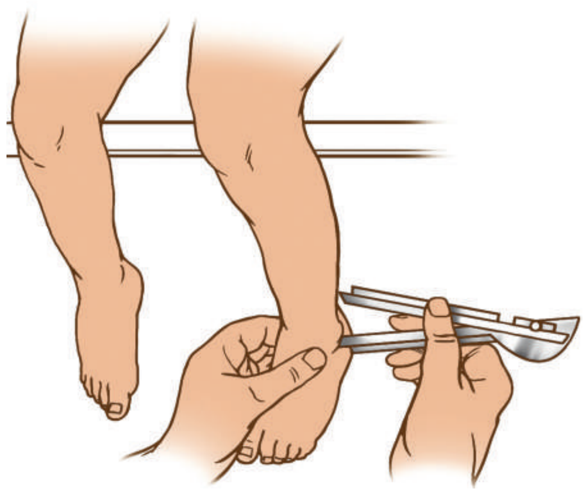

Figure 675-5 The transmalleolar angle is measured with the patient sitting at the edge of the table and the distal femoral condyles aligned with the side of the table. The angle between a line through the medial and lateral malleoli and edge of the table should be approximately 30 degrees external. *(From Bleck EE:* Orthopaedic management in cerebral palsy*, London, 1987, MacKeith Press, p. 55.)*

Figure 675-6 Thigh–foot angle.

TIBIAL ROTATION

Tibial rotation is measured using the transmalleolar angle. The transmalleolar angle is the angle between the longitudinal axis of the thigh with a line perpendicular to the axis of the medial and lateral malleolus (Fig. 675-5). In the absence of foot deformity, the thigh–foot angle is preferred (Fig. 675-6). It is measured with the child lying prone. The angle is formed between the longitudinal axis of the thigh and the longitudinal axis of the foot. It measures the tibial and hindfoot rotational status. Inward rotation is assigned a negative value, and outward rotation is designated a positive value. Inward rotation indicates internal tibial torsion, whereas outward rotation represents external tibial torsion. Infants have a mean angle of −5 degrees (range: −35 to 40 degrees) as a consequence of normal in utero position. In mid-childhood through adult life, the mean thigh–foot angle is 10 degrees (range: −5 to 30 degrees).

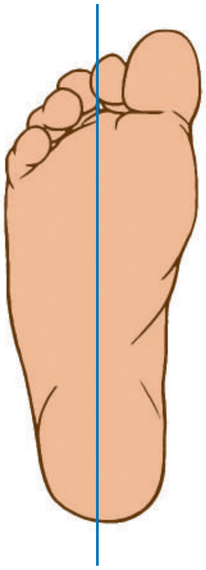

Figure 675-7 Schematic demonstration of heel bisector line.

FOOT SHAPE AND POSITION

The foot is observed for any deformities in prone and standing position. The heel bisector line (HBL) is used to evaluate the foot adduction and abduction deformities. The HBL is a line that divides the heel in 2 equal halves along the longitudinal axis (Fig. 675-7). It normally extends to the 2nd toe. When the HBL points medial to the 2nd toe, the forefoot is abducted, and when the HBL is lateral to the 2nd toe, the forefoot is adducted. Other lower-extremity problems, such as heel varus or valgus, can also make assessment of axial plane issues more difficult.

It is also important to screen every affected child for associated hip dysplasia and neuromuscular problems (cerebral palsy).

Bibliography is available at Expert Consult.

675.3 Torsional Deformities

Keith D. Baldwin and Lawrence Wells

INTERNAL FEMORAL TORSION

In-toeing gait most commonly results from excessive femoral anteversion. It occurs more commonly in girls than boys (2 : 1) in children 3-6 yr of age. The etiology of femoral torsion is controversial. Some believe that it is congenital and a result of persistent infantile femoral anteversion, whereas others believe it is acquired secondary to abnormal sitting habits. Some children are in habit of sitting in a W position or sleeping prone. On examination, most children with this condition have **generalized ligamentous laxity**. Gait examination reveals that entire leg is inwardly rotated. Internal hip rotation is increased beyond 70 degrees, and consequently the external rotation is restricted to 10-20 degrees. The patellas are pointing inward when the foot is straight, and compensatory external rotation of the tibia is demonstrated. The amount of anteversion can be roughly estimated by palpating the greater trochanter of the hip while internally rotating the limb. The point of maximal prominence of the greater trochanter corresponds to femoral anteversion.

Diagnosis is made clinically on examination; CT can provide objective measurements but is rarely indicated. The treatment is predominantly observation and correction of abnormal sitting habits. The torsion usually corrects with growth by 8-10 yr of age. Persistent deformity, unacceptable cosmesis, functional impairment, anteversion >45 degrees, and no external rotation beyond neutral are some of the indications for operative intervention. Surgery involves derotation osteotomy of the femur but is rarely performed or necessary.

INTERNAL TIBIAL TORSION

Medial (internal) tibial torsion manifests with **in-toeing gait** and is commonly associated with congenital metatarsus varus, genu valgum, or femoral anteversion. This condition is usually seen during the 2nd yr of life. Normally at birth, the medial malleolus lies behind the lateral malleolus, but by adulthood, it is reversed, with the tibia in 15 degrees of external rotation. The treatment is essentially observation and reassurance, because spontaneous resolution with normal growth and development can be anticipated. Significant improvement usually does not occur until the child begins to pull to stand and walk independently. Thereafter, correction can be seen as early as 4 yr of age and in some children by 8-10 yr of age. Persistent deformity with functional impairment is treated with supramalleolar osteotomy, which is rarely necessary.

EXTERNAL FEMORAL TORSION

External femoral torsion can follow a **slipped capital femoral epiphysis**; there is a low threshold to perform radiographs of the hips in children older than 10 yr of age. Femoral retrotorsion, when of idiopathic origin, is usually bilateral. The disorder is associated with an **out-toeing gait** and increased incidence of degenerative arthritis. The clinical examination of external femoral torsion shows excessive hip external rotation and limitation of internal rotation. The hip will externally rotate up to 70-90 degrees, whereas internal rotation is only 0-20 degrees. If slipped capital femoral epiphysis is detected, it is treated surgically. Occasionally, persistent femoral retroversion after slipped capital femoral epiphysis can produce functional impairment such as a severe out-toeing gait and difficulty opposing one's knees in the sitting position. The latter can be disabling to adolescent girls. Should this occur, a Southwick osteotomy or surgical realignment might be necessary.

EXTERNAL TIBIAL TORSION

Lateral tibial torsion is less common than medial rotation and is often associated with a **calcaneovalgus foot**. It can be compensatory to persistent femoral anteversion and idiopathic or secondary to a tight iliotibial band. The natural growth rotates the tibia externally, and hence external tibial torsion can become worse with time. Clinically, the patella faces outward when the foot is straight. The thigh–foot angle and the transmalleolar angle are increased. There may be associated patellofemoral instability with knee pain. Though some correction can occur with growth, extremely symptomatic children need supramalleolar osteotomy, which is usually done by 10-12 yr of age.

METATARSUS ADDUCTUS

Metatarsus adductus (see Chapter 674.1) manifests with forefoot adduction and inversion of all metatarsals. Ten percent to 15% are associated with hip dysplasia. The prognosis is good, because the majority get better with nonoperative intervention. The feet, which are flexible and correctable up to neutral, are treated with stretching exercises. Those that are not completely correctable are treated with serial casting. Rigid deformities, which are not correctable by stretching, are treated with medial capsulotomy of the 1st metatarsal cuneiform joint and soft-tissue release by 2 yr of age. Osteotomies of the base of the metatarsal may be performed after 6 yr of age.

knee angle. Tibial bowing is common during the 1st yr, bowlegs are common during the 2nd yr, and knock-knees are most prominent between 3 and 4 yr of age.

GENU VARUM

Physiologic bowleg is a common torsional combination that is secondary to normal in utero positioning (Fig. 675-8). Spontaneous resolution with normal growth and development can be anticipated. Persistence of varus beyond 2 yr of age may be pathologic. The different causes are metabolic bone disease (vitamin D deficiency, rickets, hypophosphatasia), asymmetric growth arrest (trauma, infection, tumor, Blount), bone dysplasia (dwarfism, metaphyseal dysplasia), and congenital and neuromuscular disorders (Table 675-1). It is prudent to differentiate physiologic bowing from Blount disease (Table 675-2). Physiologic bowing should also be differentiated from rickets and skeletal dysplasia. Rickets has classic bone changes with trumpeting widening and fraying of the metaphysis and widening of the physis (see Chapter 51).

Normal appearance of the proximal tibial growth plate	Medial sloping of the epiphysis Widening of the physis Fragmentation of the metaphysis
No significant lateral thrust	Significant lateral thrust

TIBIA VARA

Idiopathic tibia vara, or **Blount disease**, is a developmental deformity resulting from abnormal endochondral ossification of the medial aspect of the proximal tibial physis leading to varus angulation and medial rotation of the tibia (Fig. 675-9). The incidence is greater in African-Americans and in toddlers who are overweight, have an affected family member, or started walking early in life. It has been classified into 3 types, depending on the age at onset: infantile (1-3 yr of age), juvenile (4-10 yr of age), and adolescent (11 yr or older). The juvenile and adolescent forms are commonly combined as late-onset tibia vara. The exact cause of tibia vara remains unknown, although it is thought to involve abnormal growth resultant from excessive weight.

The infantile form of tibia vara is the most common; its characteristics include predominance in black females, approximately 80% bilateral involvement, a prominent medial metaphyseal beak, internal tibial torsion, and leg-length discrepancy (LLD). The characteristics of the juvenile and adolescent forms (late onset) include predominance in black males, normal or greater than normal height, approximately 50% bilateral involvement, slowly progressive genu varum deformity, pain rather than deformity as the primary initial complaint, no palpable proximal medial metaphyseal beak, minimal internal tibial torsion, mild medial collateral ligament laxity, and mild lower extremity length discrepancy. The infantile group has the greatest potential for progression.

An anteroposterior standing radiograph of both lower extremities with patellas facing forward and a lateral radiograph of the involved extremity should be obtained (Fig. 675-10). Weightbearing radiographs are preferred and allow maximal presentation of the clinical deformity. The metaphyseal–diaphyseal angle can be measured and is useful in distinguishing between physiologic genu varum and early tibia vara (Fig. 675-11). Langenskiöld has 6 stages on radiographs (Fig. 675-12). The differentiation is based on fragmentation of the epiphysis, beaking of the medial tibial epiphysis, depression of the medial tibial plateau, and formation of a bony bar. Occasionally, CT with 3-dimensional reconstructions, or MRI, may be necessary to assess the meniscus, the articular surface of the proximal tibia including the posteromedial slope, or the integrity of the proximal tibial physis.

Management is based on the stage of the disease, the age of the child, and nature of presentation (primary or recurrent deformity). In children younger than 3 yr and Langenskiöld stage <3, bracing is effective and can prevent progression in 50% of these children. A maximal trial of 1 yr of orthotic management is recommended. If complete correction is not obtained after 1 yr or if progression occurs during this

time, a corrective osteotomy may be indicated. Surgical treatment is also indicated in children >4 yr of age, those at Langenskiöld stage >3, and those with severe deformities. A proximal tibial valgus osteotomy and associated fibular diaphyseal osteotomy are usually the procedures of choice. In late-onset tibia vara, correction is also necessary to restore the mechanical axis of the knee. Hemiplateau elevation with correction of posteromedial slope has also been established as a treatment modality in relapsed cases.

GENU VALGUM (KNOCK-KNEES)

The normal valgus is achieved by 4 yr of age. Variation up to 15 degrees of valgus is possible until 6 yr of age, and thus physiologic valgus has a good chance of correction until this age. The intermalleolar distance with the knees approximated is normally <2 cm, and in a severe valgus deformity it could measure >10 cm. Pathologic conditions leading to valgus are metabolic bone disease (rickets, renal osteodystrophy), skeletal dysplasia, posttraumatic physeal arrest, tumors, and infection. The increased valgus at the knee causes lateral deviation of the mechanical axis with stretching of the medial aspect of the knee leading to knee pain. Deformities >15 degrees and occurring after 6 yr of age are unlikely to correct with growth and require surgical management. In the skeletally immature, medial tibial epiphyseal hemiepiphysiodesis or stapling (guided growth) is attempted for correction. In the skeletally mature, osteotomy is necessary at the center of rotation of angulation and is usually situated in the distal femur. Long-length anteroposterior radiographs of the leg in a weight-bearing stance are necessary for preoperative planning.

675.5 Congenital Angular Deformities of the Tibia and Fibula

Keith D. Baldwin and Lawrence Wells

POSTEROMEDIAL TIBIAL BOWING

Congenital posteromedial bowing is typically associated with a calcaneovalgus foot and rarely with secondary valgus of the tibia. The exact cause is unknown. Early operative intervention is not indicated because this bowing generally corrects with growth. However, despite the correction of angulation, there is residual shortening in the tibia and fibula. The mean growth inhibition is 12-13% (range: 5-27%). The mean LLD at maturity is 4 cm (range: 3-7 cm). The diagnosis of bowing is confirmed on radiographs, which show the posteromedial angulation without any other osseous abnormalities. The calcaneovalgus deformity of the foot improves with stretching or modified shoe wear and occasionally ankle-foot orthosis. Predicted LLD <4 cm is managed with age-appropriate epiphysiodesis of the normal leg. LLD >4 cm is managed with combination of contralateral epiphysiodesis and ipsilateral lengthening. A corrective osteotomy for distal valgus may be required and can be done in the same setting while correcting LLD.

ANTEROMEDIAL TIBIAL BOWING (POSTAXIAL HEMIMELIA)

Fibular hemimelia is the most common cause of anteromedial bowing of the tibia. The fibular deficiency can occur with complete absence of fibula or a partial development both proximally and distally. It is associated with deformities of femur, knee, tibia, ankle, and foot. The femur is short and has lateral condylar hypoplasia, causing patellar instability and genu valgum deformity. The tibia has anteromedial bowing with reduced growth potential. The keys for management are the ankle stability and foot deformities. The ankle resembles a ball-and-socket joint with lateral instability. The foot deformities are characterized by the absence of lateral digits, equinocavovarus foot, and tarsal coalition.

Various surgical options have been described, and the treatment is tailored to the patient's needs and parents' acceptance. A severely deformed foot could be best managed with Syme or Boyd amputation, with prosthesis as early as 1 yr of age. In the salvageable foot, LLD can be treated with contralateral leg epiphysiodesis or ipsilateral limb lengthening.

ANTEROLATERAL TIBIAL BOWING

Anterolateral tibial bowing is associated with congenital pseudarthrosis of tibia. Fifty percent of the patients have neurofibromatosis, but only 10% of the neurofibromatosis patients have this lesion. The pseudarthrosis or site of nonunion is typically situated at the middle third and distal third of the tibia. Boyd has classified it in increasing severity depending on the presence of cystic and dysplastic changes. The treatment for this condition has been very frustrating, with poor results. Bracing has been recommended to prevent fracture early in the course; however, it has not been successful. Numerous surgical interventions have been attempted to achieve union, such as single- and dual-onlay grafting with rigid internal fixation, intramedullary pinning with or without bone grafting, and an Ilizarov device. With the advent of microsurgery, live fibular grafts have been used with varying results. Because of the poor chances of successful union and considerable LLD, a below-knee amputation with early rehabilitation may be preferred. It is important not to attempt any osteotomy for correction of the tibial bowing.

TIBIAL LONGITUDINAL DEFICIENCY

Tibial longitudinal deficiency follows an autosomal dominant inheritance pattern and has been divided into four types depending on the deficient part of the tibia. The other associated anomalies are foot deformities, hip dysplasia, and symphalangism of the hand. The treatment revolves around presence of proximal tibial anlage and a functional quadriceps mechanism. In type Ia deformity, the proximal tibial anlage is absent and knee disarticulation with prosthesis is recommended. In types Ib and II, the tibial anlage is present and the management consists of an early Syme amputation, followed later by synostosis of the fibula with the tibia, and a below-knee prosthesis. Type III is rare and the principal management is with Syme amputation and a prosthesis. Type IV deformity is associated with ankle diastasis, which requires stabilization of the ankle and correction of LLD at a later stage.

Chapter 676

Leg-Length Discrepancy

Richard S. Davidson

A discrepancy in the leg lengths may result from a variety of congenital or acquired conditions (Table 676-1). Although up to 25% of the American public may have a difference of more than 1 cm, only a small percentage have more than a 2 cm difference. The main consequence is gait asymmetry. An increase in vertical pelvic motion is observed, and more energy must be expended during ambulation. Although a small compensatory lumbar curvature may develop, there is little evidence to suggest that leg-length discrepancy results in back pain, structural scoliosis, or degenerative arthritis. The goal of treatment is to have a discrepancy of <2-2.5 cm at skeletal maturity, and a variety of treatment methods are available to achieve this objective. Knowledge of the underlying etiology, coupled with regular follow-up to assess limb growth and skeletal maturity, allows the treating physician to project the discrepancy at skeletal maturity and to plan treatment. A subset of patients will have coexisting abnormalities in the viscera or musculoskeletal system, which must be identified and treated as well.

DIAGNOSIS AND CLINICAL FINDINGS

Gait asymmetry is the most frequent complaint. The long leg is often kept flexed in stance to level the pelvis. The diagnosis is made on physical examination, and specialized radiographs help to quantify the existing discrepancy and predict what the discrepancy will be at maturity The discrepancy may be caused by hypoplasia, hyperplasia, or angular deformity (structural discrepancy), by soft-tissue contracture at the hips, knees, or ankles (apparent or functional shortening), or by a combination of these conditions. Other contributing factors include joint subluxation or dislocation (hip), a decrease in the height of the foot (congenital or neuromuscular) or structural disorders of the pelvis. A careful physical examination is required to identify all factors contributing to the discrepancy. Muscle contracture about the hip will also create the appearance of leg-length inequality. For example, to bear weight on an abducted hip, the patient must hike up the contralateral hip and pelvis, making the contralateral leg appear short.

There are several clinical methods for measuring limb length. Our preference is to perform a standing examination, in which blocks of various sizes are placed under the short leg until the pelvis is leveled (Fig. 676-1). An alternate method is to measure the length of each leg with the patient supine by the Galiazzi and Alis tests. The traditional method of using a tape measure is very inaccurate because of, for example, the line of measurement used, muscle atrophy, and moving patients. The range of motion at the hip, knee, and ankle must be also assessed to identify any causes of apparent discrepancy. A 10 degree fixed abduction (or adduction) contracture of the hip will create an apparent leg-length discrepancy of 2-3 cm. Similarly, a flexion contracture of the hip and/or knee will create apparent shortening of the extremity, while an equinus contracture at the ankle will create apparent lengthening of the extremity. A rigid lumbar scoliosis (suprapelvic contracture) will create pelvic obliquity and an associated limb length inequality. Once a discrepancy is quantified, it must be followed at regular intervals until maturity. Assessments at 6-12 mo intervals are most common.

RADIOGRAPHIC EVALUATION

The radiologic evaluation complements the clinical examination; both are typically employed when making treatment decisions. Five

Figure 676-1 Examination with blocks under short leg until the pelvis is squared.

different techniques are available. The ***teleoroentgenogram*** is a single radiographic exposure of both lower extremities (standing) and requires a long cassette. A ruler is placed on the film, and direct measurements are made, factoring in a 6% magnification error. One advantage is that angular deformities may be assessed. Its primary indication is for young children. Unfortunately, as only one exposure is used for the leg and as the ankle is less dense than the hip, it may be difficult to "see" the whole leg. Additionally, because the x-ray source is at the knee projecting up to the hip and down to the ankle, this method projects the hip and ankle along the ruler making the leg appear longer than it really is, particularly in obese patients. The ***orthoroentgenogram*** consists of 3 separate exposures of the hips, knees, and ankles on a long cassette. The patient is supine, and a ruler is placed on the cassette for measurement of bone length. However, the patient must lie still for the 3 exposures, which is often difficult to achieve in younger children. Because the x-ray beam is pointed at the hip, knee, and ankle in each of the 3 exposures, the length measurement is accurate and each of the 3 joints can be exposed properly. The x-rays expose from the top of the pelvis to the mid femur, from the mid femur to the mid tibia, and from the mid tibia to below the foot for each of the 3 exposures, respectively, permitting angular deformity assessment in the frontal plane only. The ***scanogram*** also consists of separate exposures of the hips, knees, and ankles on a cassette with a radiographic ruler; a chest sized film cassette is used (Fig. 676-2). There is no magnification error; patients must remain still for the 3 exposures, and angular deformities cannot be assessed. While ***CT*** is an accurate technique, the assessment is time-consuming, and the technique is not available in most centers. Additionally a radiologist must normalize the axis of the leg to the screen to accurately measure the limbs. Another technique, called ***EOS***, employs a 3D, low-dose ($\frac{1}{7}$ to $\frac{1}{10}$ the radiation) scanner but requires a sophisticated radiologist to correctly align the limbs for computer measurement. Regardless of the technique it is critical that the patellae be pointed forward, that measurements be made in the plane of the limb, and that the same method be used in sequential measurements to be compared.

In the presence of flexion or extension deformities, each bone should be x-rayed individually with a ruler where the x-ray beam is perpendicular to the bone and the ruler parallel to the bone.

In addition to quantifying the discrepancy, it is essential to determine skeletal age (bone age). An anteroposterior radiograph of the hand and wrist is usually obtained at each visit and compared with the standards in the Greulich and Pyle Atlas to estimate skeletal age. While more accurate techniques are available, most are time-consuming and impractical for routine clinical application. The range of variability using the atlas is approximately 9 mo, so the method is most accurate when multiple data points have been collected.

Figure 676-2 Scanogram to demonstrate exact leg-length discrepancy.

TREATMENT

Options for treatment include observation, a shoe lift or custom orthosis, a limb-shortening procedure (acute shortening and internal fixation vs gradual shortening by growth arrest or guided growth), a limb-lengthening procedure (with internal or external fixation), or a combination of these. Deformity correction is often accomplished simultaneously. In the congenital deficiencies (femur, tibia, fibula) in which the predicted limb-length inequality will require more than 3 lengthening operations (more than 20 cm), an early foot amputation may be the best option to achieve an optimal functional outcome. In addition to the magnitude of discrepancy predicted at skeletal maturity, both the anticipated adult height of the patient (estimated from family members) and the desires of the patient and the patient's family are important considerations.

Discrepancies of up to 2.5 cm may be treated by observation or a shoe lift. Up to 1 cm may be placed within the shoe, and up to 5 cm may be placed on the outside of the shoe. Complete correction of inequality is not required, and the height of the lift should be adjusted based on the patient's gait and comfort. An orthotic may be used as a temporizing measure prior to definitive treatment. For extended discrepancies, "foot in foot" prostheses are a reasonable alternative until limb length can be accomplished or for patients who cannot or do not wish to undergo surgical correction.

For patients with a discrepancy between 2 and 5 cm, an **epiphysiodesis** is offered in skeletally immature patients, and an acute shortening may be performed in a skeletally mature patient. Epiphysiodesis refers to a temporary or permanent cessation of growth at 1 or more physes. A permanent growth arrest is most commonly performed as long as sufficient data are available with which to accurately predict when to perform the procedure. Approximately 65% of the growth of the lower extremity comes from the distal femur (37%, 9 mm/yr) and proximal tibia (28%, 6 mm/yr). Males typically grow until 16 yr of age, whereas females grow until 14 yr of age. As such, performing an epiphysiodesis of both the distal femur and the proximal tibia in a patient with 3 yr of growth remaining should achieve approximately 4.5 cm of correction. Techniques used to determine the timing of epiphysiodesis are the Menelaus method ("rule of thumb"), the Green and Anderson method, the Moseley straight-line graph, and the multiplier method (Figs. 676-3, 676-4, and 676-5). The most common surgical technique is the percutaneous epiphysiodesis, in which the physis is ablated with a drill and curette under image intensification. This is an outpatient procedure with few complications. Insertion of plates and screws or just screws across the physis is an alternative but usually requires a second operation to remove the hardware. For patients for whom sufficient data are unavailable or those for whom the underlying diagnosis is associated with an unpredictable pattern of growth, then a reversible technique, such as staples, plates, and/or screws, may be considered. Once equalization has been achieved, the hardware can be removed, allowing growth to resume. When the patient is skeletally mature or if it is deemed appropriate to wait until maturity before treatment, acute shortening may be the best option. Acute shortening is typically performed at the femur (several techniques have been described), given the increased risk of complications (compartment syndrome, neurovascular problems) associated with shortening of the tibia and fibula.

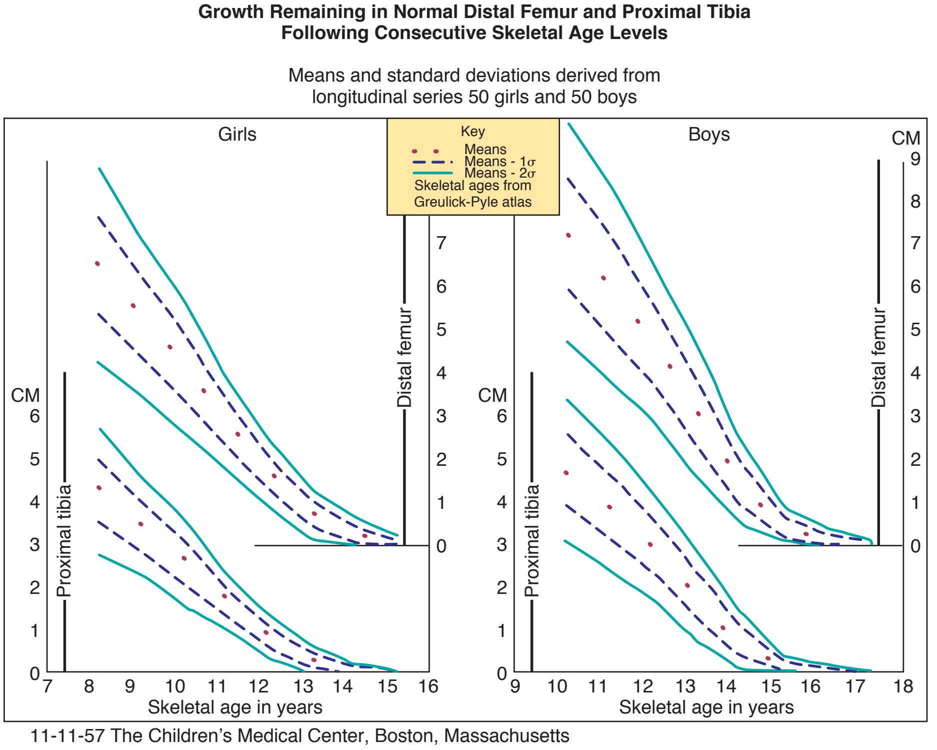

Figure 676-3 **Growth remaining charts for girls and boys.** The growth remaining charts for girls and boys are different. Actual correction is based on growth of the short limb. To use the chart correctly, the discrepancy at maturity and the percentage of growth retardation of the short limb should be calculated. *(Redrawn from Anderson M, Green WT, Messner MB: Growth and predictions of growth in lower extremities.* J Bone Joint Surg Am *45:1–4, 1963.)*

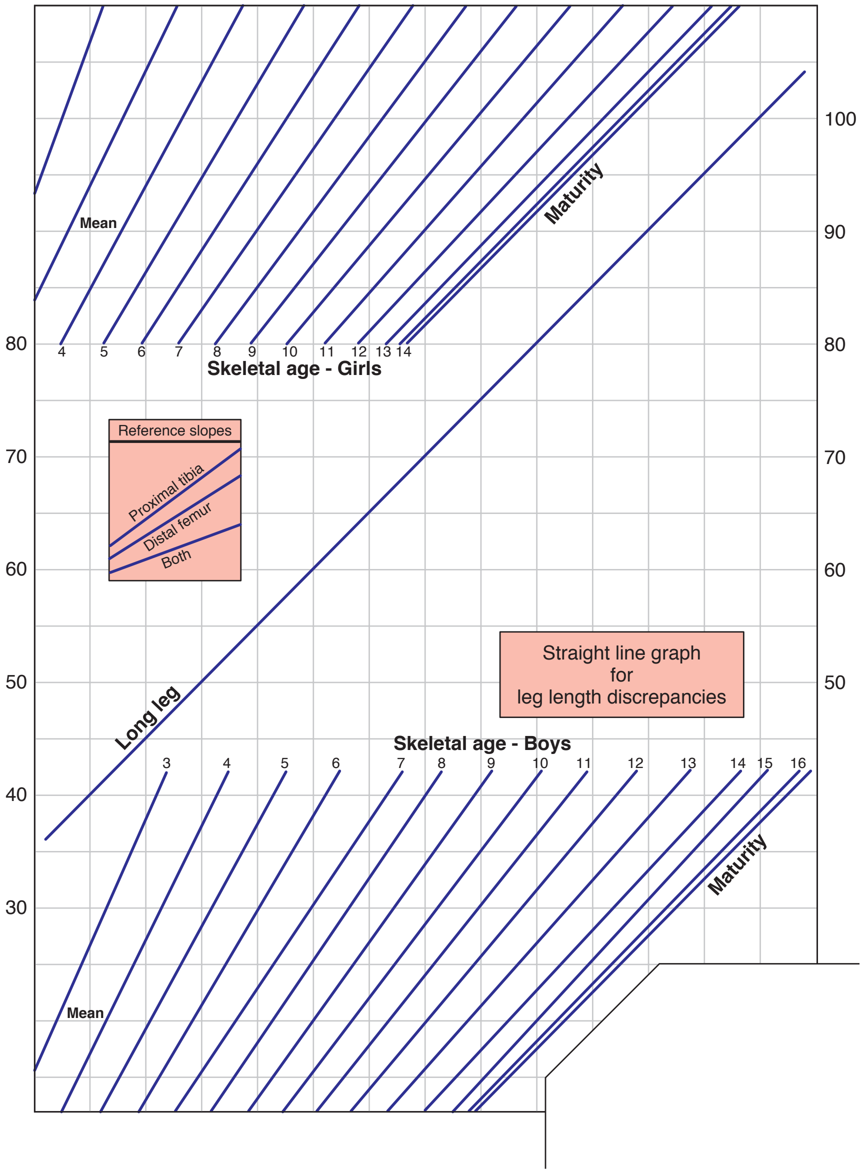

Figure 676-4 **The Moseley straight-line graph for the assessment of leg-length inequalities.** This allows simultaneous correlation of the normal leg, short leg, and bone age of the child. It will accurately predict lengths of each extremity at skeletal maturity. The reference slopes are used as a guide in determining when appropriate treatment should be performed. *(From Moseley CF: A straight-line graph for leg-length discrepancies.* J Bone Joint Surg Am *59:174–179, 1977.)*

Multiplier for Boys and Girls (Paley et al, 1999)

LLD Prediction Formulas

Prenatal LLD (congenital)
$\Delta_m = \Delta \times M$

Postnatal LLD (developmental)
$\Delta_m = \Delta + I \times G$

Inhibition $\approx I = 1 - \frac{S - S'}{L - L'}$

Growth remaining $= G = L(M - 1)$

Δ_m = LLD at maturity

Δ = Current LLD

L & S = Current length of long and short leg

L' & S' = Length of long and short leg at any other date since LLD began

Figure 676-5 Paley multiplier. This is a simple method of determining the leg-length discrepancy (LLD) at maturation. This is applicable for shortening conditions in which growth retardation is consistent. *(From Paley D, Bhave A, Herzenberg JE, Bowen JR: Multiplier methods for predicting limb-length discrepancy.* J Bone Joint Surg Am *82;1432–1446, 2000.)*

Figure 676-6 Ilizarov device demonstrating bone lengthening by distraction osteogenesis.

For discrepancies >5 cm, lengthening of the short limb is the procedure of choice. An exception would be a discrepancy secondary to overgrowth of 1 limb, in which limb shortening would be preferred so as to preserve body proportions, for which acute or gradual shortening of the abnormal limb is preferred. Patients with anticipated discrepancies greater than 8-10 cm often require 1 or more limb-lengthening procedures (several years apart) with or without an epiphysiodesis. The most common technique used for limb lengthening involves placement of an external fixator, either a ring fixator such as the Ilizarov device or a monolateral device (Fig. 676-6). The bone is cut at the metaphyseal–diaphyseal junction, and lengthening is achieved gradually through distraction at the corticotomy. The usual rate of lengthening is 1 mm/day, and it takes approximately 1 mo wearing the fixator for each centimeter of length gained with a minimum of 3 mo in the fixator. Additional time in the fixation may be required for pathologic bone or for metabolic diseases affecting bone formation. A maximum of 15-25% of the original length of the bone may be gained at each session. An advantage of the circular fixator or multiaxial external fixators is the ability to correct coexisting angular deformities at the same time. Technologic advances have allowed the development of intramedullary lengthening and compression rods driven by external magnets. These may provide improvements in patient satisfaction and reduced complications.

Complications include pin tract infection (most common), wound infection, hypertension, joint subluxation, muscle contracture, premature consolidation, delayed union, implant-related problems, and fractures after implant removal. Finally, early amputation and prosthetic fitting may provide the best long-term function in patients with projected discrepancies in excess of 18-20 cm, especially when there are coexisting deformities or deficiencies of the ipsilateral foot (Figs. 676-7 and 676-8). The alternative would be multiple reconstructive procedures throughout childhood and adolescence. The impact of multiple procedures on the child's psychosocial development must also be kept in mind when formulating the treatment plan in these complex cases.

Chapter 677
The Knee

Eric J. Sarkissian and J. Todd R. Lawrence

NORMAL DEVELOPMENT OF THE KNEE

The knee, a major synovial joint, forms between the 3rd and 4th mo of fetal development, with secondary ossification centers forming between the 6th and 9th fetal mo at the distal femur and between the 8th fetal mo and the 1st postnatal mo at the proximal tibia. The patellar ossification center appears between the ages of 2 and 4 yr in girls and 3 and 5 yr in boys.

ANATOMY AND RANGE OF MOTION

The knee is the largest joint in the body and acts primarily as a modified hinge. The distal femur is cam shaped with the medial and lateral femoral condyles having slightly different shapes. This allows for a posterior gliding motion of the femur on the tibial plateau to occur during knee flexion. This also permits about 8-12 degrees of rotation through the flexion and extension arc. The normal range of motion of the knee is from neutral (or fully straight) to 140 degrees of flexion. Increased ligament laxity including hyperextension of up to 10-15 degrees can be normal in many children. Most activities can be performed in the flexion arc of 0-70 degrees.

The knee consists of three articulations: *patellofemoral*, *tibiofemoral*, and *tibiofibular*. The anterior and posterior cruciate ligaments as well as medial and lateral collateral ligaments stabilize the knee during movement. The medial and lateral menisci provide support under compressive forces, helping to redistribute the forces from the more rounded distal femur to the more flat proximal tibia. The medial patellofemoral ligament is the primary static soft-tissue restraint against lateral patellar displacement. There are also several bursae located about the knee to cushion and reduce friction on tendons acting across the knee joint.

677.1 Discoid Lateral Meniscus

Eric J. Sarkissian and J. Todd R. Lawrence

Discoid lateral meniscus (DLM) is a congenital anatomic variation of the lateral meniscus that may be asymptomatic or cause the classic *snapping knee syndrome*. Because of asymptomatic cases, the true incidence is difficult to determine, but it is estimated to occur in 3-5% of children and adolescents. Up to 25% of DLM cases may be bilateral. Previously thought to result from a failure of an embryologic sequence of degeneration at the center of the meniscus, discoid menisci have been subsequently shown to not be the developmental precursors for normal menisci.

Anatomically, the normal meniscus (Fig. 677-1*A*) is attached around its periphery and at the tips of the C anteriorly and posteriorly onto the tibia. During knee motion, the meniscus translates anteriorly and posteriorly to match the slight rollback of the lateral femoral condyle on the tibia with knee flexion. However, with a DLM, the meniscal tissue trapped between the articular surfaces is pushed anteriorly as the knee flexes. These abnormal forces, over time, result in tears in the meniscal tissue or in the posterior attachments, creating excessive meniscal displacement anteriorly during knee flexion. This produces a pop when flexing, usually at about 90-120 degrees of knee flexion as the meniscus is extruded anteriorly, and a loud click or clunk when extending the knee, usually in the last 30 degrees of extension, as the meniscus reduces back between the joint surfaces.

There are 3 types of DLM, according to the widely used **Watanabe classification**. Type I, or **complete, most commonly produces symptoms and** is characterized by a thickened lateral meniscus with complete coverage of the tibial surface (see Fig. 677-1*B*). Meniscus tissue is always between the joint surfaces. **Type II,** or incomplete, is of variable size and covers a lower percentage of the tibial surface (see Fig. 677-1*C*) compared to the complete type. Although they can become stretched or torn over time, both the complete and the incomplete types are thought to develop with normal peripheral attachments. Type III, or the Wrisberg ligament type, is a lateral meniscus with no peripheral attachments posteriorly. Instead it is stabilized posteriorly by a prominent meniscofemoral ligament, or ligament of Wrisberg, that secures the posterior horn of the lateral meniscus to the lateral surface of the medial femoral condyle (see Fig. 677-1*D*). As a result, the Wrisberg ligament type DLM is extremely mobile. Although its shape is not necessarily discoid, the hypermobility of the posterior portion of the meniscus allows it to be extruded anteriorly with flexion and for it to pop back in place with extension, as is characteristic of the other DLM variants.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The complete and incomplete types of DLM can be asymptomatic, especially if they have stable peripheral attachments. A symptomatic DLM in early childhood is usually caused by a meniscal tear or absent peripheral attachments allowing for the anterior extrusion during flexion and reduction with extension, producing the classical **snapping knee**. These patients can present as early as 2 yr of age, but more commonly present after approximately 6 yr of age; most patients present with symptoms during their teenage years. As these patients gain weight with their adolescent growth spurt, they place increasing static and dynamic loads on the tissue, often with high-level sports. Degeneration in the central portion of the DLM with direct weight bearing makes the meniscus highly susceptible to injury and tears, producing lateral pain and swelling in the knee. Often, the classic popping is not appreciated in these patients.

Younger children usually present with no history of trauma or acute inciting event and with a complaint of popping in the knee with

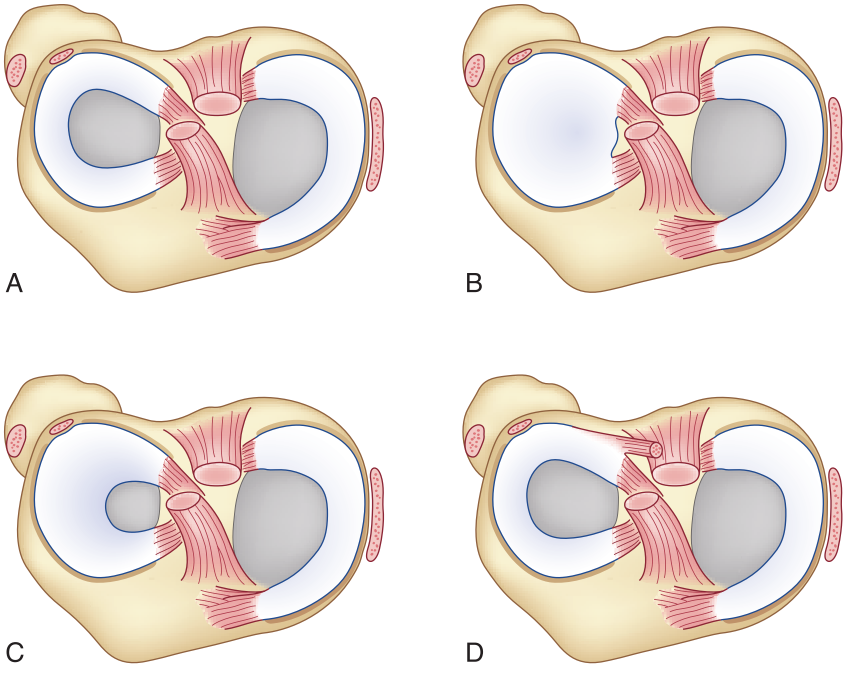

Figure 677-1 The anatomy of the normal meniscus and discoid variants. **A,** The lateral meniscus normally has a C shape with circumferential and root attachments. **B,** A type I, or complete, discoid lateral meniscus covers the entire tibial plateau and has normal attachments. **C,** A type II, or incomplete, discoid lateral meniscus partially covers the tibial plateau and also has normal attachments. **D,** A type III, or Wrisberg ligament type, appears similar in shape to a normal lateral meniscus but lacks sufficient attachments posteriorly resulting in a hypermobile meniscus. The ligament of Wrisberg secures the posterior horn of the meniscus to the lateral aspect of the medial femoral condyle.

occasional swelling. Older children and adolescents often can recall an inciting event and will sometimes report the mechanical popping, but more often note the lateral joint line pain and knee swelling. Physical examination might show a mild effusion and tenderness over the lateral joint line. With knee flexion, a pop with a slight protuberance along the lateral joint line anteriorly can sometimes be appreciated as the meniscus is extruded anteriorly. As the knee is brought back into extension at approximately 20-30 degrees short of full extension, the meniscus can be felt to snap back into the joint and the protuberance at the lateral joint line disappears.

A high index of suspicion is necessary based on history and clinical exam findings. Standard anteroposterior, lateral, merchant (patellar), and 45 degrees flexed posteroanterior (tunnel) views should be obtained if this diagnosis is considered. Radiography of the knee may show widening of the lateral aspect of the knee joint, flattening of the lateral femoral condyle resulting in a squared-off appearance, and cupping of the lateral aspect of the tibial plateau. Because these findings are very nonspecific, with any history or physical examination findings suggestive of a DLM, evaluation with MRI provides a definitive diagnosis.

TREATMENT

Patients with asymptomatic or incidentally found DLM without evidence of a tear or meniscal instability are treated nonoperatively with observation. They should be educated on symptoms to watch out for, but no activity restrictions are often necessary. If knee pain or mechanical symptoms limit activity or a meniscal tear develops, consideration is given for surgical intervention. **Partial meniscectomy**, referred to as **saucerization,** is often performed to reshape the meniscus arthroscopically with the goal of obtaining an anatomically normal-appearing meniscus (Fig. 677-2). Tears remaining in what would be the normal rim of meniscal tissue are either repaired or excised. Meniscal instability is also addressed with repairs as appropriate. If tears extend all the way to the periphery of the meniscus, sometimes a **total meniscectomy**, or complete excision of the meniscus, may be necessary. Because this leaves the joint surfaces unprotected and can lead to early osteoarthritis, addressing DLM tears as soon as they develop and before they extend to the periphery is preferred.

677.2 Popliteal Cysts (Baker Cysts)

Eric J. Sarkissian and J. Todd R. Lawrence

Popliteal cysts, or **Baker cysts,** are cystic masses filled with gelatinous material that develop in the popliteal fossa, the shallow depression located at the posterior part of the knee. They are considered rare in children. They most commonly occur in the region of the medial head of the gastrocnemius and semimembranosus. They occur as an isolated fluid-filled bursa or via herniation through the posterior joint capsule of the knee into this same location. Histologically, the cysts are classified as fibrous, synovial, inflammatory, or transitional. Typically, popliteal cysts resolve spontaneously, although the process may take several years.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients commonly present with a mass behind the knee that may be fairly large when first noted. There are usually no symptoms of internal derangement of the knee. Physical examination reveals a firm mass in the popliteal fossa, often medially located and distal to the popliteal crease. The mass is usually most prominent when the knee is extended. Transillumination of the cyst on physical examination is a simple diagnostic test. Knee radiographs are normal and should be obtained to identify other lesions, such as osteochondromas, osteochondritis dissecans, and malignancies. The diagnosis may be confirmed by ultrasonography, MRI, or aspiration. Ultrasound differentiates a solid mass from a cystic lesion. In the presence of a knee effusion, consideration should be given to an MRI to evaluate for knee intraarticular pathology that may be causing the swelling, such as a meniscal tear or a DLM. These children should also be assessed for *other pathology* that may cause recurrent or intermittent knee effusions, including Lyme disease, juvenile idiopathic arthritis, or other autoimmune processes. The presence of a solid mass detected on ultrasound or MRI warrants additional diagnostic testing and referral for biopsy consideration.

TREATMENT

In most cases, popliteal cysts are observed because they often resolve spontaneously. Rest and leg elevation are beneficial to promote drainage of fluid accumulating within the cyst. If necessary, aspiration can reduce the size of the cyst and a corticosteroid injection can reduce inflammation. Cysts will often recur after aspiration. Surgical excision of a popliteal cyst is indicated only when symptoms are debilitating and have not resolved after several months.

Bibliography is available at Expert Consult.

677.3 Osteochondritis Dissecans

Eric J. Sarkissian and J. Todd R. Lawrence

Osteochondritis dissecans (OCD) is a localized pathologic process of the subchondral bone that secondarily affects the overlying articular cartilage and can progress to cartilage separation and fragmentation. The precise cause for OCD remains unclear, although repetitive microtrauma appears to be the leading candidate. Roles for genetics and ischemia have also been implicated in the etiology. The disorder is being seen with rising frequency in children and adolescents, likely in large part, as a consequence of increased sports participation in young athletes. In the knee, OCD most commonly affects the lateral aspect of the medial femoral condyle. The lateral femoral condyle and patella may also be affected, as well as joints other than the knee, such as the elbow or ankle. Characteristic pathology of the lesion includes an area of avascular necrosis in the subchondral bone, the segment of bone just below the joint surface, and varying degrees of ischemia and fibrosis of the overlying hyaline cartilage. Failure of both the bone and the cartilage surface to heal completely is associated with an increased risk for developing premature osteoarthritis.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The most common presenting complaint is a vague or **deep knee pain** that may localize along the medial or lateral joint line. If the osteochondral fragment becomes unstable, the patient may also develop **mechanical symptoms**, such as catching or locking. Physical exam findings include effusion, tenderness to palpation over the femoral condyles, quadriceps atrophy, and diminished range of motion.

Because most OCD lesions are located more on the posterior aspect of the femoral condyle, a posteroanterior radiograph with a 45 degree flexed knee (tunnel view) is often required to evaluate for the presence of an OCD. Many of these patients also have some degree of patellar-related pain, necessitating merchant (patellar) view plain films. Thus, standard radiographic evaluation of nontraumatic adolescent knee pain should routinely include anteroposterior, lateral, tunnel, and merchant radiographs of the knee. An early lesion may appear as a small radiolucency at the articular surface. A more advanced lesion may have a well-demarcated segment of subchondral bone with a lucent line demonstrating separation from the condyle. In children younger than age 10 yr, irregularities in the ossification center of the developing epiphysis may be difficult to distinguish from an OCD lesion.

MRI is useful for determining the size of the OCD, integrity of the articular cartilage, and presence of loose bodies. Fluid observed between the fragment and subchondral bone suggests an unstable lesion and high risk for detachment. Any linear signal through the articular cartilage or displacement of the fragment indicates a potentially unstable lesion as well. For an unstable-appearing OCD, either based on the patients' symptoms and signs, or the imaging, arthroscopy should be performed to evaluate the status of the lesion.

TREATMENT

Treatment for juvenile OCD includes nonoperative and surgical management, with treatment decisions being based on many factors, including the growth status and skeletal maturity of the patient, the presence of symptoms, the lesion size, and whether the lesion appears intact and stable or if there is any suggestion of instability. Skeletal immaturity (i.e., younger age), smaller lesion size, and the absence of mechanical symptoms or pain have been associated with a higher likelihood of OCD healing with nonoperative treatment. Unstable lesions will not usually heal with conservative treatment.

Thus, young patients with stable lesions, as evidenced by an intact articular surface on imaging (Fig. 677-3*A*), are deemed to have an acceptable probability of healing and are often initially managed conservatively with a period of non–weightbearing and immobilization, followed by a period of strict activity restriction and physical therapy for 3-6 mo. OCD healing is followed with radiographs, usually at approximately 3 mo intervals, until lesion healing has been noted. If healing has not been radiographically confirmed in 3-6 mo, surgical intervention is often considered. Because of the low rate of healing in skeletally mature patients, even intact lesions are not usually managed conservatively in this patient population, but recommended for surgery.

Although nonsurgical treatment can be successful in intact lesions, surgical treatment of intact lesions is often more successful and induces healing at a faster rate. Consequently, patients often choose to pursue early surgical intervention. For stable and intact lesions, surgical management involves arthroscopic evaluation of the joint followed by either a transarticular or retroarticular drilling to stimulate bony healing by creating channels in the subchondral bone that allow revascularization to occur. Both techniques are comparably effective in producing short-term patient-oriented outcomes and radiographic healing.

More advanced lesions with edema beneath the fragment, subchondral cyst formation, and partial (see Fig. 677-3*B*) or complete (see Fig. 677-3*C*) fragment detachment on arthroscopy are potentially salvageable. Treatment involves drilling or fixation with possible bone grafting. OCD lesions may progress to become unstable and dislodge into the joint space (see Fig. 677-3*D*). Removal of the loose body in addition to cartilage repair and restoration are typically performed for such unsalvageable lesions. In the postoperative period, patients undergo

physical therapy to regain strength and range of motion, with a gradual return to baseline activity levels. Treating OCD early and effectively often prevents recurrent symptoms in adulthood and reduces risk for early-onset osteoarthritis.

677.4 Osgood-Schlatter Disease and Sinding-Larsen-Johansson Syndrome

Eric J. Sarkissian and J. Todd R. Lawrence

In skeletally immature patients, the tibial tubercle is an extension of the proximal tibial epiphysis. As the femur rapidly grows in length, patients often develop tight musculature, particularly of the quadriceps, across the knee joint. These patients also develop movement patterns that preferentially place stress at the knees during activities instead of distributing that stress across other joints in the lower extremity. The repetitive tensile microtrauma sustained during sports or other athletic activities then creates traction injuries at the weak points in the extensor mechanism at the knee, as the stress exceeds the developing skeleton's ability to repair the damage.

Sinding-Larsen-Johansson syndrome is an insertional periostitis at the inferior pole of the patella. **Osgood-Schlatter (OS) disease** is an irritation of the patellar tendon at its insertion into the tibial tubercle or a traction apophysitis of the tibial tubercle growth plate. These conditions typically present during periods of relative accelerated growth. Sinding-Larsen-Johansson syndrome tends to occur in a slightly younger patient population, whereas OS disease presents in slightly older patients with most symptomatic between the ages of 10 and 15 yr. These conditions are most common in very physically active boys. However, as the number and intensity of female athletics has increased, the incidence in females seems to be on the rise.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Anterior knee pain, very specifically localized to the inferior pole of the patella (Sinding-Larsen-Johansson syndrome) or over the tibial tubercle (OS disease) is the most common patient complaint. Swelling, as well as an eventual firm and fixed increased prominence at the tibial tubercle, may occur with OS disease and may also be part of the initial complaint (Fig. 677-4). There is typically no acute traumatic inciting event. The pain is aggravated by sports activities, but may often persist with daily activities and even at rest. Physical examination reveals point tenderness over the tibial tubercle and the distal portion of the patellar tendon (OS disease). Diagnosis is usually made clinically, but radiographs may reveal fragmentation of the tibial tubercle and soft tissue swelling (Fig. 677-5).

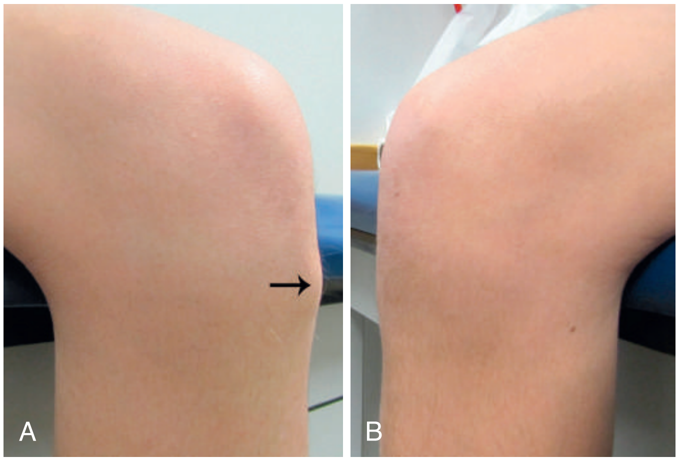

Figure 677-4 Clinical manifestations of Osgood-Schlatter disease. The increased prominence of the tibial tubercle, indicated by the *arrow*, **(A)** from traction apophysitis in a 15 yr old boy's knee is contrasted with the normal appearance of the tibial tubercle **(B)** in his contralateral, unaffected knee.

TREATMENT

In most patients, Sinding-Larsen-Johansson syndrome and OS disease are self-limited processes and resolve with rest. Patients are treated with an escalating treatment regime until they are pain free with activity. If they are pain free with normal daily activities, they may maintain this level of activity for 2 additional wk. In more-severe cases, a knee immobilizer or even crutches with restricted weightbearing are required to get the patient comfortable. Patients are usually advised to maintain a level of activity for 1-2 wk before attempting to advance. Sports and other dynamic activities are restricted until the patient has been pain free to palpation for at least 2 wk. During this rest period, addressing some of the contributing factors, such as muscular tightness, can help prevent recurrence with activity resumption. A self-directed stretching regime concentrating on the quadriceps and hamstrings may be provided. Some patients and resistant cases may benefit from formal instruction in these exercises with a physical therapist.

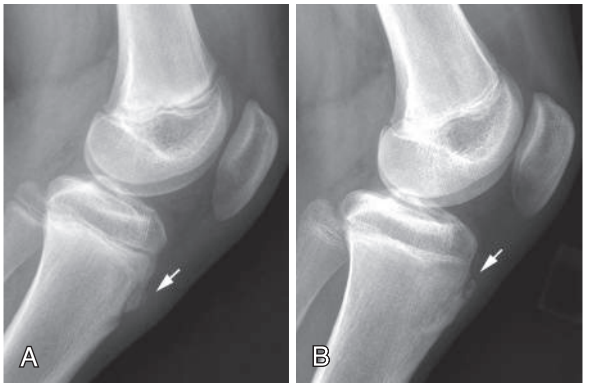

Figure 677-5 Radiographic findings of Osgood-Schlatter disease. **A,** Lateral radiograph of the knee of a 13 yr old male demonstrates a sliver of new bone formation *(arrow)* at the tibial tubercle. **B,** Lateral radiograph of the same child at 15 yr of age demonstrates characteristic fragmentation *(arrow)* of the tibial tubercle.

Reassurance is important, because some patients and parents fear that the swollen tubercle may be a sign of malignancy. Patients and family members should be advised, however, that the tibial tubercle swelling will not likely resolve. Hyperosmolar dextrose local injections may improve outcomes in patients with recalcitrant disease. Removal of ossicles from the tubercle is rarely necessary in pediatric patients but may be required with persistent disabling symptoms in young adults. Complications are rare and include early closure of the tibial tubercle with recurvatum, or hyperextension, deformity, and rarely, patellar tendon rupture or avulsion fracture of the tibial tubercle. Although rare, these complications can have significant long-term consequences and should thus prompt counseling to avoid playing through the pain.

677.5 Patellofemoral Pain Syndrome

Eric J. Sarkissian and J. Todd R. Lawrence

Also known as anterior knee pain syndrome, patellofemoral pain syndrome (PFPS) is one of the most common causes of knee pain, particularly in adolescent girls. Previously, PFPS was thought to arise from a deranged patellar articular surface, hence, the former term chondromalacia patella. Increasing evidence shows that anterior knee pain is frequently present even with normal articular cartilage of the patella, resulting in more appropriate labeling of the condition. The precise etiology of the knee pain remains unknown and is likely multifactorial.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Pain beneath or near the patella is the most common symptom. Classically, walking up and down stairs, which puts the patella under high compressive loads, aggravates the pain. Squatting, running, and other vigorous physical activities also exacerbate the anterior knee pain. Sitting in a flexed knee position for an extended period of time, the so-called theater sign, is another common complaint. There is usually no history of antecedent trauma, although falling onto a flexed knee is sometimes noted. Buckling or a sense of the knee *giving way* can occur, but there is rarely any true knee instability. Swelling is not common and if present should prompt further investigation. Pain is often relieved through knee extension.

Physical exam reveals isolated tenderness with palpation about the medial or lateral aspects of the patella. With the knee extended and the quadriceps relaxed, placing pressure on the patella and translating it distally into the top of the trochlear groove, the so-called **grind test**, often also causes pain. Reproduction of the patient's pain with these maneuvers is an important component of the exam. Active and passive range of motion of the knee, alignment of the lower extremity, knee ligamentous stability, patellar tracking, and gait should be evaluated to identify any obvious causes of malalignment or an unstable patella. These patients often have tight quadriceps, hamstrings, and heel cords, as well as weak hip musculature and poor overall balance. A single leg squat can often highlight the hip weakness and balance and alignment issues that contribute to this condition. Routine radiographs of the knee, including anteroposterior, lateral, tunnel (posteroanterior with 45 degrees flexed knee), and merchant (patellar) views, are usually normal, but are helpful in eliminating other etiologies. Radiographs of the hip should be considered in suspected cases to rule out hip pathology, such as a slipped capital femoral epiphysis, that can manifest as ill-defined knee pain in adolescents as well. An MRI is not routinely required for evaluation but should be considered in any patient with a history of mechanical symptoms or an effusion.

TREATMENT

Several methods of nonoperative treatment are utilized to address PFPS. The mainstay of treatment is continued physiotherapy, involving overall lower-extremity stretching and strengthening, including short-arc quadriceps strengthening, hip and core strengthening, and exercises designed to address balance and overall body positioning during dynamic activities. No one particular regime seems to demonstrate results superior to the others. Home exercise programs can be effective for the properly disciplined and motivated patient, but formal physical therapy should be considered in resistant cases or in patients who may not have the motivation or wherewithal to adhere to a self-directed program. Orthoses, including patellar taping, knee sleeves, customized knee braces, or even shoe inserts are often used in conjunction with physical therapy. However, evidence for long-term benefit from orthotic use is unclear. Treatment with Botulinum toxin injections, nonsteroidal antiinflammatory medications, or therapeutic ultrasound is not substantiated. Most cases of PFPS resolve spontaneously over a period of years. Arthroscopic evaluation of the knee and patellofemoral joint is rarely necessary.

Bibliography is available at Expert Consult.

677.6 Patellofemoral Instability

Eric J. Sarkissian and J. Todd R. Lawrence

Patellofemoral joint stability depends on a balance of the static restraints and the dynamic forces acting on the patella. These include the restraining ligaments and the articular anatomy of the patellofemoral groove that serve to balance the dynamic forces of the quadriceps mechanism and overall limb positioning. During knee flexion, the pull of the quadriceps mechanism tends to place an overall lateral displacing force at the patella. The **Q angle** refers to the deviation between the angle of the patellar tendon and the line of the quadriceps. Wider hips and valgus (knock-kneed) positioning increase the Q angle and thus the lateral force applied at the patella. In extension, the static restraints, including the medial restraining ligaments, primarily the medial patellofemoral ligament, are responsible for guiding the patella into the trochlear grove in the distal femur. The pull of the vastus medialis obliquus is the only dynamic restraint. Once in the trochlea, the bony congruity becomes the primary restraint to the net lateral muscular forces.

Factors that contribute to patellofemoral instability are multifactorial and include vastus medialis insufficiency, ligamentous laxity, shallow sulcus, condylar hypoplasia, patella alta (high riding patella), or malalignment that effectively increases the Q angle, such as genu valgum, internal femoral torsion, or external tibial torsion.

Acute patellofemoral dislocation is the most common acute knee disorder in children and adolescents and often occurs after a sudden valgus strain during a sporting activity but may be the result of direct

trauma. **Recurrent patellofemoral subluxation** is more than 1 episode of patellar subluxation without frank dislocation. Lateral malalignment of the quadriceps mechanism is the most common etiologic factor. **Habitual dislocation of the patella** describes patellar dislocation occurring during every knee flexion. A dysplastic knee with contracture of the lateral portion of the quadriceps mechanism is often associated. Several syndromes are associated with patellar instability, including Down syndrome (see Chapter 81), Turner syndrome (see Chapter 81), Kabuki syndrome, and Rubinstein-Taybi syndrome.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

With an acute patellar dislocation, patients will recall the acute event and the sensation that their knee cap was out of place. Straightening the knee is all that is usually required to reduce the patella, but sometimes this requires medical attention. Swelling is usually almost immediate following the injury and appreciable on examination with an effusion. The patella may appear laterally displaced when the knee is fully extended or higher than normal with the knee slightly flexed. Pain along the medial knee from the medial patella to the medial epicondyle of the femur is common. Lateral patellar translocation with the knee slightly flexed should be tested with the **patellar apprehension test**. In the acute setting there will be increased translation and pain as well as a feeling of insecurity. Patellar tracking is also an important component to the exam but may not be possible due to pain in the acute setting. The **J sign** refers to the inverted J-path the patella takes, beginning in a laterally subluxated position and then suddenly shifting medially to engage the femoral groove with early knee flexion. The torsional profile of the patient is also important to assess to rule out possible rotational abnormalities of the femur or tibia.

Radiographs of a patient with patellar instability should include anteroposterior, lateral, and merchant views (obtained with the knee bent 45 degrees, with the beam of the x-ray through the knee from head to toe) of the patella. Radiographs should also be carefully examined for occult fractures. In the presence of a significant knee effusion, mechanical symptoms, acute traumatic patellar dislocation, or uncertainty in the diagnosis, further investigation may warrant an MRI to evaluate for loose bodies or cartilage damage. MRI will illustrate bone bruise patterns typical of patellar dislocation at the medial patellar facet and at the lateral femoral condyle. A tear in the medial patellofemoral ligament may also be seen, especially in cases of an acute patellofemoral dislocation.

TREATMENT

Nonoperative management is initially recommended for acute patellar dislocation and recurrent patellar subluxation, unless an osteochondral fracture or additional intra-articular pathology is seen on imaging studies. Although early physical therapy has also been shown to be successful, a brief 4-6 wk period of immobilization in full extension may help with healing of the medial knee restraints following an initial traumatic dislocation. After this, transition to a patellar stabilizing brace usually improves symptoms. Successful treatment is usually achieved with formal physical therapy aimed at improving extensor muscle tone, particularly the vastus medialis obliquus, activity-related body positioning, and hip and core muscle strengthening. The reported redislocation rate following an initial traumatic patellar dislocation ranges from 15-44%.

Failure to improve after nonoperative treatment and persistent episodes of patellar subluxation or dislocation are indications for surgical intervention to address patellofemoral instability. Patients with loose bodies, osteochondral fractures, or chondral damage are surgical candidates for early intervention. Many different types of surgical procedures exist to prevent lateral excursion of the patella from occurring. These include proximal realignment of the patella, distal realignment of the patellar tendon insertion, lateral release, medial patellofemoral ligament reconstruction, or guided growth techniques. The surgical approach that is selected should be individualized for each patient depending on the pathoanatomy contributing to the recurrent subluxations or dislocations.

677.7 Anterior Cruciate Ligament Rupture

Eric J. Sarkissian and J. Todd R. Lawrence

Pediatric anterior cruciate ligament (ACL) reconstruction has become more prevalent as ACL tears in skeletally immature patients have greatly increased in recent years. Increased sports participation, increased intensity of training and competition, participation on multiple teams, heightened awareness, and improved methods for diagnosis are all cited as contributing factors to the growing awareness of ACL injuries in children and adolescents.

Females are also known to have a greater risk for ACL injury than males. The gender-specific discrepancy appears to be caused mostly by insufficient neuromuscular activation patterns in females, resulting in increased **genu valgum**, or knock-knee, biased landing and, therefore, a heightened tendency toward landing or stopping in an injury prone position. Various pediatric ACL injury prevention programs show benefit in not only reducing the rate of injuries but also in increasing athletic strength and performance.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The majority of ACL tears occurs as a result of a noncontact injury. Patients may report a pop associated with the acute onset of knee pain. Later they develop swelling, limited range of motion, and sometimes a sensation of instability. After the initial injury, patients may have surprisingly little pain. On physical exam, the anterior drawer sign or Lachman test may indicate increased anterior tibial translation. The Lachman examination is performed by applying an anteriorly directed force to the proximal tibia with the femur stabilized and the knee flexed 20-30 degrees. The amount of translation and the end point are assessed, with increased translation and an indistinct end point indicating a positive test. A pivot shift test can also be performed to confirm the diagnosis but is rarely successful in the conscious patient. It is conducted by gently bending the knee while just supporting the lower leg. A gentle valgus stress and slight internal rotation can enhance the shift.

Radiographs of the knee are performed, including anteroposterior, lateral, tunnel (posteroanterior with 45 degrees flexed knee), and merchant (patellar) views, to assess for other potential injuries common in pediatric and adolescent patients, such as tibial spine avulsion fractures or OCD. In traumatic injuries, internal and external oblique radiographs can also be helpful. Ultimately, knee MRI can confirm the presence of an intrasubstance ACL tear, as well as meniscal or chondral pathology. Arthroscopic evaluation is the gold standard for diagnosis and treatment.

TREATMENT

The management of ACL injury in this patient population can be challenging and the severity of the ACL tear is important to differentiate. Incomplete ACL tears may be treated nonoperatively and the patient and family's understanding and willingness to adhere to a protocol of bracing and activity restriction are important factors in optimizing outcomes. For complete tears of the ACL, because of the risk of ongoing knee damage if stabilization of the knee is delayed, surgical reconstruction is now recommended for patients who are physically, mentally, and emotionally capable after a thorough discussion with the patient and family about the risks and benefits. All-epiphyseal, partial transphyseal, or traditional transphyseal reconstruction techniques are used based upon the skeletal maturity of the patient to minimize the risk for growth disturbance across the distal femoral and proximal tibial physes.

Depending on the technique used for reconstruction and any associated meniscal pathology addressed, weight bearing is restricted and a brace is used for the 1st 4-6 wk postoperatively. Physical therapy is used postoperatively and continued until strength and functional testing are equal to the contralateral, unaffected limb. Routine follow-up visits and radiographs are conducted to monitor progress and signs of growth disturbance. Patients return to sports typically at a minimum of 9 mo postoperatively and are followed on a yearly basis thereafter until skeletal maturity.

Chapter 678

The Hip

Wudbhav N. Sankar, B. David Horn, Lawrence Wells, and John P. Dormans

Anatomically, the hip joint is a ball-and-socket articulation between the femoral head and acetabulum.

The hip joint is a pivotal joint of the lower extremity, and its functional demands require both stability and flexibility.

GROWTH AND DEVELOPMENT

The hip joint begins to develop at about the 7th wk of gestation, when a cleft appears in the mesenchyme of the primitive limb bud. These precartilaginous cells differentiate into a fully formed cartilaginous **femoral head** and **acetabulum** by the 11th wk of gestation (see Chapter 8). At birth, the neonatal acetabulum is completely composed of cartilage, with a thin rim of fibrocartilage called the **labrum**.

The very cellular hyaline cartilage of the acetabulum is continuous with the triradiate cartilages, which divide and interconnect the 3 osseous components of the pelvis (the **ilium**, **ischium**, and **pubis**). The concave shape of the hip joint is determined by the presence of a spherical femoral head.

Several factors determine acetabular depth, including interstitial growth within the acetabular cartilage, appositional growth under the perichondrium, and growth of adjacent bones (the ilium, ischium, and pubis). In the neonate, the entire proximal femur is a cartilaginous structure, which includes the femoral head and the greater and lesser trochanters. The 3 main growth areas are the physeal plate, the growth plate of the greater trochanter, and the femoral neck isthmus. Between the 4th and 7th mo of life, the proximal femoral ossification center (in the center of the femoral head) appears. This ossification center continues to enlarge, along with its cartilaginous anlage, until adult life, when only a thin layer of articular cartilage remains. During this period of growth, the thickness of the cartilage surrounding this bony nucleus gradually decreases, as does the thickness of the acetabular cartilage. The growth of the proximal femur is affected by muscle pull, the forces transmitted across the hip joint with weight bearing, normal joint nutrition, circulation, and muscle tone. Alterations in these factors can cause profound changes in the development of the proximal femur.

VASCULAR SUPPLY

The blood supply to the capital femoral epiphysis is complex and changes with growth of the proximal femur. The proximal femur receives its arterial supply from intraosseous (primarily the medial femoral circumflex artery) and extraosseous vessels (Fig. 678-1). The **retinacular vessels** (extraosseous) lie on the surface of the femoral neck but are intracapsular because they enter the epiphysis from the periphery. This makes the blood supply vulnerable to damage from septic arthritis, trauma, thrombosis, and other vascular insults. Interruption of this tenuous blood supply can lead to avascular necrosis of the femoral head and permanent deformity of the hip.

678.1 Developmental Dysplasia of the Hip

Wudbhav N. Sankar, B. David Horn, Lawrence Wells, and John P. Dormans

Developmental dysplasia of the hip (DDH) refers to a spectrum of pathology in the development of the immature hip joint. Formerly called *congenital dislocation of the hip*, DDH more accurately describes the variable presentation of the disorder, encompassing mild dysplasias as well as frank dislocations.

CLASSIFICATION

Acetabular **dysplasia** refers to abnormal morphology and development of the acetabulum. Hip **subluxation** is defined as partial contact between the femoral head and acetabulum. Hip **dislocation** refers to a hip with no contact between the articulating surfaces of the hip. DDH is classified into 2 major groups**:** **typical** and **teratologic**. Typical DDH occurs in otherwise normal patients or those without defined syndromes or genetic conditions. Teratologic hip dislocations usually have identifiable causes, such as arthrogryposis or a genetic syndrome, and occur before birth.

ETIOLOGY AND RISK FACTORS

Although the etiology remains unknown, the final common pathway in the development of DDH is increased laxity of the joint, which fails to maintain a stable femoroacetabular articulation. This increased laxity is probably the result of a combination of hormonal, mechanical, and genetic factors. A positive family history for DDH is found in 12-33% of affected patients. DDH is more common among female patients (80%), which is thought to be because of the greater susceptibility of female fetuses to maternal hormones such as relaxin, which increases ligamentous laxity. Although only 2-3% of all babies are born

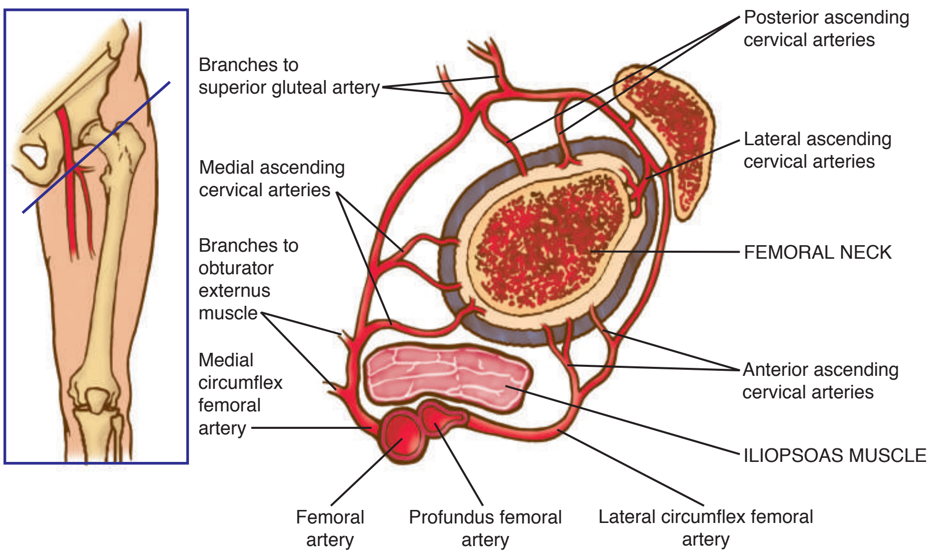

Figure 678-1 Diagram of vascular anatomy of the proximal femur.

in breech presentation, the incidence of DDH in these patients is 16-25%.

Any condition that leads to a tighter intrauterine space and, consequently, less room for normal fetal motion may be associated with DDH. These conditions include oligohydramnios, large birth weight, and 1st pregnancy. The high rate of association of DDH with other *intrauterine molding abnormalities*, such as torticollis and metatarsus adductus, supports the theory that the *crowding phenomenon* has a role in the pathogenesis. The left hip is the most commonly affected hip; in the most common fetal position, this is the hip that is usually forced into adduction by the mother's sacrum.

EPIDEMIOLOGY

Although most newborn screening studies suggest that some degree of hip instability can be detected in 1 in 100 to 1 in 250 babies, actual dislocated or dislocatable hips are much less common, being found in 1-1.5 of 1,000 live births.

There is marked geographic and racial variation in the incidence of DDH. The reported incidence based on geography ranges from 1.7 in 1,000 babies in Sweden to 75 in 1,000 in Yugoslavia to 188.5 in 1,000 in a district in Manitoba, Canada. The incidence of DDH in Chinese and African newborns is almost 0%, whereas it is 1% for hip dysplasia and 0.1% for hip dislocation in white newborns. These differences may be the result of environmental factors, such as child-rearing practices, rather than to genetic predisposition. African and Asian caregivers have traditionally carried babies against their bodies in a shawl so that a child's hips are flexed, abducted, and free to move. This keeps the hips in the optimal position for stability and for dynamic molding of the developing acetabulum by the cartilaginous femoral head. Children in Native American and Eastern European cultures, which have a relatively high incidence of DDH, have historically been swaddled in confining clothes that bring their hips into extension. This position increases the tension of the psoas muscle-tendon unit and might predispose the hips to displace and eventually dislocate laterally and superiorly.

PATHOANATOMY

In DDH, several secondary anatomic changes can develop that can prevent reduction. Both the fatty tissue in the depths of the socket, known as the **pulvinar,** and the ligamentum teres can hypertrophy, blocking reduction of the femoral head. The transverse acetabular ligament usually thickens as well, which effectively narrows the opening of the acetabulum. In addition, the shortened iliopsoas tendon becomes taut across the front of the hip, creating an hourglass shape to the hip capsule, which limits access to the acetabulum. Over time, the dislocated femoral head places pressure on the acetabular rim and labrum, causing the labrum to infold and become thick.

The shape of a normal femoral head and acetabulum depends on a concentric reduction between the two. The more time that a hip spends dislocated, the more likely that the acetabulum will develop abnormally. Without a femoral head to provide a template, the acetabulum will become progressively shallow, with an oblique acetabular roof and a thickened medial wall.

CLINICAL FINDINGS

The Neonate

DDH in the neonate is asymptomatic and must be screened for by specific maneuvers. Physical examination must be carried out with the infant unclothed and placed supine in a warm, comfortable setting on a flat examination table.

The **Barlow** provocative maneuver assesses the potential for dislocation of a nondisplaced hip. The examiner adducts the flexed hip and gently pushes the thigh posteriorly in an effort to dislocate the femoral head (Fig. 678-2). In a positive test, the hip is felt to slide out of the acetabulum. As the examiner relaxes the proximal push, the hip can be felt to slip back into the acetabulum.

The **Ortolani** test is the reverse of Barlow test: The examiner attempts to reduce a dislocated hip (Fig. 678-3). The examiner grasps the child's thigh between the thumb and index finger and, with the 4th and 5th

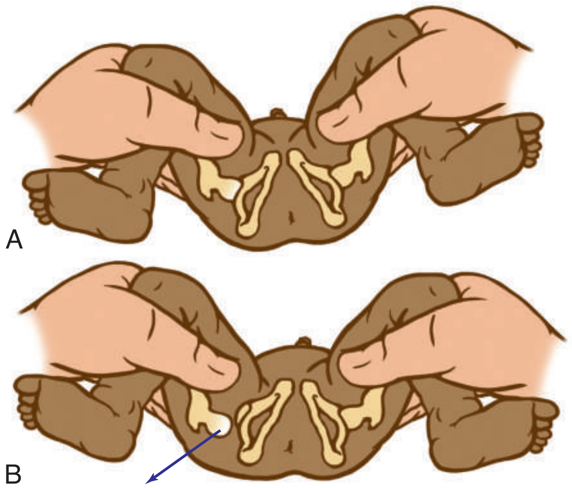

Figure 678-2 The Barlow provocative test is performed with the patient's knees and hips flexed. **A,** Holding the patient's limbs gently, with the thigh in adduction, the examiner applies a posteriorly directed force. **B,** This test is positive in a dislocatable hip.

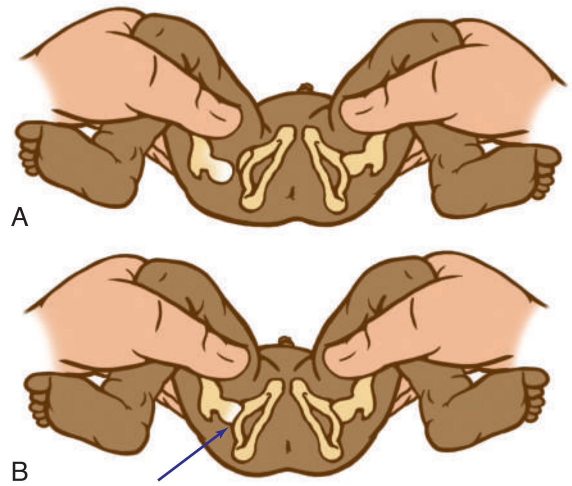

Figure 678-3 The Ortolani maneuver is the sign of the ball of the femoral head moving in and out of the acetabulum. **A,** The examiner holds the patient's thigh and gently abducts the hip while lifting the greater trochanter with 2 fingers. **B,** When the test is positive, the dislocated femoral head falls back into the acetabulum with a palpable clunk as the hip is abducted.

fingers, lifts the greater trochanter while simultaneously abducting the hip. When the test is positive, the femoral head will slip into the socket with a delicate clunk that is palpable but usually not audible. It should be a gentle, nonforced maneuver.

A **hip click** is the high-pitched sensation (or sound) felt at the very end of abduction during testing for DDH with Barlow and Ortolani maneuvers. Classically, a hip click is differentiated from a **hip clunk**, which is felt as the hip goes in and out of joint. Hip clicks usually originate in the ligamentum teres or occasionally in the fascia lata or psoas tendon and do not indicate a significant hip abnormality.

The Infant

As the baby enters the 2nd and 3rd mo of life, the soft tissues begin to tighten and the Ortolani and Barlow tests are no longer reliable. In this age group, the examiner must look for other specific physical findings, including limited hip abduction, apparent shortening of the thigh, proximal location of the greater trochanter, asymmetry of the gluteal

Figure 678-4 Asymmetry of thigh folds in a child with developmental dysplasia of the hip.

Figure 678-5 Positive Galeazzi sign noted in a case of untreated developmental dysplasia of the hip.

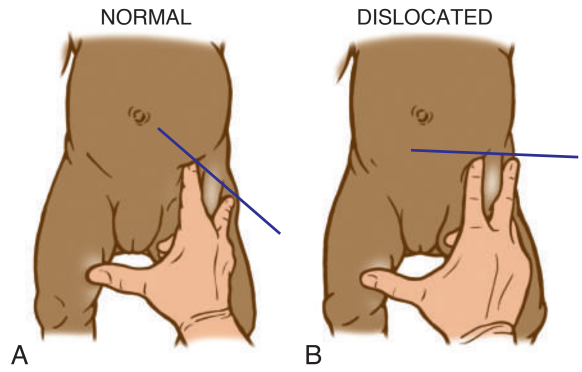

Figure 678-6 Klisic test. **A,** In a normal hip, an imaginary line drawn down through the tip of an index finger placed on the patient's iliac crest and the tip of the long finger placed on the patient's greater trochanter should point to the umbilicus. **B,** In a dislocated hip, this line drawn through the 2 fingertips runs below the umbilicus because the greater trochanter is abnormally high.

or thigh folds (Fig. 678-4), and positioning of the hip. Limitation of abduction is the most reliable sign of a dislocated hip in this age group.

Shortening of the thigh, the **Galeazzi sign,** is best appreciated by placing both hips in 90 degrees of flexion and comparing the height of the knees, looking for asymmetry (Fig. 678-5). Asymmetry of thigh and gluteal skin folds may be present in 10% of normal infants but suggests DDH. Another helpful test is the **Klisic test,** in which the examiner places the 3rd finger over the greater trochanter and the index finger of the same hand on the anterior superior iliac spine. In a normal hip, an imaginary line drawn between the 2 fingers points to the umbilicus. In the dislocated hip, the trochanter is elevated, and the line projects halfway between the umbilicus and the pubis (Fig. 678-6).

The Walking Child

The walking child often presents to the physician after the family has noticed a limp, a waddling gait, or a leg-length discrepancy. The affected side appears shorter than the normal extremity, and the child toe-walks on the affected side. The Trendelenburg sign is positive in these children, and an abductor lurch is usually observed when the child walks. As in the younger child, there is limited hip abduction on the affected side and the knees are at different levels when the hips are flexed (the Galeazzi sign). Excessive lordosis, which develops secondary to altered hip mechanics, is common and is often the presenting complaint.

DIAGNOSTIC TESTING

Ultrasonography

Because it is superior to radiographs for evaluating cartilaginous structures, ultrasonography is the diagnostic modality of choice for DDH before the appearance of the femoral head ossific nucleus (4-6 mo). During the early newborn period (0-4 wk), however, physical examination is preferred over ultrasonography because there is a high incidence of false-positive sonograms in this age group. In addition to elucidating the static relationship of the femur to the acetabulum, ultrasonography provides dynamic information about the stability of the hip joint. The ultrasound examination can be used to monitor acetabular development, particularly of infants in Pavlik harness treatment; this method can minimize the number of radiographs taken and might allow the clinician to detect failure of treatment earlier.

In the Graf technique, the transducer is placed over the greater trochanter, which allows visualization of the ilium, the bony acetabulum, the labrum, and the femoral epiphysis (Fig. 678-7). The angle formed by the line of the ilium and a line tangential to the boney roof of the acetabulum is termed the **α angle** and represents the depth of the acetabulum. Values >60 degrees are considered normal, and those <60 degrees imply acetabular dysplasia. The **β angle** is formed by a line drawn tangential to the labrum and the line of the ilium; this represents the cartilaginous roof of the acetabulum. A normal β angle is <55 degrees; as the femoral head subluxates, the β angle increases. Another useful test is to evaluate the position of the center of the head compared to the vertical line of the ilium. If the line of the ilium falls lateral to the center of the head, the epiphysis is considered reduced. If the line falls medial to the center of the head, the epiphysis is uncovered and is either subluxated or dislocated.

Screening for DDH with ultrasound remains controversial. Although routinely performed in Europe, meta-analyses indicate that data are insufficient to give clear recommendations. In the United States, the current recommendations are that every newborn undergo a clinical examination for hip instability. Children who have findings suspicious for DDH should be followed up with ultrasound. Most authors agree that infants with *risk factors* for DDH (breech position, family history, torticollis) should be screened with ultrasound regardless of the clinical findings.

Radiography

Radiographs are recommended for an infant once the proximal femoral epiphysis ossifies, usually by 4-6 mo. In infants of this age, radiographs have proved to be more effective, less costly, and less operator dependent than an ultrasound examination. An anteroposterior (AP) view of the pelvis can be interpreted with the aid of several classic lines drawn on it (Fig. 678-8).

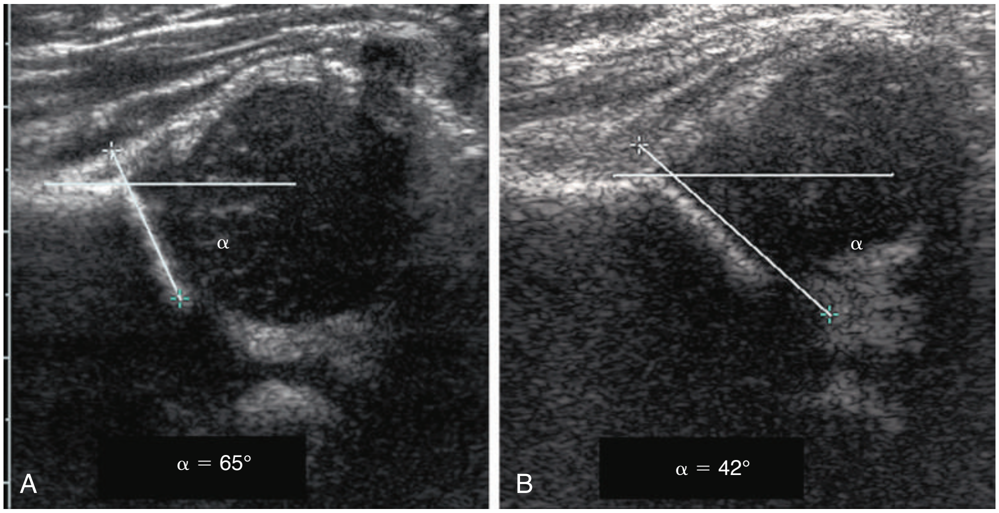

Figure 678-7 **A,** Normal ultrasonographic image of the hip in an infant. The α angle is >60 degrees. Note that a line drawn tangential to the ilium falls lateral to the center of the femoral head. **B,** In this child with developmental dysplasia of the hip, the left hip demonstrates an α angle of 42 degrees, and a line drawn tangential to the ilium shows that <50% of the femoral head is contained within the acetabulum.

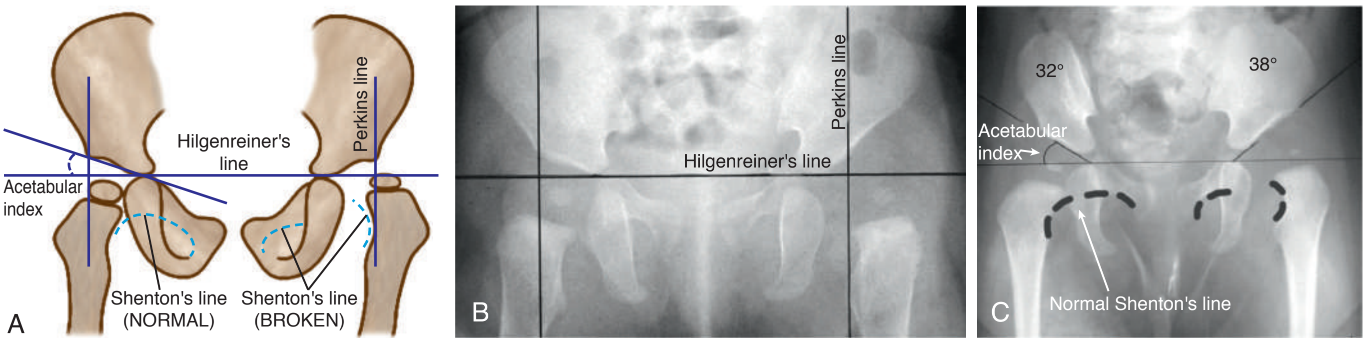

Figure 678-8 **A-C,** Radiographic measurements are useful in evaluating developmental dysplasia of the hip. Hilgenreiner's line is drawn through the triradiate cartilages. Perkins line is drawn perpendicular to Hilgenreiner's line at the lateral edge of the acetabulum. The ossific nucleus of the femoral head should be located in the medial lower quadrant of the intersection of these 2 lines. Shenton's line curves along the femoral metaphysis and connects smoothly to the inner margin of the pubis. In a child with hip subluxation or dislocation, this line consists of 2 separate arcs and is described as broken. The acetabular index is the angle between a line drawn along the margin of the acetabulum and Hilgenreiner's line; in normal newborns, it averages 27.5 degrees and decreases with age.

Hilgenreiner's **line** is a horizontal line drawn through the top of both triradiate cartilages (the clear area in the depth of the acetabulum). **Perkins line** is a vertical line through the most lateral ossified margin of the roof of the acetabulum, drawn perpendicular to Hilgenreiner's line. The ossific nucleus of the femoral head should be located in the medial lower quadrant of the intersection of these 2 lines. **Shenton's line** is a curved line drawn from the medial aspect of the femoral neck to the lower border of the superior pubic ramus. In a child with normal hips, this line is a continuous contour. In a child with hip subluxation or dislocation, this line consists of 2 separate arcs and is described as "broken."

The **acetabular index** is the angle formed between Hilgenreiner's line and a line drawn from the depth of the acetabular socket to the most lateral ossified margin of the roof of the acetabulum. This angle measures the development of the osseous roof of the acetabulum. In the newborn, the acetabular index can be up to 40 degrees; by 4 mo in the normal infant, it should be no more than 30 degrees. In the older child, the **center-edge angle** is a useful measure of femoral head coverage. This angle is formed at the juncture of the Perkins line and a line connecting the lateral margin of the acetabulum to the center of the femoral head. In children 6-13 yr old, an angle >19 degrees is normal, whereas in children 14 yr and older, an angle >25 degrees is considered normal.

TREATMENT

The goals in the management of DDH are to obtain and maintain a concentric reduction of the femoral head within the acetabulum in order to provide the optimal environment for the normal development of both the femoral head and acetabulum. The later the diagnosis of DDH is made, the more difficult it is to achieve these goals, the less potential there is for acetabular and proximal femoral remodeling, and the more complex the required treatments.

Newborns and Infants Younger Than 6 Months

Newborns hips that are Barlow-positive (reduced but dislocatable) or Ortolani-positive (dislocated but reducible) should generally be treated with a Pavlik harness as soon as the diagnosis is made. The management of newborns with dysplasia who are younger than 4 wk of age is less clear. A significant proportion of these hips normalize within 3-4 wk; consequently, many physicians prefer to reexamine these newborns after a few weeks before making treatment decisions. A study of 128 newborns with mildly dysplastic hips based on the results of an ultrasound (alpha angles between 43 and 50 degrees) who were randomly assigned to receive immediate abduction splinting or active sonographic surveillance from birth with Frejka splinting provided if treatment was subsequently needed revealed no difference in radiologic findings at 6 yr of age.

Figure 678-9 Photograph of a Pavlik harness.

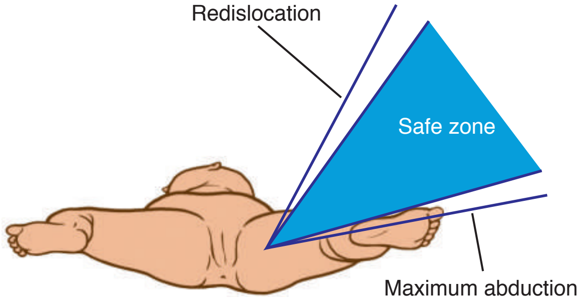

Figure 678-10 Diagram of the safe zone of Ramsey.

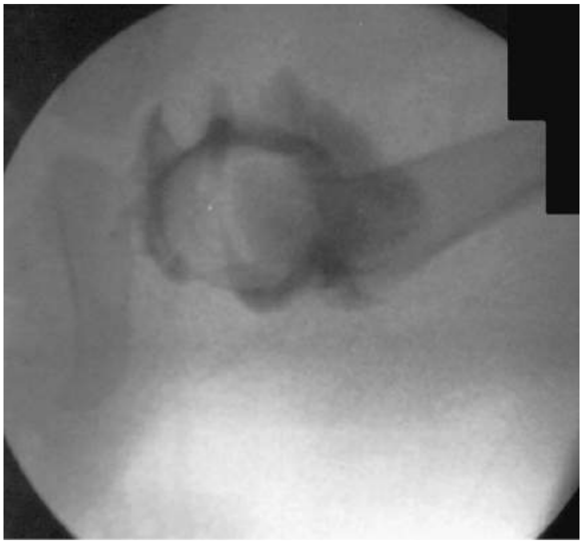

Figure 678-11 Arthrogram of a reduced hip for evaluating the stability of reduction.

Triple diapers or abduction diapers have no place in the treatment of DDH in the newborn; they are usually ineffective and give the family a false sense of security. *Acetabular dysplasia, subluxation, or dislocation can all be readily managed with the Pavlik harness.* Although other braces are available (von Rosen splint, Frejka pillow), the Pavlik harness remains the most commonly used device worldwide (Fig. 678-9). By maintaining the Ortolani-positive hip in a Pavlik harness on a full-time basis for 6 wk, hip instability resolves in 95% of cases. After 6 mo of age, the failure rate for the Pavlik harness is >50% because it is difficult to maintain the increasingly active and crawling child in the harness. Frequent examinations and readjustments are necessary to ensure that the harness is fitting correctly. The anterior straps of the harness should be set to maintain the hips in flexion (usually ~90-100 degrees); excessive flexion is discouraged because of the risk of femoral nerve palsy. The posterior straps are designed to encourage abduction. These are generally set to allow adduction just to neutral, as forced abduction by the harness can lead to avascular necrosis of the femoral epiphysis.

If follow-up examinations and ultrasounds do not demonstrate concentric reduction of the hip after 3-4 wk of Pavlik harness treatment, the harness should be abandoned. Continued use of the harness beyond this period in a persistently dislocated hip can cause *Pavlik harness disease*, or wearing away of the posterior aspect of the acetabulum, which can make the ultimate reduction less stable.

Children 6 Months to 2 Years of Age

The principal goals in the treatment of late-diagnosed dysplasia are to obtain and maintain reduction of the hip without damaging the femoral head. **Closed reductions** are performed in the operating room under general anesthesia. The hip is moved to determine the range of motion in which it remains reduced. This is compared to the maximal range of motion to construct a "safe zone" (Fig. 678-10). An arthrogram obtained at the time of reduction is very helpful for evaluating the depth and stability of the reduction (Fig. 678-11). The reduction is maintained in a well-molded spica cast, with the "human position" of moderate flexion and abduction being the preferred position. After the procedure, single-cut CT or MRI may be used to confirm the reduction. Twelve weeks after closed reduction, the plaster cast is removed; an abduction orthosis is often used at this point to encourage further remodeling of the acetabulum. Failure to obtain a stable hip with a closed reduction indicates the need for an **open reduction**. In patients younger than 2 yr of age, a secondary acetabular or femoral procedure is rarely required. The potential for acetabular development after closed or open reduction is excellent and continues for 4-8 yr after the procedure.

Children Older Than 2 Years

Children 2-6 yr of age with a hip dislocation usually require an open reduction. In this age group, a concomitant femoral shortening osteotomy is often performed to reduce the pressure on the proximal femur and minimize the risk of osteonecrosis. Because the potential for acetabular development is markedly diminished in these older children, a pelvic osteotomy is usually performed in conjunction with the open reduction. Postoperatively, patients are immobilized in a spica cast for 6-12 wk.

COMPLICATIONS

The most important complication of DDH is **avascular necrosis** of the femoral epiphysis. Reduction of the femoral head under pressure or in extreme abduction can result in occlusion of the epiphyseal vessels and produce either partial or total infarction of the epiphysis. Revascularization soon follows, but if the physis is severely damaged, abnormal growth and development can occur. The hip is most vulnerable to this complication before 4-6 mo, when the ossific nucleus appears. Management, as previously outlined, is designed to minimize this complication. With appropriate treatment, the incidence of avascular necrosis for DDH is reduced to 5-15%. Other complications in DDH include redislocation, residual subluxation, acetabular dysplasia, and postoperative complications, including wound infections.

678.2 Transient Monoarticular Synovitis (Toxic Synovitis)

Wudbhav N. Sankar, B. David Horn, Lawrence Wells, and John P. Dormans

Transient synovitis (toxic synovitis) is a reactive arthritis and is one of the most common causes of hip pain in young children.

ETIOLOGY

The cause of transient synovitis remains unknown. It has been variously described as a nonspecific inflammatory condition or as a postviral immunologic synovitis because it tends to follow recent viral illnesses.

CLINICAL MANIFESTATIONS

Although transient synovitis can occur in all age groups, it is most prevalent in children between 3 and 8 yr of age, with a mean onset at age 6 yr. Approximately 70% of all affected children have had a nonspecific upper respiratory tract infection 7-14 days before the onset of symptoms. Symptoms often develop acutely and usually consist of pain in the groin, anterior thigh, or knee, which may be referred from the hip. These children are usually able to bear weight on the affected limb and typically walk with a painful, limping gait. The hip is not held flexed, abducted, or laterally rotated unless a significant effusion is present. They are often afebrile or have a low-grade fever <38°C (100.4°F).

DIAGNOSIS

Transient synovitis is a clinical diagnosis, but laboratory and radiographic tests can be useful to rule out other more serious conditions. In transient synovitis, infection labs (erythrocyte sedimentation rate, serum C-reactive protein, and white blood cell counts) are relatively normal, but on occasion a mild elevation in the erythrocyte sedimentation rate is observed. AP and Lauenstein (frogleg) lateral radiographs of the pelvis may be acquired and are also usually found to be normal. Ultrasonography of the hip is preferred to x-rays and often demonstrates a joint effusion.

The most important condition to exclude before confirming a diagnosis of toxic synovitis is septic arthritis. Children with septic arthritis usually appear more systemically ill than those with transient synovitis. The pain associated with septic arthritis is more severe, and children often refuse to walk or move their hip at all. High fever, refusal to walk, and elevations of the erythrocyte sedimentation rate, serum C-reactive protein, and white blood cell count all point toward a diagnosis of septic arthritis. If the clinical scenario is suspicious for septic arthritis, an ultrasound-guided aspiration of the hip joint should be performed to make the definitive diagnosis (see Chapter 685). An exception to these criteria is hip septic arthritis due to *Kingella kingae*, which may have minimal inflammation and low grade or no fever (see Chapter 685). MRI may be needed to detect an associated osteomyelitis.

TREATMENT

The treatment of transient monoarticular synovitis of the hip is symptomatic. Recommended therapies include activity limitation and relief of weight bearing until the pain subsides. Antiinflammatory agents and analgesics can shorten the duration of pain. Most children recover completely within 3-6 wk.

Bibliography is available at Expert Consult.

678.3 Legg-Calvé-Perthes Disease

Wudbhav N. Sankar, B. David Horn, Lawrence Wells, and John P. Dormans

Legg-Calvé-Perthes disease (LCPD) is a hip disorder of unknown etiology that results from temporary interruption of the blood supply to the proximal femoral epiphysis, leading to osteonecrosis and femoral head deformity.

ETIOLOGY

Although the underlying etiology remains obscure, most authors agree that the final common pathway in the development of LCPD is disruption of the vascular supply to the femoral epiphysis, which results in ischemia and osteonecrosis. Infection, trauma, and transient synovitis have all been proposed as causative factors but are unsubstantiated. Factors leading to thrombophilia, an increased tendency to develop thrombosis and hypofibrinolysis, and a reduced ability to lyse thrombi have been identified. Factor V Leiden mutation, deficiency of proteins C and S, lupus anticoagulant, anticardiolipin antibodies, antitrypsin, and plasminogen activator might play a role in the abnormal clotting mechanism. These abnormalities in the clotting cascade are thought to increase blood viscosity and the risk for venous thrombosis. Poor venous outflow leads to increased intraosseous pressure, which, in turn, impedes arterial inflow, causing ischemia and cell death.

EPIDEMIOLOGY

The incidence of LCPD in the United States is 1 in 1,200 children with boys 4-5 times more likely to be affected than girls. The peak incidence of the disease is between the ages of 4 and 8 yr. Bilateral involvement is seen in approximately 10% of the patients, but the hips are usually in different stages of collapse. East Asians have the lowest incidence of the disease and whites the highest.

PATHOGENESIS

Early pathologic changes in the femoral head are the result of ischemia and necrosis; subsequent changes result from the repair process. The disease course may have 4 stages, although variations have been described. The **initial** stage of the disease, which often lasts 6 mo, is characterized by synovitis, joint irritability, and early necrosis of the femoral head. Revascularization then leads to osteoclastic-mediated resorption of the necrotic segment. The necrotic bone is replaced by fibrovascular tissue rather than new bone, which compromises the structural integrity of the femoral epiphysis. The second stage is the **fragmentation** stage, which typically lasts 8 mo. During this stage, the femoral epiphysis begins to collapse, usually laterally, and begins to extrude from the acetabulum. The **healing** stage, which lasts approximately 4 yr, begins with new bone formation in the subchondral region. Reossification begins centrally and expands in all directions. The degree of femoral head deformity depends on the severity of collapse and the amount of remodeling that occurs. The final stage is the **residual** stage, which begins after the entire head has reossified. A mild amount of remodeling of the femoral head still occurs until the child reaches skeletal maturity. LCPD often damages the proximal femoral physis leading to a short neck (coxa breva) and trochanteric overgrowth.

CLINICAL MANIFESTATIONS

The most common presenting symptom is a limp of varying duration. Pain, if present, is usually activity related and may be localized in the groin or referred to the anteromedial thigh or knee region. *Failure to recognize that thigh or knee pain in a child may be secondary to hip pathology can cause further delay in the diagnosis.* Less commonly, the onset of the disease may be much more acute and may be associated with a failure to ambulate.

Antalgic gait (a limp characterized by a shortening of gait phase on the injured side to alleviate weight-bearing pain) may be particularly prominent after strenuous activity at the end of the day. Hip motion, primarily internal rotation and abduction, is limited. Early in the course of the disease, the limited abduction is secondary to synovitis and muscle spasm in the adductor group; however, with time and the subsequent deformities that can develop, the limitation of abduction can become permanent. A mild hip flexion contracture of 10-20 degrees may be present. Atrophy of the muscles of the thigh, calf, or buttock from disuse secondary to pain may be evident. An apparent leg-length inequality may be caused by an adduction contracture or true shortening on the involved side from femoral head collapse.

DIAGNOSIS

Routine plain radiographs are the primary diagnostic tool for LCPD. AP and Lauenstein (frogleg) lateral views are used to diagnose, stage, provide prognosis for, and follow the course of the disease (Fig. 678-12). It is important when evaluating disease progression that all radiographs be viewed sequentially and compared with previous radiographs to assess the stage of the disease and to determine the true extent of epiphyseal involvement.

In the initial stage of LCPD, the radiographic changes include a decreased size of the ossification center, lateralization of the femoral head with widening of the medial joint space, a subchondral fracture, and physeal irregularity. In the fragmentation stage, the epiphysis appears fragmented, and there are scattered areas of increased radiolucency and radiodensity. During the reossification stage, the bone density returns to normal by new (woven) bone formation. The residual stage is marked by the reossification of the femoral head, gradual remodeling of head shape until skeletal maturity, and remodeling of the acetabulum.

In addition to these radiographic changes, several classic radiographic signs have been reported that describe a "head at risk" for severe deformity. Lateral extrusion of the epiphysis, a horizontal physis, calcification lateral to the epiphysis, subluxation of the hip, and a radiolucent horizontal V in the lateral aspect of the physis (Gage's sign) are all associated with a poor prognosis.

In the absence of changes on plain radiographs, particularly in the early stages of the disease, MRI is useful to diagnose early infarction and determine the degree of impaired perfusion. During the remodeling or residual stages, MRI is extremely helpful to define the abnormal anatomy and determine the extent of intra-articular injury. Arthrography can be useful to dynamically assess the shape of the femoral head, demonstrate whether a hip can be contained, and diagnose hinge abduction. Table 678-1 outlines the differential diagnosis.

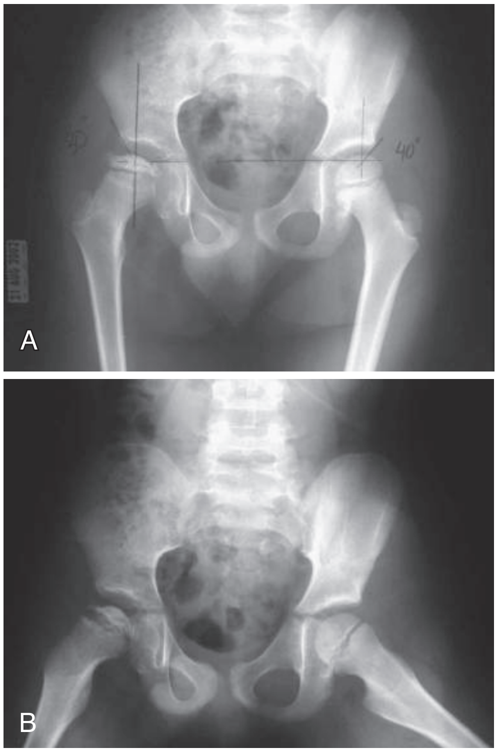

Figure 678-12 **A,** Anteroposterior radiograph of the pelvis shows epiphyseal fragmentation in the right hip, characteristic of the fragmentation phase of Legg-Calvé-Perthes disease. **B,** The frogleg lateral view demonstrates subchondral fracture, increased density of the femoral head, and some collapse.

CLASSIFICATION

Catterall proposed a 4-group classification based on the amount of femoral epiphysis involvement and a set of radiographic "head at-risk" signs. Group I hips have anterior femoral head involvement of 25%, no sequestrum (an island of dead bone within the epiphysis), and no metaphyseal abnormalities. Group II hips have up to 50% involvement and a clear demarcation between involved and uninvolved segments. Metaphyseal cysts may be present. Group III hips display up to 75% involvement and a large sequestrum. In group IV, the entire femoral head is involved. Use of the Catterall classification system has been limited because of a high degree of interobserver variability.

The **Herring lateral pillar classification** is the most widely used radiographic classification system for determining treatment and prognosis during the active stage of the disease (Fig. 678-13). Unlike the Catterall system, the Herring classification has a high degree of interobserver reliability. Classification is based on several radiographs taken during the early fragmentation stage. The lateral pillar classification system for LCPD evaluates the shape of the femoral head epiphysis on AP radiograph of the hip. The head is divided into 3 sections or pillars. The lateral pillar occupies the lateral 15-30% of the head width, the central pillar is approximately 50% of the head width, and the medial pillar is 20-35% of the head width. The degree of involvement of the lateral pillar can be subdivided into 3 groups. In group A, the lateral pillar is radiographically normal. In group B, the lateral pillar has some lucency but >50% of the lateral pillar height is maintained. In group C, the lateral pillar is more lucent than in group B and <50% of the pillar height remains. Herring has added a B/C border group to the

classification system to describe patients with approximately 50% collapse of the lateral pillar.

NATURAL HISTORY AND PROGNOSIS

Children who develop signs and symptoms of LCPD before the age of 6 yr tend to recover with fewer residual problems. Patients older than 9 yr of age at presentation usually have a poor prognosis. The reason for this difference is that the remodeling potential of the femoral head is higher in younger children. Greater extent of femoral head involvement and duration of the disease process are additional factors associated with a poor prognosis. Hips classified as Catterall groups III and IV and lateral pillar group C generally have a poor prognosis.

TREATMENT

The goal of treatment in LCPD is preservation of a spherical, well-covered femoral head and maintenance of hip range of motion that is close to normal. Although the treatment of LCPD remains controversial, most authors agree that the general approach to these patients should be guided by the principle of containment. This principle is predicated on the fact that while the femoral head is fragmenting, and therefore in a softened condition, it is best to contain it entirely within the acetabulum; by doing so, the acetabulum acts as a mold for the regenerating femoral head. Conversely, failure to contain the head permits it to deform, with resulting extrusion and impingement on the lateral edge of the acetabulum. To be successful, containment must be instituted early while the femoral head is still moldable; once the head has healed, repositioning the femoral epiphysis will not aid remodeling and can, in fact, worsen symptoms.

Initial options to manage symptoms include activity limitation, protected weightbearing, and nonsteroidal antiinflammatory medications. "Nonoperative" containment can be achieved by using a Petrie cast to restore abduction and to direct the femoral head deeper into the acetabulum. Petrie casts are 2 long-leg casts that are connected by a bar and can be helpful to keep the hips in abduction and internal rotation (the best position for containment). Casting is generally done in conjunction with an arthrogram to confirm containment and a tenotomy of the adductor tendons. After 6 wk, patients can be transitioned into an abduction orthosis with limited weightbearing. Several older studies did not support the efficacy of casting and long-term bracing as a means of containment, but a subsequent large series reported excellent results with this form of treatment.

Surgical containment may be approached from the femoral side, the acetabular side, or both sides of the hip joint. A varus osteotomy of the proximal femur is the most common procedure. Pelvic osteotomies in LCPD are divided into 3 categories: acetabular rotational osteotomies, shelf procedures, and medial displacement or Chiari osteotomies. Any of these procedures can be combined with a proximal femoral varus osteotomy when severe deformity of the femoral head cannot be contained by a pelvic osteotomy alone.

After healing of the epiphysis, surgical treatment shifts from containment to managing the residual deformity. Patients with hinge abduction or joint incongruity might benefit from a valgus-producing proximal femoral osteotomy. Coxa breva and overgrowth of the greater trochanter can be managed by performing an advancement of the trochanter. This helps restore the length–tension relationship of the abductor mechanism and can alleviate abductor fatigue. Patients with femoroacetabular impingement from irregularity of the femoral head can often be helped with an osteoplasty or cheilectomy of the offending prominence.

678.4 Slipped Capital Femoral Epiphysis

Wudbhav N. Sankar, B. David Horn, Lawrence Wells, and John P. Dormans

Slipped capital femoral epiphysis (SCFE) is a hip disorder that affects adolescents, most often between 10 and 16 yr of age, and involves failure of the physis and displacement of the femoral head relative to the neck.

CLASSIFICATION

SCFEs may be classified temporally, according to onset of symptoms (acute, chronic, acute-on-chronic); functionally, according to patient's ability to bear weight (stable or unstable); or morphologically, as the extent of displacement of the femoral epiphysis relative to the neck (mild, moderate, or severe), as estimated by measurement on radiographic or CT images.

An **acute** SCFE is characterized as one occurring in a patient who has prodromal symptoms for ≤3 wk and should be distinguished from a purely traumatic separation of the epiphysis in a previously normal hip (a true Salter-Harris type I fracture; see Chapter 683). The patient with an acute slip usually has some prodromal pain in the groin, thigh, or knee, and usually reports a relatively minor injury (a twist or fall) that is not sufficiently violent to produce an acute fracture of this severity.

Chronic SCFE is the most common form of presentation. Typically, an adolescent presents with a few-month history of vague groin, thigh, or knee pain and a limp. Radiographs show a variable amount of posterior and inferior migration of the femoral epiphysis and remodeling of the femoral neck in the same direction.

Children with **acute-on-chronic** SCFE can have features of both acute and chronic conditions. Prodromal symptoms have been present for >3 wk with a sudden exacerbation of pain. Radiographs demonstrate femoral neck remodeling and further displacement of the capital epiphysis beyond the remodeled point of the femoral neck.

The stability classification separates patients based on their ability to ambulate and is more useful in predicting prognosis and establishing a treatment plan. The SCFE is considered **stable** when the child is able to walk with or without crutches. A child with an **unstable** SCFE is unable to walk with or without walking aids. Patients with unstable SCFE have a much higher prevalence of osteonecrosis (up to 50%) compared to those with stable SCFE (nearly 0%). This is most likely because of the vascular injury caused at the time of initial displacement.

SCFE may also be categorized by the degree of displacement of the epiphysis on the femoral neck. The head-shaft angle difference is <30 degrees in mild slips, between 30 and 60 degrees in moderate slips, and >60 degrees in severe slips, compared to the normal contralateral side.

ETIOLOGY AND PATHOGENESIS

SCFEs are most likely caused by a combination of mechanical and endocrine factors. The plane of cleavage in most SCFEs occurs through the hypertrophic zone of the physis. During normal puberty, the physis becomes more vertically oriented, which converts mechanical forces from compression to shear. In addition, the hypertrophic zone becomes elongated in pubertal adolescents due to high levels of circulating hormones. This widening of the physis decreases the threshold for mechanical failure. Normal ossification depends on a number of different factors, including thyroid hormone, vitamin D, and calcium. Consequently, it is not surprising that SCFEs occur with increased incidence in children with medical disorders such as hypothyroidism, hypopituitarism, and renal osteodystrophy. Obesity, one of the largest risk factors for SCFE, affects both the mechanical load on the physis and the level of circulating hormones. The combination of mechanical and endocrine factors results in gradual failure of the physis, which allows posterior and inferior displacement of the head in relation to the femoral neck.

EPIDEMIOLOGY

The annual incidence of SCFE is 2 per 100,000 in the general population. Incidence has ranged from 0.2 per 100,000 in eastern Japan to 10.08 per 100,000 in the northeastern United States. The African-American and Polynesian populations are reported to have an increased incidence of SCFE. Obesity is the most closely associated risk factor in the development of SCFE; approximately 65% of the patients are >90th percentile in weight-for-age profiles. There is a predilection for boys to

be affected more often than girls and for the left hip to be affected more often than the right. Bilateral involvement has been reported in as many as 60% of cases, nearly half of which may be present at the time of initial presentation.

CLINICAL MANIFESTATIONS

The classic patient presenting with a SCFE is an obese, African-American boy between the ages of 11 and 16 yr. Girls present earlier, usually between 10 and 14 yr of age. Patients with chronic and stable SCFEs tend to present after weeks to months of symptoms. Patients usually limp to some degree and have an externally rotated lower extremity. Physical examination of the affected hip reveals a restriction of internal rotation, abduction, and flexion. Commonly, the examiner notes that as the affected hip is flexed, the thigh tends to rotate progressively into more external rotation with increased flexion (Fig. 678-14). Most patients complain of groin symptoms, but isolated thigh pain or knee pain is a common presentation from referred pain along the course of the obturator nerve. Missed or delayed diagnosis often occurs in children who present with knee pain and do not receive appropriate imaging of the hip. Patients with unstable SCFEs usually present in an urgent fashion. Children typically refuse to allow any range of motion of the hip; much like a hip fracture, the extremity is shortened, abducted, and externally rotated.

DIAGNOSTIC STUDIES

AP and frogleg lateral radiographic views of both hips are usually the only imaging studies needed to make the diagnosis. Because approximately 25% of patients have a contralateral slip on initial presentation, it is critical that both hips be carefully evaluated by the treating physician. Radiographic findings include widening and irregularity of the physis, a decrease in epiphyseal height in the center of the acetabulum, a crescent-shaped area of increased density in the proximal portion of the femoral neck, and the "blanch sign of Steel" corresponding to the double density created from the anteriorly displaced femoral neck overlying the femoral head. In an unaffected patient, Klein's line, a straight line drawn along the superior cortex of the femoral neck on the AP radiograph, should intersect some portion of the lateral capital femoral epiphysis. With progressive displacement of the epiphysis, Klein's line no longer intersects the epiphysis (Fig. 678-15). Although some of these radiographic findings can be subtle, most diagnoses can be readily made on the frogleg lateral view, which reveals the characteristic posterior and inferior displacement of the epiphysis in relation to the femoral neck (Fig. 678-16).

TREATMENT

Once the diagnosis is made, the patient should be admitted to the hospital immediately and placed on bed rest. Allowing the child to go home without definitive treatment increases the risk that a stable SCFE will become an unstable SCFE and that further displacement will occur. Children with atypical presentations (younger than 10 yr of age, thin body habitus) should have screening labs sent to rule out an underlying endocrinopathy.

The goal of treatment is to prevent further progression of the slip and to stabilize (i.e., close) the physis. Although various forms of treatment have been used in the past, including spica casting, the current gold standard for the treatment of SCFE is in situ pinning with a single, large screw (Fig. 678-17). The term *in situ* implies that no attempt is made to reduce the displacement between the epiphysis and femoral neck because doing so increases the risk of osteonecrosis. Screws are typically placed percutaneously under fluoroscopic guidance. Postoperatively, most patients are allowed partial weightbearing with crutches for 4-6 wk, followed by a gradual return to normal activities. Patients should be monitored with serial radiographs to be sure that the physis is closing and that the slip is stable. After healing from the initial stabilization, patients with severe residual deformity may be candidates for proximal femoral osteotomy to correct the deformity, reduce impingement, and improve range of motion.

Because 20-40% of children will develop a contralateral SCFE at some point, many orthopedists advocate prophylactic pin fixation of the contralateral (normal) side in patients with a unilateral SCFE. The benefits of preventing a possible slip must be balanced with the risks of performing a potentially unnecessary surgery. Several recent studies have attempted to analyze decision models for prophylactic pinning, but controversy remains regarding the optimal course of treatment.

COMPLICATIONS

Osteonecrosis and chondrolysis are the 2 most serious complications of SCFE. Osteonecrosis, or avascular necrosis, usually occurs as a result of injury to the retinacular vessels. This can be caused by an initial force of injury, particularly in unstable slips, forced manipulation of an acute or unstable SCFE, compression from intracapsular hematoma, or as a direct injury during surgery. Partial forms of osteonecrosis can also appear following internal fixation; this can be caused by a disruption of the intraepiphyseal blood vessels. Chondrolysis, on the other

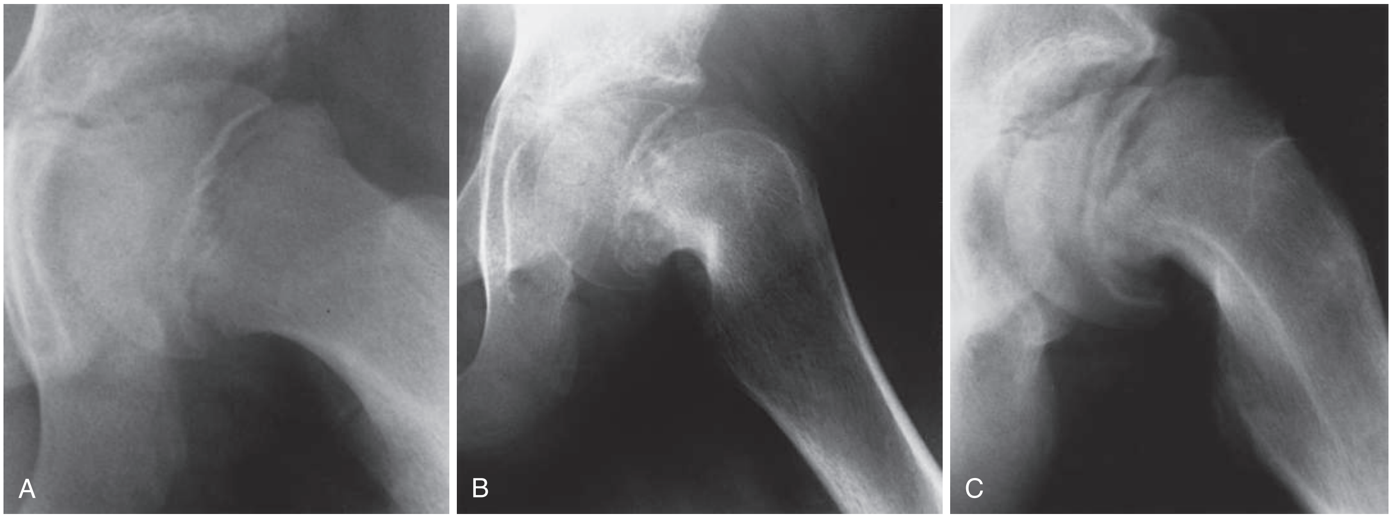

Figure 678-16 **Radiographic appearance of slipped capital femoral epiphysis (SCFE) on presentation. A,** Appearance of acute SCFE on a frogleg lateral view. The displacement of the epiphysis is suggestive of a Salter-Harris type I fracture of the upper femoral physis. There are no secondary adaptive changes noted in the femoral neck. **B,** Frogleg lateral radiographs in a patient with many months of thigh discomfort and a chronic slipped epiphysis. Adaptive changes in the femoral neck predominate, and the epiphysis is centered on the adapted femoral neck. **C,** Frogleg lateral radiographs of a patient with acute-on-chronic SCFE. The patient had several months of vague thigh pain, with sudden, severe exacerbation of that pain. The acute displacement of the epiphysis is evident. Unlike in acute SCFE (see **A**), secondary adaptive remodeling changes are also present in the femoral neck, beyond which the epiphysis has acutely displaced. *(From Herring JA: Slipped capital femoral epiphysis. hand, is an acute dissolution of articular cartilage in the hip. There are no clear causes of this complication, but it is believed to be associated with more-severe slips, to occur more commonly among African-Americans and girls, and to be associated with pins or screws protruding out of the femoral head.

Chapter 679

The Spine

R. Justin Mistovich and David A. Spiegel

Abnormalities of the spine can result from a variety of causes including congenital, developmental, and traumatic. In addition to spinal deformities, back pain has become increasingly prevalent in childhood and adolescence, and a thoughtful diagnostic evaluation is required to establish the diagnosis while minimizing the overutilization of healthcare resources. The most common deformities are scoliosis and kyphosis. An early diagnosis is important, as a subset of patients may be candidates for "preventive" strategies such as bracing. Early intervention may potentially reduce the number requiring surgery, or at least reduce the magnitude or risks if surgical treatment is required.

Scoliosis may be from congenital bony deformities, may be idiopathic, including infantile, juvenile, or adolescent idiopathic scoliosis, or may be associated with a variety of underlying conditions, including neuromuscular diseases, connective tissue diseases, and genetic

syndromes (Table 679-1). The pediatrician is often the first to diagnose these conditions. A familiarity with the physical examination, as well as the natural history and treatment options, will help the pediatrician to not only establish an early diagnosis but also to provide basic counseling for the patient and family regarding the diagnosis, general prognosis, and whether any referral and/or further workup might be indicated.

While parents and families are primarily concerned about the resulting cosmetic abnormalities, the physician diagnosing a patient with a spine deformity must carefully consider both the potential for underlying causes requiring treatment and the patient's long-term prognosis. If a certain curve magnitude is crossed in a patient with adolescent idiopathic scoliosis, the curve will be likely to continue to progress in adulthood and may require surgical treatment. Progressive curvatures in the neuromuscular population may result in respiratory insufficiency in addition to a loss of sitting balance. Additionally, while the majority of patients with excessive thoracic kyphosis have benign flexible curves and require no active treatment, a subset will have a progressive or rigid deformity which may require treatment. Parents and the patient must have an understanding of the deformity, how it may progress, and potential complications associated with the diagnosis. Table 679-1 presents a classification of common spinal abnormalities.

NORMAL SPINAL CURVATURES

The spine has curvatures that are anatomically normal in the lateral (sagittal) plane. Cervical lordosis (convex anteriorly), thoracic kyphosis (convex posteriorly), and lumbar lordosis regions are biomechanically advantageous as they maintain relationships of the body relative to the forces of gravity, which is important for balance. These curvatures also help to conserve energy by minimizing the amount of muscular activity required to maintain an upright posture.

Abnormalities affecting these normal curvatures, termed *sagittal plane imbalances*, can be measured on a sagittal spine radiograph. A vertical line, or *plumb line*, drawn from the center of the 7th cervical vertebra should normally fall through the posterosuperior corner of the sacrum. Disorders affecting sagittal alignment include thoracic hyperkyphosis and lumbar hyperlordosis. Although scoliosis is a 3-dimensional deformity, it is most commonly described as a lateral curvature of the spine in the frontal (coronal) plane.

679.1 Idiopathic Scoliosis

R. Justin Mistovich and David A. Spiegel

DEFINITION

The word *scoliosis* takes its origin from the Greek word *skolios*, meaning bent or curved. Medically recognized for centuries, Hippocrates described scoliosis in his treatise *On Articulations*. Scoliosis is a complex 3-dimensional spinal deformity that is defined in the coronal plane as a curve of at least 10 degrees, measured by the Cobb method, on a **posteroanterior (PA)** radiograph of the spine. The deformity also includes rotation of the vertebrae and also malalignment in the sagittal plane, such as a segmental apical lordosis in thoracic curves.

ETIOLOGY

The etiology of idiopathic scoliosis remains unknown; it is likely that the cause is multifactorial with genetic, hormonal, cellular, anatomic, and functional contributions.

A genetic link has been proposed with sex-linked dominant, autosomal dominant and polygenetic inheritance patterns all suggested. Genetic involvement has been substantiated in studies of twins, demonstrating a 73% concordance rate for **adolescent idiopathic scoliosis (AIS)** in monozygotic twins compared to a 36% concordance rate in dizygotic twins.

AIS is 2-10 times more common in females than males. Investigators have attempted to explain this difference as a genetic effect: It has been hypothesized that males are not as susceptible to the involved genes as females. Therefore, affected males must inherit a larger number of susceptibility genes to have a scoliosis phenotype. Males would pass more susceptibility genes onto their children and would therefore have more affected children. This polygenetic prediction is known as the Carter effect; fathers with AIS *transmit* the disease to 80% of their children, but mothers with AIS *transmit* the disease to only 56% of their children.

Certain polymorphisms in the estrogen receptor gene are linked to an increased curve progression and higher risk of requiring operative treatment. Genetic analysis may also be able to determine curve progression, although data concerning the effectiveness and validity of this are limited.

Endocrine factors may have a possible role in the disease pathology. Lower plasma melatonin levels have been noted in patients with progressive curvatures. Abnormal levels of growth hormone and insulin-like growth factor-1 have also been discovered. Leptin, the hormone responsible for satiety, is found at lower levels in patients with AIS.

Cellular structures may be involved in the disease process. Calmodulin, a regulator of the contractile properties of muscle, occurs at increased levels in the platelets of patients with progressive AIS.

MRI studies of the brain in patients with AIS have found that the cerebellum of affected patients is hypertrophied in areas involving the somatosensory tracts, motor control, and response to visual stimulation. These areas of hypertrophy may be a compensation for impaired balance resulting from malalignment of the spine. Other studies have noted a decrease in regional brain volumes and white matter in the corpus callosum and internal capsule between patients affected with AIS and normal adolescents. Girls with AIS have also been noted to have a larger foramen magnum. The importance of these imaging findings remains unclear.

Functional evaluations of patients with AIS have noted abnormalities in proprioception, postural balance, somatosensory function, somatosensory evoked potentials and electromyography. Patients with AIS have differences in vestibular-evoked myogenic potentials, suggesting that otolith system dysfunction may play a role in the disease. Approximately one-third of girls with AIS have osteopenia on dual-energy x-ray absorptiometry studies, and of these, 80% will have lifelong osteopenia. Osteopenia is linked to an increased risk of curve

progression. It is nonetheless difficult to determine which findings are primary or causative, and which are secondary to the disease.

EPIDEMIOLOGY

The overall prevalence of idiopathic scoliosis in skeletally immature patients ranges from 1-3% of the population. Most curves are mild and do not require treatment, with only 0.5% greater than 20 degrees and 0.3% exceeding 30 degrees. While curves of ≤10 degrees occur equally in males and females, those requiring an intervention occur in a 7 : 1 female : male ratio.

CLASSIFICATION OF IDIOPATHIC SCOLIOSIS

Idiopathic scoliosis is classified according to the age at onset. **Infantile scoliosis** is rare, comprising 0.5-4% of all cases of idiopathic scoliosis. It describes patients with spinal curves noted from birth to 3 yr of age. Juvenile scoliosis accounts for 8-16% of cases of idiopathic scoliosis and affects children age 3-10 yr. AIS affects patients 11 yr of age and older, and comprises 70-80% of all cases of idiopathic scoliosis.

CLINICAL PRESENTATION OF IDIOPATHIC SCOLIOSIS

When evaluating a patient with a structural spinal curvature, a thorough history and physical examination are required because idiopathic scoliosis is a diagnosis of exclusion. All other potential causes, including congenital bone malformations, neuromuscular and connective tissue diseases, and tumors, must carefully be excluded.

Patients often present after a positive screening by their primary care physician, through a school screening program, or because they (or their family or friends) have noticed a cosmetic deformity. It should be noted that school screening programs have become controversial, as some authors claim that the programs do not change the outcomes of patients requiring intervention, result in unnecessary physician visits and radiographs, and are not cost-effective. The British Orthopaedic Association and the U.S. Preventive Services Task Force have both issued statements recommending against routine screening for the above reasons. However, citing the need for early identification of scoliosis to reduce the risk of operative complications common to correction of large, neglected curves, the Scoliosis Research Society, an international organization of spine surgeons, still advocates for school screening.

Back pain is not commonly a primary presenting complaint of patients with scoliosis, although when questioned, one-third of adolescents with idiopathic scoliosis will endorse some degree of back discomfort at some point in time. To keep this finding in perspective, approximately 35% of healthy adolescents complain of episodes of low back pain and discomfort. However, if a patient presents with the complaint of significant back pain associated with a curvature, the physician must perform a careful physical exam, check spinal radiographs, and evaluate for other causes of pain, including spondylosis, spondylolisthesis, tethered cords or a syrinx, herniated discs, or tumors such as osteoid osteoma or spinal cord tumor (see Chapter 679.5 below).

PHYSICAL EXAMINATION OF IDIOPATHIC SCOLIOSIS

Evaluate the patient in the standing position, from both the front and the side, to identify any asymmetry in the chest wall, trunk, and/or shoulders.

Begin the examination focusing on the back. The earliest abnormality noted on physical exam in patients with scoliosis is asymmetry of the posterior chest wall on forward bending. This test, called the Adams forward-bending test (Fig. 679-1) is performed by placing a scoliometer at the apex of the deformity with the patient bending 45 degrees forward. An inclination measuring 7 degrees or more has been suggested as the cut off for orthopaedic referral. Scoliosis is a 3-dimensional deformity. Patients develop a posterior rib hump on the convex side of the spinal curve as a result of the rotational component of the deformity. The anterior chest wall may be prominent on the concavity of the curve as a result of outward rib rotation. Other

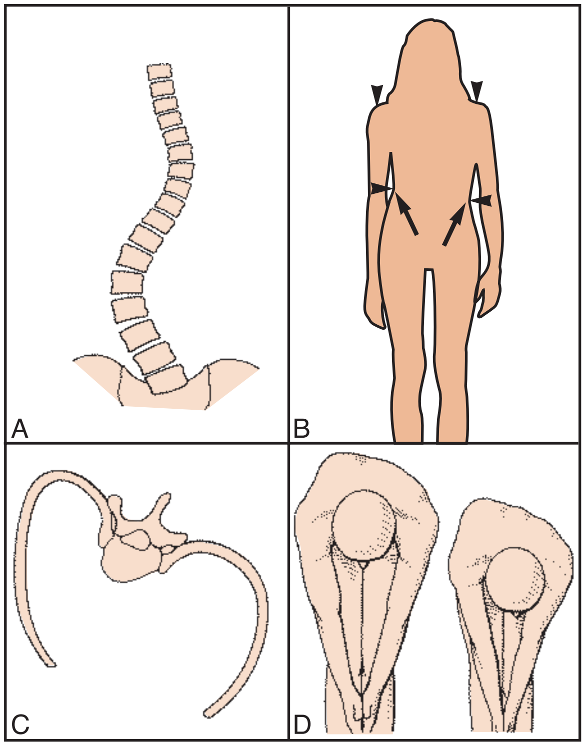

Figure 679-1 Structural changes in idiopathic scoliosis. **A,** As curvature increases, alterations in body configuration develop in both the primary and compensatory curve regions. **B,** Asymmetry of shoulder height, waistline, and elbow-to-flank distance are common findings. **C,** Vertebral rotation and associated posterior displacement of the ribs on the convex side of the curve are responsible for the characteristic deformity of the chest wall in scoliosis patients. **D,** In the school screening examination for scoliosis, the patient bends forward at the waist. Rib asymmetry of even a small degree is obvious. *(From Scoles PV: Spinal deformity in childhood and adolescence. In Behrman RE, Vaughn VC III, editors:* Nelson textbook of pediatrics, update 5, *Philadelphia, 1989, WB Saunders.)*

associated findings may include elevation of the shoulder, a lateral shift of the trunk, or an apparent leg-length discrepancy. A lumbar curve may also compensate for a primary limb-length discrepancy, with the apex toward the shorter leg.

Next, examine the patient from the side to evaluate the degree of kyphosis and lordosis. The upper thoracic spine normally has a smooth, gently rounded kyphotic curve with an apex in the midthoracic region. The cervical spine and lower lumbar spine have concave, or lordotic curves. The magnitude of these sagittal contours varies both with age and among individuals of the same age. Children have less cervical lordosis and more lumbar lordosis than do adults or adolescents. When examining a patient with idiopathic scoliosis, a common finding is a loss of the normal thoracic kyphosis, resulting in what is called a relative thoracic lordosis. A common benign finding in normal adolescent thoracic spines is a flexible roundback, or postural kyphosis. This can be corrected voluntarily when the patient extends his or her spine. This is different from sharp, abrupt, or accentuated forward angulation in the thoracic or thoracolumbar region, which is indicative of a pathologic kyphotic deformity.

The final exam component is a careful neurologic examination, as scoliosis may be associated with an underlying neurologic diagnosis. Check superficial abdominal reflexes, extremity reflexes, muscle strength, and examine for clonus. A high suspicion is necessary in patients with infantile and juvenile idiopathic scoliosis because 20% have an associated intraspinal abnormality such as a tethered spinal cord or syringomyelia. The index of suspicion for neurologic involvement is further raised in the presence of back pain or neurologic symptoms, café-au-lait spots, a sacral dimple, midline cutaneous

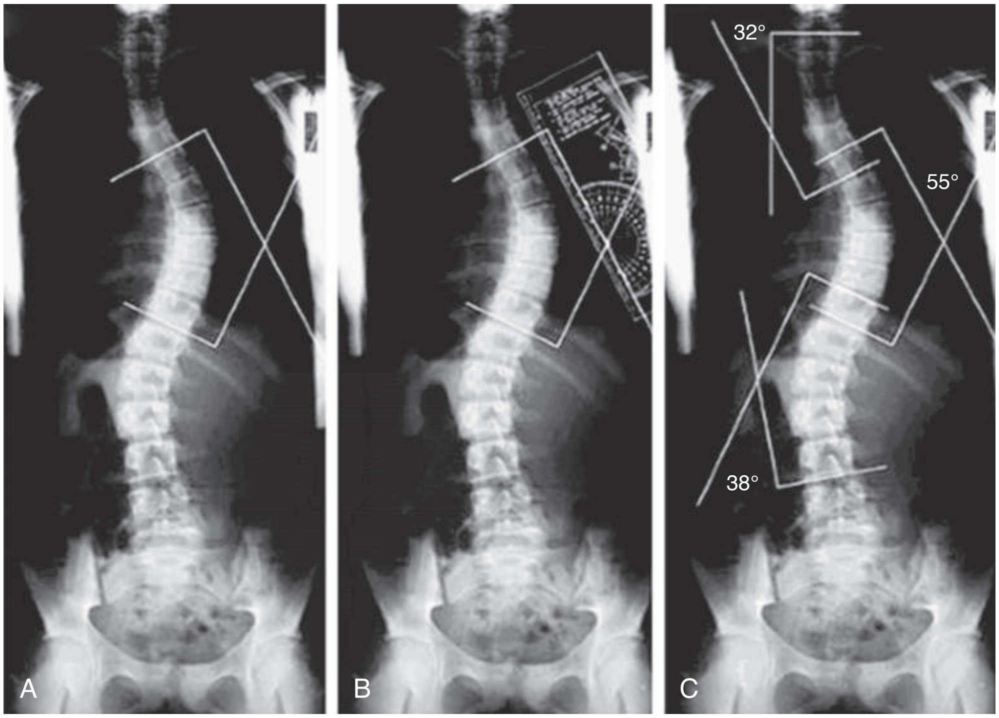

Figure 679-2 **A-C,** Cobb angles measurements. *(From Morrissy, RT, Weinstein, SL:* Lovell & Winter's pediatric orthopaedics, *ed 6, Philadelphia, 2006, Lippincott Williams & Wilkins.)*

abnormalities such as a hair patch or skin tag, or a unilateral foot deformity.

RADIOGRAPHIC EVALUATION OF IDIOPATHIC SCOLIOSIS

Standing, high-quality, PA and lateral radiographs of the entire spine are recommended at the initial evaluation for patients with clinical findings suggestive of a spinal deformity. On the PA radiograph, the degree of curvature is determined by the Cobb method, in which the angle between the superior and inferior vertebrae tilted into the curve is measured (Fig. 679-2). A line is drawn across the superior end plate of each end vertebra, and the angle between perpendicular lines drawn from each of these is measured.

Spinal MRI is indicated when there is suspicion of an underlying cause for the scoliosis, such as spinal cord abnormality based on age (infantile or juvenile curves), abnormal findings on the history and physical examination, and atypical radiographic features. Atypical radiographic findings may include certain curve patterns such as a left thoracic curve, double thoracic curves, or high thoracic curves. Other radiographic abnormalities include widening of the spinal canal and erosive or dysplastic changes in the vertebral body or ribs. On the lateral radiograph, an increase in thoracic kyphosis or an absence of segmental lordosis may be suggestive of an underlying neurologic abnormality.

NATURAL HISTORY OF IDIOPATHIC SCOLIOSIS

The decision to treat the patient is based on the natural history of idiopathic scoliosis. Uniquely, infantile idiopathic scoliosis may spontaneously resolve in 20-90% of cases. Patients with infantile scoliosis who have developmental delay, curves presenting after 1 yr of age, and larger magnitude curves are more likely to progress. A radiographic parameter called the *Mehta angle* can also be used to predict curve progression. This measurement examines the vertebra at the apex of the thoracic curve. It measures the angle formed by a line perpendicular from the vertebral end plate and a line down the center of the rib. The measurement is calculated on the convex and concave side, and the final *rib vertebral angle difference* is calculated by subtracting the convex side from the concave side. A curve with an rib vertebral angle difference <20 degrees will resolve in approximately 80% of cases, whereas a curve with an rib vertebral angle difference >20 degrees will progress in more than 80% of cases. Curves that resolve typically do so before 2 yr of age.

Several factors affect the rate of curve progression in patients with AIS. Curves are more likely to progress in patients with significant growth remaining and skeletal immaturity, meaning that the growth plates, or physes, remain open allowing for continued skeletal growth. Findings associated with significant growth remaining are younger age, premenarchal status, Tanner stage I or II, and Risser sign (a radiographic measurement of ossification of the iliac crest) of 0 or 1. Other factors affecting progression are the curve magnitude, pattern, and patient gender. There is a relationship between curve progression and 3-dimensional spinal measurements of vertebral wedging, axial rotation, and torsion, possibly allowing for better prognostication of curves at risk. In general, female patients are more likely than males to have curves that progress. Younger, premenarchal girls with curves between 20 degrees and 30 degrees have a significantly higher risk of progression than do girls 2 yr after menarche with similar curves, demonstrating the significance of age on progression. The older group is unlikely to have any progression at all while premenarchal girls with the same curve are likely to progress. Thoracic curves <30 degrees rarely progress after skeletal maturity, whereas those >45-50 degrees may progress approximately 1 degree per year through life.

Functionally, there are not many significant, clinically detrimental effects of smaller curves. Idiopathic thoracic curvatures greater than 60-70 degrees may be associated with abnormalities on pulmonary function testing, and curves of higher magnitude may cause clinically significant cardiopulmonary impairment and even cor pulmonale in severe curves. Long-term studies demonstrate that a degree of chronic back pain may be a problem for patients with scoliosis, although there is no definitive connection between pain and the curve magnitude or location. Furthermore, nearly 70% of patients with pain reported low or moderate severity of symptoms, stating that the pain does not interfere with normal activities.

TREATMENT OF IDIOPATHIC SCOLIOSIS

Brace treatment may prevent curve progression in a significant number of patients with AIS and is most successful when an early diagnosis is established. The success rate depends upon the amount of growth remaining; patients with infantile or juvenile scoliosis are much more likely to require a surgical procedure than those with AIS. Adherence with the recommended protocol for wearing the brace will influence the outcome. Although various schedules for brace wear have been reported, from 12-23 hr daily, the brace is generally worn for 16 or more hours per day, maximizing wear when the patient is upright. Adherence can be a challenge in the adolescent population. Braces are offered for treatment of skeletally immature patients with curves >30 degrees at the first visit, or in patients who are being followed and have developed progression of their curvature beyond 25 degrees. Bracing is ineffective in curvatures >45 degrees. The brace is worn until cessation of growth in males, but in females some authors will consider weaning from the brace when the patient is more than 1.5 yr postmenarchal, is a Risser 4 or greater and/or has grown less than 1 cm over the previous 6 mo.

Surgical treatment involves spinal arthrodesis or fusion and is usually recommended for skeletally immature patients with progressive curves >45 degrees and skeletally mature patients with curves >50 degrees. The goals of surgery are to arrest progression of the deformity, to improve cosmesis, and to achieve a balanced spine, all while minimizing the number of vertebral segments that are stabilized.

Implants, including pedicle screws, sublaminar wires, and hooks, are attached to 2 longitudinal rods (Fig. 679-3). These are used to apply mechanical forces to the spine, correcting the deformity in both the frontal and lateral planes. The spine is decorticated and bone graft is placed for the fusion portion of the procedure. Correction also maintains normal frontal and sagittal spinal balance. The strength of the spinal implants maintains correction without requiring a postoperative brace in the majority of cases.

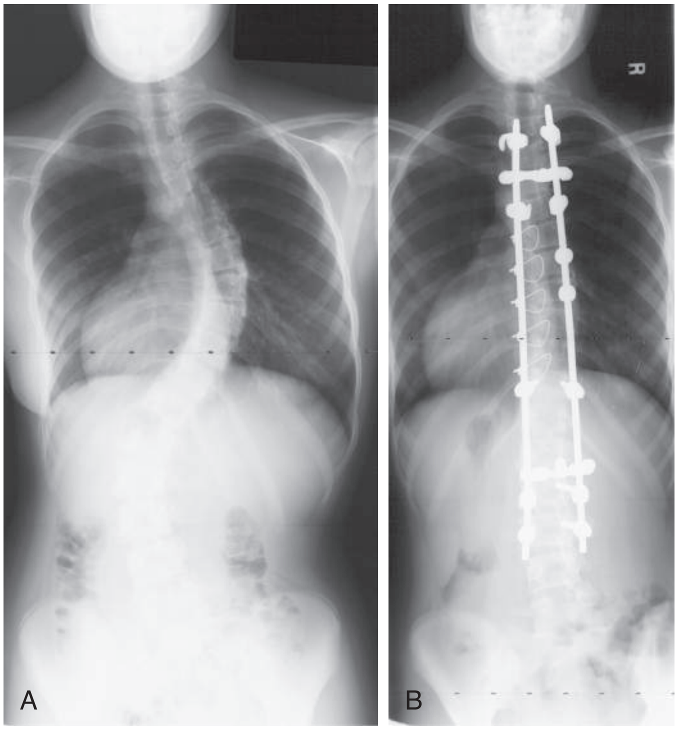

Figure 679-3 **A,** Preoperative standing posteroanterior radiograph of a 14 yr old girl who was skeletally immature and developed a 68 degree right thoracic and a 53 degree left lumbar scoliosis. Her trunk was shifted to the right, and the left shoulder was slightly depressed. **B,** Based upon the risk of future progression, she was treated by an instrumented posterior spinal fusion from T3 to L3 with correction of the right thoracic curve to 20 degrees and the left lumbar curve to 10 degrees. Coronal spinal balance was restored, and shoulder height was maintained.

Most procedures are performed posteriorly using pedicle screw fixation, which affords excellent correction, especially of the rotational component of the deformity. Posterior osteotomies are often added to enhance flexibility and improve the degree of correction in stiffer curves. Anterior spinal releases requiring a thoracotomy are performed infrequently. Open anterior thoracic and thoracolumbar procedures violate the chest wall and often the diaphragm, and pulmonary function may take up to 2 yr to return to normal values. Even though thoracoscopic techniques can be utilized to perform anterior spinal release with or without instrumentation and fusion, their use is limited. Patients with conditions such as neurofibromatosis (see Chapter 596.1) and myelomeningocele (see Chapter 591.4) have a higher likelihood of achieving a non-union of their fusion, and an anterior fusion is considered in addition to the posterior fusion in these groups. Younger patients, in whom the triradiate cartilage remain open, are at risk for crankshaft, or progressive deformity/loss of correction as a consequence of continued anterior spinal growth, after a posterior fusion. Traditionally, these patients were treated by simultaneous anterior fusion to remove the growth potential; however, the rigidity of constructs with pedicle screws negates the need for this additional surgery. For idiopathic thoracolumbar and lumbar curves, an anterior fusion with instrumentation can be considered, although the posterior approach with osteotomies and pedicle screw fixation is being used more frequently to avoid the need for anterior surgery. Posterior spinal fusion has been associated with accelerated degeneration of the unfused levels. In many, this remains asymptomatic, but the long-term effects remain unknown.

Several emerging techniques are being evaluated in the management of idiopathic scoliosis. These include new approaches to the spine, attempts to preserve remaining growth in younger patients, and even specialized treatments to save the lives of young patients with curves so significant that they result in mortality secondary to inadequate pulmonary volume. There are techniques to correct curves without limiting future growth and even to modulate spinal growth and prevent future fusion surgeries. The FDA-approved **VEPTR (vertical expandable prosthetic titanium rib)** helps young children with thoracic insufficiency syndrome caused by severe spinal curves with restrictive lung disease, often associated with a high mortality rate (see Chapter 679.2 below). The chest wall device can enlarge the thorax and correct scoliosis without adverse effect to somatic growth, likely triggering lung growth. After implantation, it is lengthened twice a year by minor surgery. Long-term survival rates are favorable for these extremely severe scoliosis patients treated by VEPTR. The device obtains and maintains correction without fusing the spine, which allows for alveolar development and maximizes trunk height prior to definitive spinal fusion.

Growing rods have also been used in young children with scoliosis. These devices have fixation points placed at the proximal and distal ends of the deformity, with expandable rods placed subcutaneously, spanning the length of the deformity. Similar to the VEPTR, growing rods require additional minor operations to lengthen the rods twice a year until skeletal maturity or definitive spinal fusion.

Intervertebral stapling is an experimental technique that attempts to dynamically modify spinal growth in immature individuals with smaller curves. Staples are placed through either an open or thoracoscopic approach across the intervertebral disk space (growth zone) on the convex side of the curve. This technique holds the spine in a corrected position and limits growth on the convex side, preventing further curvature, and achieving correction through concave growth. It remains to be seen whether this technique will play a role in the management of patients with idiopathic scoliosis.

679.2 Congenital Scoliosis

R. Justin Mistovich and David A. Spiegel

DEFINITION

Congenital scoliosis is a spinal deformity that results from abnormal development of the bony spinal column. Asymmetric spinal growth as a result of 1 or more vertebral anomalies leads to spinal curvature. The malformation(s) is (are) present at birth but may not become clinically apparent until a later time as growth progresses.

ETIOLOGY

Although the underlying cause of congenital scoliosis remains unknown, embryologic development of the spine begins at the 5th wk of gestation. An insult to the normal developmental process occurs, resulting in abnormal growth of 1 or more vertebrae.

ASSOCIATED CONDITIONS

The developmental insult is typically not limited to the spine alone: it is extremely common for children with congenital scoliosis to have associated malformations in other organ systems, which must be ruled out. Nearly 60% of patients with congenital scoliosis have other developmental malformations.

Genitourinary abnormalities are identified in 20-40% of children with congenital scoliosis and include unilateral renal agenesis, ureteral duplication, horseshoe kidney, and genital anomalies. Approximately 2% of these patients have a silent obstructive uropathy that may be life-threatening. Renal ultrasonography should be performed early on in all children with congenital scoliosis, and other studies such as CT or MRI may also be required.

Cardiac anomalies are identified in 10-25% of patients. A careful cardiac examination should be performed. Some clinicians recommend routine echocardiography.

Intraspinal anomalies are identified in approximately 15-40% of patients. Spinal dysraphism is the general term applied to such lesions (see Chapters 591 and 606). Examples include diastematomyelia, split-cord malformations, intraspinal lipomas, arachnoid cysts, teratomas, dermoid sinuses, fibrous bands, and tight filum terminale. Cutaneous findings that may be seen in patients with closed spinal dysraphism include hair patches, skin tags or dimples, sinuses, and hemangiomas. Infants with these cutaneous abnormalities overlying the spine may benefit from ultrasonography to rule out an occult spinal dysraphic condition. MRI is indicated in infants, but in the past was delayed in older patients until a clinical indication is present, such as tethering of the spinal cord, which may present as back or leg pain, calf atrophy, progressive unilateral foot deformity (especially cavovarus), and problems with bowel or bladder function.

CLASSIFICATION OF CONGENITAL SCOLIOSIS

Congenital scoliosis is classified by the type of developmental abnormality: either a failure of formation or a failure of segmentation. The deformities are then further described by the anatomic features of the affected vertebra. Failures of formation result in wedge vertebrae or hemivertebrae. Failures of segmentation result in unilateral bars vertebrae, or block vertebrae. Lastly, some instances of congenital scoliosis result from a combination of both failure of formation and failure of segmentation (Fig. 679-4). One or more bony anomalies may occur in isolation or in combination.

NATURAL HISTORY OF CONGENITAL SCOLIOSIS

The risk of progression depends on the growth potential of each anomaly, which may vary considerably. Close radiographic follow-up is required. Progression of these curves is most pronounced during periods of rapid growth associated with the 1st 2-3 yr of life and during the adolescent growth spurt.

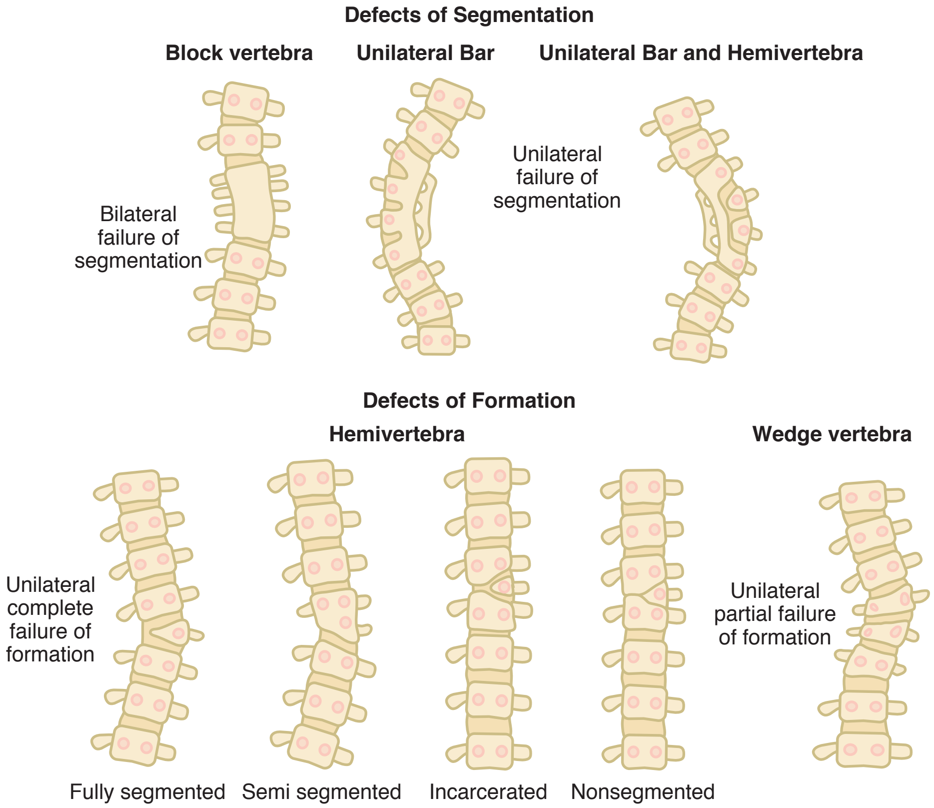

Figure 679-4 The defects of segmentation and formation that can occur during spinal development. *(From McMaster MJ: Congenital scoliosis. In Weinstein SL, editor:* The pediatric spine: principles and practice*, ed 2, Philadelphia, 2001, Lippincott Williams & Wilkins, p. 163.)*

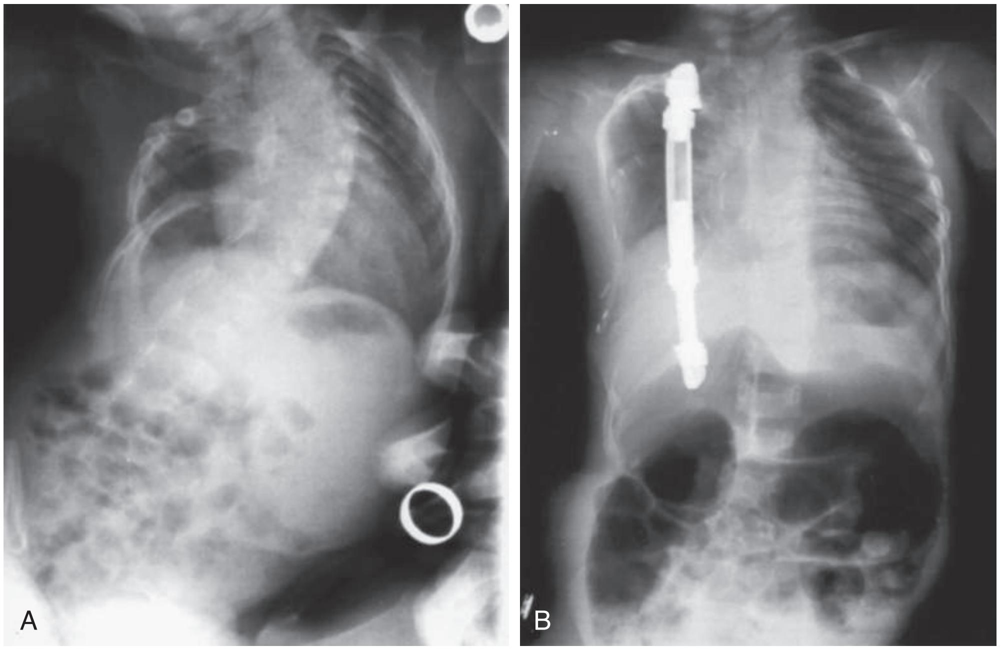

Figure 679-5 **A,** Anteroposterior preoperative radiograph of a 7 mo old boy with congenital scoliosis and fused ribs. A 3-dimensional reconstruction of a CT scan of the chest of this infant estimated his lung volume to be 173.2 mL^3. **B,** Anteroposterior radiograph after implantation of a vertically expandable prosthetic titanium rib and several expansions over 33 mo. The lung volume now measures 330.3 mL^3, an increase of 90.7%. *(From Gollogly S, Smith JT, Campbell RM: Determining lung volume with three-dimensional reconstructions of CT scan data: a pilot study to evaluate the effects of expansion thoracoplasty on children with severe spinal deformities.* J Pediatr Orthop *23:323–328, 2004.)*

The anatomic characteristics of the malformed vertebra play a significant role in the progression of deformity. The most severe form of congenital scoliosis is a unilateral unsegmented bar with a contralateral hemivertebra. In this anomaly, the spine is fused the side of the unsegmented bar but also has a growth center on the other side at the location of the hemivertebra at the same level. This combination of deformities in the bony spine results in a rapidly progressive curve. As a result, all affected patients usually require surgical stabilization. A unilateral unsegmented bar is also associated with significant progression and in most cases will require surgical intervention. An isolated hemivertebra must be followed closely, and many, but not all, of these will be associated with a progressive deformity that requires surgical intervention. In contrast, an isolated block vertebra has little growth potential and rarely requires treatment.

TREATMENT OF CONGENITAL SCOLIOSIS

Early diagnosis and prompt treatment of progressive curves are essential. Bracing is not indicated for most congenital curves because of their structural nature, except in rare cases to treat additional curves not associated with the congenital abnormality. The treatment of progressive curves is spinal fusion, or *arthrodesis*. Once a bony abnormality is identified that is likely to progress, surgery is performed before progression occurs, preventing development or further inevitable progression of spinal deformity. If the deformity has already developed, surgical correction is difficult to achieve and the risk of neurologic complications is high.

Both anterior and posterior spinal fusion is often required. Other procedures that are employed in selected patients include an isolated posterior spinal fusion. A convex hemiepiphysiodesis can be performed with certain deformities, fusing only 1 side of the spine to allow some correction of the deformity by permitting growth on the noninvolved side of the curve. Complete excision of a hemivertebra, along with fusion of a short segment of the spine, can be performed via a posterior approach and may result in better correction and spinal balance in selected cases.

It should be noted that surgery in these young, syndromic patients is not without risk. One recent study found a complication rate of nearly 85% and a mortality rate of >15% in patients who underwent operative treatment for all types of early onset scoliosis, including those with congenital scoliosis as well as other associated syndromes producing early onset scoliosis.

THORACIC INSUFFICIENCY SYNDROME

When multiple levels of the thoracic spine are involved in the presence of fused ribs, a progressive 3-dimensional deformity of the chest wall may impair lung development and function. This development is termed **thoracic insufficiency syndrome**. As a result of thoracic insufficiency syndrome, the chest wall cannot support normal respiration resulting in decreased life expectancy.

Thoracic insufficiency syndrome may be seen in patients with several recognized conditions such as Jarcho-Levin syndrome (spondylocostal or spondylothoracic dysplasia; see Chapter 108) and Jeune syndrome (asphyxiating thoracic dystrophy; see Chapter 417.3), as well as patients with severe spinal deformities. These difficult cases are being treated with a technique called *expansion thoracoplasty*, in which the thoracic cage is gradually expanded over time by progressive lengthening of the chest wall on the concavity of the spinal deformity (or in some cases on both sides of the spine). The procedure involves an opening wedge thoracostomy, followed by placement of a vertical expandable titanium prosthetic rib. The implant is then lengthened at regular intervals (Fig. 679-5). The primary goal is to gradually correct the chest wall deformity to improve pulmonary function, and a secondary goal is correction of an associated spinal deformity. This technique is currently not approved by the FDA for the treatment of scoliosis in the absence of a thoracic insufficiency, and further study will help to refine and possible expand the indications for this new technique.

679.3 Neuromuscular Scoliosis, Genetic Syndromes, and Compensatory Scoliosis

R. Justin Mistovich and David A. Spiegel

NEUROMUSCULAR SCOLIOSIS

Scoliosis is frequently identified in children with neuromuscular diseases such as cerebral palsy, muscular dystrophies and other myopathies, spinal muscular atrophy, Friedreich ataxia, myelomeningocele, polio, and arthrogryposis. Children with spinal cord injuries are also at high risk for a progressive curvature. The etiology and natural history of these patients differ from idiopathic and congenital scoliosis. Most cases result from weakness and/or imbalance of the trunk musculature. Spasticity may also contribute to spinal curvatures. In some cases, such as myelomeningocele, coexisting congenital vertebral anomalies may be present, further contributing to curve development.

As might be expected, neuromuscular scoliosis is most common in patients with higher degrees of neurologic impairment, usually those who are nonambulatory and may not have adequate control of their trunk. It is diagnosed in more than 70% of nonambulatory patients with cerebral palsy (see Chapter 598.1), and in more than 90% of patients with Duchenne muscular dystrophy (see Chapter 609.1).

The diagnosis is suspected on physical examination. In nonambulators, the most common curve pattern is a C-shaped thoracolumbar or lumbar curve (Fig. 679-6). This curve is typically associated with pelvic obliquity. In contrast, ambulatory patients with diagnoses such as Friedreich ataxia may have curve patterns more similar to idiopathic scoliosis.

In ambulatory patients, the examination is similar to the previously described physical examination for idiopathic scoliosis. In nonambulators, the back is inspected with the patient sitting upright. Any asymmetry should be noted. These patients often need manual support to maintain an upright position. If any progressive asymmetry is observed, then sitting PA and lateral radiographs are obtained. Because prophylactic treatment cannot alter the natural history of the disease, it is appropriate to establish the diagnosis clinically and obtain radiographs if the curve is noted to progress.

The clinical course of patients with neuromuscular scoliosis depends on the severity of neuromuscular involvement as well as the nature of the underlying disease process. Progressive diseases are often associated with progressive curvatures. The consequences of a progressive scoliosis in the neuromuscular population involve both function, especially sitting and standing balance, as well ease of hygiene and personal care. Pulmonary dysfunction may be expected with the gradual deformation of the rib cage and vertebra–pelvic axis, as well as collapse of the spine with the pelvis impinging on the rib cage. Diaphragmatic function is impaired, and changes in chest volume and chest wall architecture will undoubtedly exacerbate the pulmonary dysfunction owing to underlying muscle weakness. Pulmonary function may be difficult to document in some patient populations, especially those with severe cerebral palsy. Additionally, patients who initially were marginal ambulators may lose the ability to walk altogether as their scoliosis advances. Curves associated with pelvic obliquity result in asymmetric seating pressures, which may limit sitting endurance and may rarely cause skin breakdown and decubitus ulcers. Patients may also experience pain from impingement of the rib cage on the iliac crest.

Figure 679-6 Imaging shows a long C-shaped curve with convexity to the left side and significant pelvic obliquity, a curve pattern often seen in patients with neuromuscular scoliosis. *(From Pruthi S: Scoliosis. In Coley BD, editor:* Caffey's pediatric diagnostic imaging, *ed 12, Philadelphia, 2013, WB Saunders, eFig. 135-10B.)*

The treatment of neuromuscular scoliosis depends on the age of the patient, the underlying diagnosis, and the magnitude of the deformity. The goal is to achieve or maintain a straight spine over a level pelvis, especially in patients who are wheelchair bound, and to intervene early before curve magnitude and rigidity become severe. In contrast to idiopathic and congenital scoliosis, neuromuscular curves often continue to progress after skeletal maturity. In general, curves of greater than 40-50 degrees will continue to worsen over time. Brace treatment does not affect the natural history of neuromuscular scoliosis, and standard braces used for idiopathic scoliosis are poorly tolerated in neuromuscular patients. A soft spinal orthosis may improve sitting balance and ease of care, although it does not prevent progression of the curvature.

In general, a spinal arthrodesis is offered to patients with progressive curvatures >40-50 degrees. The indications will differ somewhat based on the underlying diagnosis. For example, patients with Duchenne muscular dystrophy are offered surgery when their curves progress beyond 20-30 degrees, thereby having surgery before the anticipated decline in pulmonary or cardiac function preclude their ability to tolerate it. Ambulatory patients with curvatures similar to those seen in idiopathic scoliosis are managed by similar principles. Patients who are nonambulatory with pelvic obliquity are usually managed by a spinal fusion extending from the upper thoracic spine to the pelvis, similar to that described in the idiopathic scoliosis section. A brace is not required following this procedure. Treatment decisions must be individualized in those nonambulatory patients with spastic quadriplegia, and are based on loss of function, the potential to improve hygiene or personal care, and the desires of the family and/or caregivers.

Although complications are relatively frequent in comparison with patients with nonneuromuscular curves, the available literature suggests that most patients benefit in terms of function and ease of care. To better identify patients at risk of complications, a recent study found that nonambulatory patients and those with curves 60 degrees or greater had a significantly increased risk of postoperative major complications, including ileus, pneumonia, infection, and wound problems. Because of the risks involved and potential for complications, this surgery should ideally be performed at centers with significant experience.

SYNDROMES AND GENETIC DISORDERS

Representative examples of this diverse group of diagnoses include neurofibromatosis, osteogenesis imperfecta, connective tissue diseases including Marfan syndrome (see Chapter 702), Ehlers-Danlos syndrome (see Chapter 659), and Prader-Willi syndrome (see Chapter 81), among many others. Patients with these diagnoses should have their spine examined routinely during visits to their primary care physician. Similar to other types of scoliosis, the follow-up and treatment are based on the age of the patient, the degree of deformity, whether progression has been documented, and the underlying diagnosis.

COMPENSATORY SCOLIOSIS

Leg-length inequality is a common clinical diagnosis and is usually associated with a small compensatory lumbar curvature (see Chapter

676). This is one cause of false-positive screening examinations. Patients with leg-length inequality may have the pelvis become tilted toward the shorter limb and subsequently develop an associated lumbar curve. The apex of the curve points toward the short leg. There is little evidence to suggest that a small compensatory lumbar curve places the patient at risk of progression or back pain. However, children with leg-length inequality may also have idiopathic or congenital scoliosis. A standing radiograph may be obtained with a block under the foot on the short side, which corrects the leg-length discrepancy and levels the pelvis. If the curvature disappears when the limb-length discrepancy is corrected, then a diagnosis of a compensatory curve is made. An alternative is a PA radiograph with the patient seated.

In neuromuscular disorders such as polio or cerebral palsy, an adduction or abduction contracture of the hip, described as a fixed infrapelvic contracture, may have an associated compensatory lumbar scoliosis to maintain standing balance. For patients who ambulate, a 10-degree fixed contracture will result in up to 3 cm apparent leg-length discrepancy.

Bibliography is available at Expert Consult.

679.4 Kyphosis (Round-Back)

R. Justin Mistovich and David A. Spiegel

The normal thoracic spine has 20-50 degrees of kyphosis as measured from T3 to T12. This is measured using the Cobb method on a standing lateral radiograph of the thoracolumbar spine. A thoracic kyphosis in excess of the normal range of values is termed *hyperkyphosis*. These patients may present with cosmetic concerns, back pain, or both. A flexible or postural kyphosis may be overcorrected voluntarily or with postural adjustment, whereas a rigid kyphosis cannot be corrected passively. Causes of rigid kyphosis include Scheuermann disease and congenital kyphosis, among others. Table 679-2 lists conditions associated with hyperkyphosis.

The evaluation and treatment depends on the underlying diagnosis, the degree of deformity and its flexibility, whether the deformity is progressive, and whether any symptoms are present.

FLEXIBLE KYPHOSIS (POSTURAL KYPHOSIS)

Postural kyphosis is a common cosmetic concern and is most often recognized by family and friends. Adolescents with postural kyphosis can correct the curvature voluntarily. A standing lateral radiograph will show an increase in kyphosis but no pathologic changes of the involved vertebrae. There is no evidence to suggest that postural kyphosis progresses to a structural deformity. Although mild aching discomfort is sometimes reported, there is no evidence that the conditions leads to long-term symptoms or alterations in function or quality of life. The mainstay of treatment is reassurance. Physical therapy can be considered for muscular discomfort, although there are no data to suggest that a permanent alteration in alignment can be maintained.

Table 679-2 Conditions Associated with Hyperkyphosis
• Trauma causing spinal fractures
• Spinal infections resulting from bacterial, tuberculosis, and fungal diseases
• Metabolic diseases such as osteogenesis imperfecta or osteoporosis
• Iatrogenic (laminectomy, spinal irradiation)
• Neuromuscular diseases
• Neoplasms
• Congenital/developmental
• Disorders of collagen such as Marfan syndrome
• Dysplasias such as neurofibromatosis, achondroplasia, and mucopolysaccharidoses

Neither bracing nor surgery plays a role in the management of this condition.

STRUCTURAL KYPHOSIS

Scheuermann Disease

Scheuermann disease is the most common form of structural hyperkyphosis and is defined by wedging of greater than 5 degrees of 3 or more consecutive vertebral bodies at the apex of the deformity on a lateral radiograph. In addition, the apex of the thoracic kyphosis is lower than expected. Other radiographic findings include irregularities of the vertebral end plates and Schmorl nodes, which are herniations of the vertebral disc into the surface of the vertebral body. The etiology remains unknown but most likely involves the influence of mechanical forces in a genetically susceptible individual. Histologic specimens taken from patients with Scheuermann disease show a disordered pattern of endochondral ossification. However, it remains unclear whether these findings are the primary result of a genetic or metabolic pathologic process, or simply the secondary result of mechanical overload. The reported incidence varies from 0.4-10%, affecting boys 3 times more frequently than girls.

Physical Exam and Clinical Manifestations

Examine the patient from the side. There is a hyperkyphosis of the thoracic spine typically associated with a sharp contour. The apex of the deformity will often be in the lower thoracic spine. Patients are unable to correct the deformity voluntarily. Pain is a relatively common complaint. It is typically mild and near the apex of the kyphosis. The symptoms are intermittent, rarely severe, and occasionally limit certain activities. Neurologic symptoms are uncommon.

Radiographic Evaluation

The standard imaging protocol includes standing PA and lateral radiographs (Fig. 679-7). A specific, standardized technique in which the

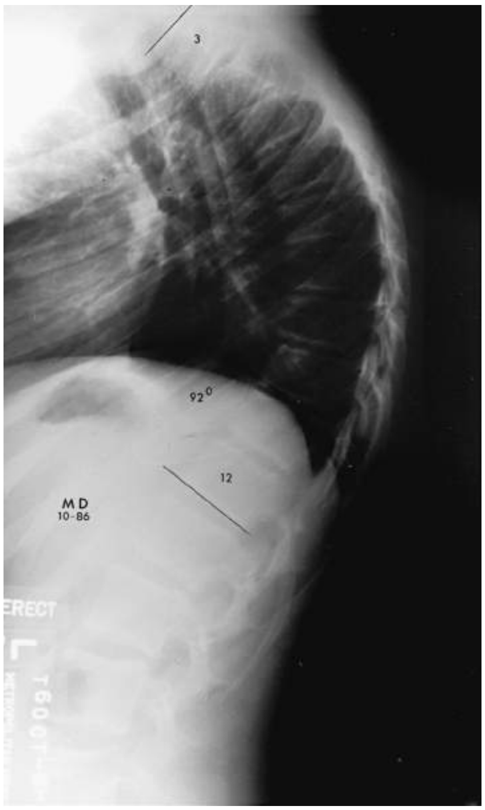

Figure 679-7 Standing lateral radiograph of a 14 yr old boy with severe Scheuermann kyphosis. This measures 92 degrees between T3 and T12. Note the wedging of the vertebrae at T6, T7, T8, and T9. The normal thoracic kyphosis is ≤40 degrees.

arms are folded across the chest is recommended for the lateral view. In addition to the diagnostic findings noted above, a mild scoliosis is commonly seen. Less frequently, a spondylolisthesis may be identified on the lateral radiograph.

Natural History

Treatment depends on the age of the patient, the degree of deformity, and whether any symptoms are present. As adolescents, patients with Scheuermann kyphosis may have more complaints of back pain compared to other adolescents, but this often improves after skeletal maturity. With regard to back pain, several studies have found no difference between Scheuermann patients and controls, whereas others have noted an increased incidence of constant back pain. Patients' self-esteem, participation in activities of daily living and recreational activities, and level of education are not different than in the general population. Kyphotic deformities greater than 90 degrees are more likely to be aesthetically unacceptable, symptomatic, and progressive. Deformities in excess of 100 degrees may be associated with restrictive pulmonary dysfunction.

Treatment

Because there are few absolute guidelines for treatment, treatment decisions must be individualized. Skeletally immature patients with mild deformity may benefit from a hyperextension exercise program, but the effects of this strategy on pain relief and spinal alignment, or the natural history, remain unknown. Patients with more than 1 yr of growth remaining and a kyphosis of greater than 55-60 degrees may benefit from a bracing program. A Milwaukee brace, which extends up to the neck, is recommended for curves with an apex above T7, while curves with a lower apex often may be treated by a thoracolumbar orthosis. The brace should be worn for up to 23 hr daily. Consideration also may be given to a serial casting or stretching program to gain flexibility prior to instituting the brace program. The goal of the brace is to prevent progression. A permanent improvement in alignment is seen less frequently. Skeletally mature patients with little or no pain and acceptable cosmesis are not treated. A spinal fusion may be considered in the rare patient with progressive deformity >70-80 degrees who is dissatisfied with his or her cosmetic appearance or who has persistent back pain despite nonoperative measures. An instrumented posterior spinal fusion from the upper thoracic to the mid lumbar spine is commonly performed, with spinal osteotomies to promote shortening of the spine when correcting with compressive forces. Some surgeons have recommended an anterior spinal release (discectomies and fusion) in addition to the posterior spinal fusion; however, this procedure is performed less frequently because of the increased neurologic risks of this combined procedure as the spine is lengthened during the correction.

CONGENITAL KYPHOSIS

Congenital kyphosis results from congenital anomalies of the vertebrae. In an anterior failure of formation (type I), a portion of the vertebral body fails to form. A kyphosis is typically identified after birth, and there is a high risk of progression and neurologic dysfunction. Spinal cord dysfunction commonly results from compression at the apex of the deformity. The second type of congenital kyphosis involves an anterior failure of segmentation, in which 2 vertebrae are fused (type II). The posterior elements of the spine continue to grow but the anterior spine does not, resulting in a variably progressive kyphosis and a much lower risk of neurologic dysfunction. Patients must be followed closely, and treatment is required in a significant number of cases. Similar to congenital scoliosis, abnormalities of other organ systems should be ruled out.

The treatment depends on the type of malformation, the degree of deformity, and whether neurologic symptoms are present. Bracing is ineffective, and surgical treatment is the only option for progressive curves. Because the natural history is so poor for type I deformities, spinal fusion is usually performed shortly after the diagnosis is made. The surgical goals are to prevent or treat kyphotic deformities, avoid neurologic deterioration, while maximizing spinal growth to the extent possible. This usually involves some form of spinal fusion, which may include anterior and/or posterior components, with or without resection of the vertebral remnant, and spinal instrumentation. Ideally, only a short segment of the spine will be fused to try and maximize trunk height. Deformities caused by anterior failure of segmentation also require spinal stabilization in some cases, but progression is typically slower, and patients are often followed over years to determine whether surgical stabilization will be required.

Bibliography is available at Expert Consult.

679.5 Back Pain in Children

R. Justin Mistovich and David A. Spiegel

With a lifetime prevalence of >70%, only the common cold affects individuals more frequently than back pain. Back pain is a frequent complaint in the pediatric and adolescent patient, affecting approximately 35% of adolescents. Back pain may be a physical manifestation of psychosocial factors in adolescents, similar to adults. Traditionally, the pediatric patient presenting with back pain warranted an aggressive clinical evaluation as the probability of establishing a specific diagnosis was high. Recent literature suggests that the incidence of both pediatric and adolescent back pain is increasing, while the proportion of patients having a diagnosable pathology is decreasing. In fact, a recent large cohort found no diagnosable pathology in 76% of patients. These trends add further complexity to determining the proper approach to diagnosis and treatment. The differential diagnosis is extensive (Table 679-3). Given the potential for serious pathology, a complete history and careful physical exam must be performed on all patients presenting with back pain, with appropriate diagnostic follow-up of concerning findings.

CLINICAL EVALUATION

A full, careful history is very important. Identify the location, character, and duration of symptoms. Any history of acute trauma or repetitive physical activities should be sought. Identify patients with at-risk athletic pursuits, including football lineman and gymnasts, who have a high incidence of spondylolysis (see Chapter 679.6). Symptoms consistent with a neoplastic or infectious etiology include pain that is constant or unrelenting, not relieved by rest, and wakes the patient from sleep. Fevers, chills, or constitutional symptoms of weight loss or malaise are additional red flags for infectious or neoplastic processes.

Symptoms of neurologic dysfunction must also be uncovered. Patients should be questioned about the presence of any radicular symptoms, gait disturbance, muscle weakness, alterations in sensation, and changes in bowel or bladder function.

The physical examination includes a complete musculoskeletal and neurologic assessment. The patient should be adequately undressed for the clinical exam. Inspect the patient from the back and the side, identifying any changes in alignment in the frontal or sagittal plane. Assess range of motion in flexion, extension, and lateral bending. Pain with extension suggests pathology within the posterior elements of the spine such as spondylolysis. Forward flexion will exacerbate pain linked to abnormalities of the anterior column of the spine (vertebral body or disc), such as a herniated disc or discitis. Younger children may be asked to pick up an object off the floor to assess spinal flexion.

Palpation will reveal any areas of point tenderness over the posterior elements or the muscles and identify muscle spasm.

As spinal pain may be referred, an abdominal examination should be performed, and a gynecologic evaluation should also be considered. Pathology at the sacroiliac joint may also mimic low back pain. This joint should be stressed by compression of the iliac wings or by external rotation at the hip (Faber test).

A careful neurologic examination should be performed, including manual muscle testing, sensation, proprioception, and reflexes. Examine for myelopathy by performing the Babinski test, assessing for hyperreflexia, and checking for sustained, or greater than 3 beats, of

clonus. The superficial abdominal reflex should be tested by gently stroking the skin on each of the four quadrants surrounding the umbilicus. Normally, the umbilicus will move toward the area stimulated. A normal examination includes symmetry in the response on both sides of the midline, even if the reflex cannot be elicited on either side. An abnormal test suggests the presence of a subtle abnormality of spinal cord function, most commonly syringomyelia. Perform a straight-leg raise test to check for nerve root tension caused by a herniated disk, slipped vertebral apophysis, or other pathology. This examination should reproduce any neurologic symptoms distal to the knee.

MEDICAL DECISION MAKING

A detailed history and physical exam are the most important components of the initial evaluation, and should focus on identifying *red flags* and differentiating between mechanical and nonmechanical back pain. Findings consistent with a nonmechanical etiology, warrant a more aggressive evaluation and/or prompt referral (Table 679-4).

Patients with mechanical back pain and symptoms that are activity-related and improve with rest are typically treated by rest or activity restrictions and nonnarcotic analgesics. Physical therapy for core strengthening can be considered. The patient is asked to return for a follow-up appointment after 4-6 wks. Plain radiographs are commonly obtained at the discretion of individual practitioners, although, if no red flags are present, consider delaying radiographs until the follow-up appointment because of the cumulative adverse effects of radiation exposure. Patients presenting with concerning findings or those who have not improved after 6 wk of conservative care are subject to further investigation.

Table 679-4 Findings Consistent with a Nonmechanical Etiology Warranting Further Evaluation

- History of trauma
- Pain that wakes the patient from sleep
- Constant pain unrelieved by rest
- Constitutional or systemic symptoms of fevers, chills, malaise, weight loss
- Any neurologic dysfunction including weakness, numbness, radicular pain, gait changes, or bowel and bladder changes
- Abnormalities in spinal alignment
- Bony tenderness to palpation or vertebral step-offs
- Significant pain with provocative tests (spinal flexion or extension)
- Positive straight-leg raise test for neurologic symptoms below the knee
- Abnormal neurologic exam

RADIOGRAPHIC AND LABORATORY EVALUATION

When further workup is indicated, posteroanterior and lateral radiographs of the involved region of the spine are the initial images of choice. Some clinicians will also utilize oblique radiographs of the lumber spine when spondylolysis is in the differential diagnosis. If plain radiographs are normal, advanced imaging modalities are considered including a 3-phase technetium bone scan, a bone scan with single-photon emission CT if spondylolysis is suspected, CT for viewing osseous detail, and MRI for viewing soft tissue and intraspinal detail. There are advantages and disadvantages with each, and no evidenced-based guidelines are available for the work-up or back pain in the pediatric population.

When systemic signs or constitutional symptoms are present, a complete blood cell count with differential, erythrocyte sedimentation rate, and C-reactive protein should be ordered. In certain cases, laboratory tests to evaluate for inflammatory diseases, such as juvenile idiopathic arthritis, seronegative spondyloarthropathies, and ankylosing spondylitis, are indicated.

679.6 Spondylolysis and Spondylolisthesis

R. Justin Mistovich and David A. Spiegel

Spondylolysis represents a defect in the pars interarticularis, the segment of bone connecting the superior and inferior articular facets in the vertebra. It is thought to result from repetitive hyperextension stresses, in which compressive forces are transmitted from the inferior articular facet of the superior vertebra to the pars interarticularis of the inferior vertebra. A stress fracture, unilateral or bilateral, may progress to a spondylolysis. In many cases, this stress fracture does not heal, resulting in a pseudarthrosis or false joint, and thereby allowing motion through this bony area where motion should not normally exist.

Spondylolysis is common in athletes who engage in repetitive spinal hyperextension, especially gymnasts, football interior lineman, weight lifters, and wrestlers. Approximately 4-8% of the entire pediatric population is affected, making it the most common cause of back pain in

adolescents when a diagnosis can be established. Patients with excessive lordosis in the lumbar spine may be predisposed to developing a spondylolysis, and a genetic component has also been suggested. The lesion is most common at L5, but it may be identified at upper lumbar levels as well.

Spondylolisthesis represents a forward slippage of 1 vertebra on another and is also identified in approximately 4-5% of the population. There are multiple causes of spondylolisthesis, including dysplastic/congenital, isthmic (from a pars stress fracture), traumatic, and neoplastic. In children and adolescents, the most common types are dysplastic and isthmic. Between 5% and 15% of patients with spondylolysis will develop *spondylolisthesis*.

Spondylolisthesis is assessed on a standing lateral radiograph of the lumbosacral junction according to (1) percentage of forward translation of 1 vertebra on the other, (2) rotation of the involved vertebrae in the sagittal plane (slip angle), and (3) relative position of the sacrum during upright posture. For example, a grade 1 slip of L5 on S1 has less than 25% of the width of the vertebral body of L5 translated anteriorly on S1. Similarly, grade 2 is 25-50%, grade 3 is 50-75%, grade 4 is 75-100%. *Spondyloptosis*, or grade 5, describes a complete displacement of 1 vertebral body on the level below. The slip angle, which demonstrates the degree to which the superior vertebra is flexed forward relative to the underlying vertebra, and the verticality of the sacrum, both have a significant effect on sagittal balance or relationship of the sagittal weightbearing axis to the body segments. Abnormalities in sagittal spinal balance may be associated with compensatory flexion of the knees during ambulation, hamstring spasm and/or contracture, and back pain.

CLINICAL MANIFESTATIONS

Spondylolysis may occasionally be asymptomatic and diagnosed incidentally on imaging obtained for other reasons. Usually though, it presents with mechanical low back pain that may radiate to the buttocks, with or without spasm of the hamstring muscles. Neurologic symptoms are rare in patients with spondylolysis. However, patients with spondylolisthesis may experience neurologic symptoms from compression of the nerve roots causing radiculopathy or even the surgical emergency of cauda equina in which bowel and bladder function is affected.

PHYSICAL EXAM

Patients with spondylolysis often have discomfort with spinal extension or hyperextension. Provocative testing may include keeping the spine extended for 10-20 seconds to see if back pain can be reproduced. There may be discomfort with palpation of the spinous process of the involved vertebra. Patients with higher grades of spondylolisthesis demonstrate loss of lumbar lordosis, flattening of the buttocks on visual inspection, and a vertical sacrum caused by posterior rotation of the pelvis. A step off may be palpated between the spinous processes of the involved vertebrae. Hamstring contracture is testing by measuring the popliteal angle. The hip is flexed to 90 degrees while fully extending the contralateral hip to level the pelvis. The knee is then passively extended, and the popliteal angle represents the angle between the thigh (vertical) and the lower leg axis. The involved spinous processes may be tender to palpation. A careful, complete neurologic examination is essential.

RADIOGRAPHIC EVALUATION

The initial evaluation of the lumbar region should include high-quality anteroposterior and lateral radiographs. Some authors also prefer to obtain oblique radiographs, which demonstrate the classic "Scotty dog" finding. One study suggests that a series of 4 views may not offer greater diagnostic accuracy than 2 views. Standing PA and lateral radiographs are obtained if findings suggestive of scoliosis or hyperkyphosis are also present (Figs. 679-8 and 679-9). In patients with normal plain films, a bone scan with single-photon emission CT may help to diagnose a spondylolysis during the earliest stage of a stress reaction, prior to the formation of a stress fracture or an established pseudarthrosis. A CT scan with thin cuts may provide additional information to establish the presence of a pars defect. MRI is indicated in the presence of signs or symptoms of cauda equina or nerve root involvement.

TREATMENT

The asymptomatic patient with spondylolysis requires no treatment. Patients with pain are treated initially by activity modification, physical therapy for core strengthening, and nonnarcotic analgesics. The use of a lumbosacral orthosis, which immobilizes the spine in slight flexion to decompress the posterior elements, may lead to a faster resolution of symptoms. This orthosis is typically worn for 3-4 mo. Participation

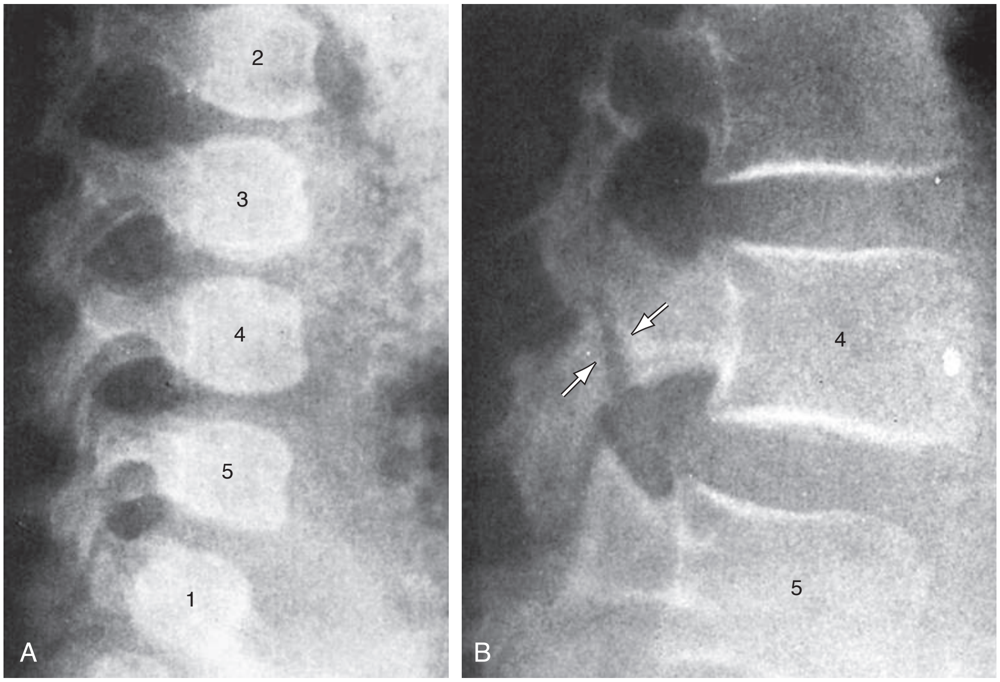

Figure 679-8 A, Normal spine at 9 mo of age. **B,** Spondylolysis in the L4 vertebra at 10 yr of age. *(From Silverman FN, Kuhn JP:* Essentials of Caffey's pediatric x-ray diagnosis, *Chicago, 1990, Year Book Medical Publishers, p. 94.)*

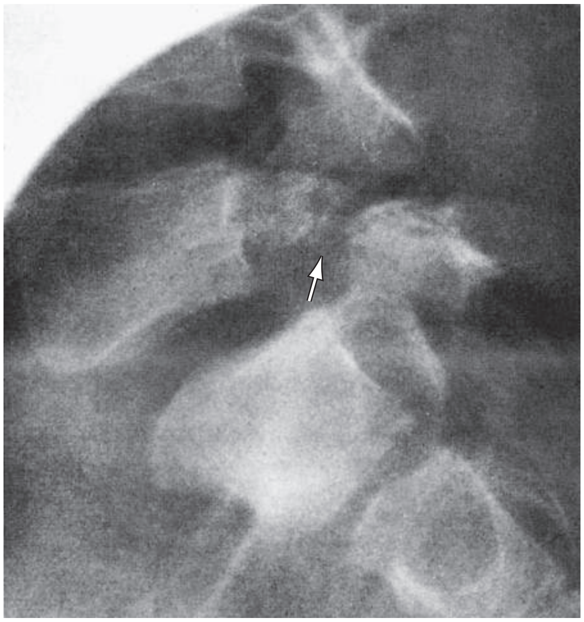

Figure 679-9 Defect in the pars interarticularis *(arrow)* of the neural arch of L5 (spondylolysis) that has permitted the body of L5 to slip forward (spondylolisthesis) on the body of S1. *(From Silverman FN, Kuhn JP:* Essentials of Caffey's pediatric x-ray diagnosis, *Chicago, 1990, Year Book Medical Publishers, p. 95.)*

in sports or other activities that exacerbate pain should be restricted until the symptoms have resolved.

Most patients experience resolution of their symptoms even though the spondylolysis heals in only a small number of patients. Surgery is offered for chronic, refractory back pain when conservative measures have failed. For those with spondylolysis at L5, a posterior spinal fusion from L5 to S1 is indicated as the mobility at this joint is limited relative to that observed at higher levels in the spine. For the infrequent cases in which the defect is at higher levels in the lumbar spine, techniques for repairing the pseudarthrosis without fusion are considered.

Recommendations for the management of spondylolisthesis depend on the age of the patient, the presence of pain or neurologic symptoms, and the degree of deformity. For low-grade lesions with a slip <50%, the management is similar to that for spondylolysis. As progressive slippage may occur in a subset of skeletally immature patients, patients must be followed through skeletal maturity. Guidelines for the timing of follow-up, and whether or not to obtain routine radiographs at each follow-up, differ between individuals and institutions. The authors typically follow asymptomatic patients yearly with a standing lateral of the lumbosacral junction.

For low-grade slips (<50% translation) with persistent symptoms despite nonoperative measures, an in situ posterior spinal arthrodesis is suggested. Surgery is also offered to skeletally immature patients with a high-grade slip (>50% translation) based on the likelihood of slip progression. The surgical approach for these high-grade slips varies between surgeons and institutions. The main principle is to stabilize the unstable segment of the spine and avoid neurologic complications. The typical components of these complex procedures include (1) posterior decompression of the L5 and S1 nerve roots (laminectomy and takedown of pseudarthrosis), (2) instrumented posterior spinal fusion from L5-S1, (3) discectomy at L5-S1 with placement of anterior column support (transforaminal cage or fibular allograft from sacrum to L5), and (4) reduction of the slippage by positioning the hips in extension or by an "instrumented reduction" utilizing the spinal implants. The risk of neurologic complications is higher when an instrumented reduction is attempted.

679.7 Spine Infection

R. Justin Mistovich and David A. Spiegel

Spondylitis, meaning inflammation of the vertebrae, is most commonly caused by infectious or autoimmune processes. Both *diskitis* and *vertebral osteomyelitis* are causes within the spectrum of **infectious spondylitis**. Most causes of infectious spondylitis result from hematogenous seeding of osteoarticular structures. Diskitis involves bacterial infection of the disc space and is generally seen in children younger than 5 yr of age. In contrast, vertebral osteomyelitis most often occurs in older children and adolescents and involves the vertebral body. Differences in anatomic location of the infectious focus relate to the vascular development of the spine. Patients in the younger age range have vascular channels between the vertebral end plate and the disc space, explaining the prevalence of discitis. In older children these channels have closed, and the infection remains in the vertebra causing osteomyelitis.

Staphylococcus aureus (see Chapter 181) is the most common organism causing spine infections. Other, less-common organisms include *Kingella kingae*, group A streptococcus, *Bartonella henselae*, *Salmonella*, and *Escherichia coli*. Blood cultures have a sensitivity of only 30%. Percutaneous or open biopsy of the disc space is positive only 50-85% of the time. The differential diagnosis must include tuberculosis of the spine.

CLINICAL MANIFESTATIONS

A high index of suspicion is required to establish the diagnosis of infectious spondylitis. Patients may experience back pain, abdominal pain, fever, or malaise. Fever is less common and may be present in only 30% of patients. Toddlers may develop a limp, or refuse to walk or sit. In an effort to reduce the pain associated with spinal motion, the child will hold the spine in a rigid position. There may also be paraspinal muscle spasm. Local point tenderness over the affected spinous process is common. There may be a list or leaning of the trunk when the patient is viewed from the front or back, and from the side there may be a loss of lumbar lordosis. Neurologic manifestations are rare and if present suggest that an epidural abscess may be present. The L3-4 or L4-5 spaces are most commonly affected in diskitis.

Spine flexion compresses the anterior elements of the spine and will elicit an increase in pain. Asking a child to pick up an object from the ground is a simple way to elicit this provocative test.

Although the white blood count may remain normal, the erythrocyte sedimentation rate is elevated in 80% of cases, and the C-reactive protein is also elevated.

RADIOGRAPHIC EVALUATION

The earliest radiographic finding is loss of lumbar lordosis. The characteristic features on plain radiographs are disc space narrowing, or loss of disc height, and irregularity of the adjacent vertebral end plates. However, these findings do not develop until 2-3 wk after the onset of symptoms. The diagnosis may be established earlier using either a technetium bone scan or MRI, although MRI is the most sensitive and specific imaging to diagnose osteomyelitis and to identify abscesses and/or neural compression (Fig. 679-10).

TREATMENT

Once the diagnosis is suspected clinically, the treatment involves symptomatic care and empiric antistaphylococcal antibiotics. Blood cultures should be obtained **prior** to the administration of antibiotics. The antibiotic agent may be modified if blood cultures are positive. Symptomatic care includes rest and analgesics, and a spinal orthosis may also be considered. The typical antibiotic course is from 4-6 wk; conversion from intravenous to oral agents may be acceptable after several days of improvement of the clinical course. A CT-guided needle biopsy of the disk space is usually reserved for patients who do not respond to empiric antibiotics. Surgical treatment is rarely required, and indications include establishing the diagnosis in patients who fail to respond

679.8 Intervertebral Disc Herniation/ Slipped Vertebral Apophysis

R. Justin Mistovich and David A. Spiegel

Intervertebral disc herniation is the result of a tear in the outer layer of the vertebral disc, called the *annulus fibrosus*, which then allows for protrusion of the inner *nucleus pulposus*. At times, a free fragment of disc can rupture and compress the nerve roots or spinal cord. Bulging of the annulus without rupture may also be observed, resulting in back pain and occasionally radicular symptoms. Symptoms are from either direct mechanical compression and/or a local inflammatory response.

Slipped vertebral apophysis, also called a posterior ring apophysis separation, is caused by an injury and is only found in the skeletally immature. A small fragment of osseous or osteocartilagenous material from the posterior corner of the vertebral body apophysis avulses and may cause direct mechanical compression to the spinal cords and/or nerve roots, similar to a disc herniation. Both disc herniations and ring apophysis separations can cause back pain, radicular symptoms (nerve root compression or irritation), and/or spinal cord compression.

ETIOLOGY

The etiology remains unknown, but predisposing activities for both of these conditions include heavy lifting, repetitive axial loading activities, and occasionally traumatic injury such as a fall. Approximately 30-60% of patients with symptomatic herniated discs have a history of

a trauma or sports-related injury. Other associations include preexisting disc degeneration, congenital malformation, and genetic or environmental factors. There is also a potential association between disc degeneration and the herpes virus, adding the possibility of an infectious etiology.

CLINICAL MANIFESTATIONS

Symptoms of intervertebral disc herniation or slipped vertebral apophysis in adolescents are similar to adult herniated disc symptoms. The major complaint is back pain, present in nearly 90% of patients. More than 30% of patients complain of radicular symptoms, or radiating sciatic-type pain into the legs. The back pain is often made worse by coughing, a Valsalva maneuver, or sitting. Pain may be relieved by standing or back extension. Inquire about weight loss, fever, or other constitutional symptoms to rule out an infectious or neoplastic etiology.

On physical examination, both paraspinal muscle spasm and a generalized spinal stiffness are common. Patients may lean toward the unaffected side to increase the size of the affected neural foramen thereby partially relieving symptoms. This results in a *reactive scoliosis*, not a true spinal curve, which improves with symptom resolution. Although overt signs of neurologic involvement are absent in most patients, a positive straight-leg raise test, causing radicular pain to shoot down the affected leg, is usually present. Pain is also worsened by spinal flexion.

It is critical perform a full neurologic evaluation. Evaluate sensation to light touch, pinprick, and proprioception. Check muscle strength and reflexes. It is critical to evaluate for perineal numbness, or *saddle anesthesia*. This finding, combined with changes in bowel or bladder function, which is also critical to specifically discern in the history, is indicative of cauda equina syndrome, a surgical emergency in which the nerve roots at the caudal end of the spinal cord are compressed or damaged.

RADIOGRAPHIC EVALUATION

Radiographs often show loss of lumbar lordosis, which is a result of muscle spasm, and sometimes a mild lumbar scoliosis. Other radiographic findings include degenerative changes and a loss of intervertebral disc height. MRI is the best study to establish the diagnosis of a disc herniation. CT is especially helpful to visualize a partially ossified fragment associated with a slipped apophysis.

TREATMENT

The initial treatment is nonoperative in the vast majority of patients—even if symptoms or findings of radiculopathy are observed. Treatment focuses on rest, activity modification, nonsteroidal antiinflammatory drugs, and physical therapy. An orthosis may provide additional symptomatic relief. Complete bed rest is not recommended. **Epidural steroid injection** may be discussed with patients after approximately 6 wk of treatment if symptoms persist; evidence suggests faster short-term pain relief but no difference in long-term outcome. However, if patients elect to undergo an epidural steroid injection, they should only have a single injection, even if the first did not provide any relief. Multiple injections are no more likely to provide relief than a single injection, and multiple injections expose patients to additional risks of infection, scarring, and neural injury. If a patient experiences substantial relief from an epidural steroid injection and has a later recurrence of symptoms, consideration may be given for a repeat injection after performing a complete physical exam and ruling out any new pathology.

Surgical treatment should be considered when nonoperative measures have failed or when a profound neurologic deficit such as cauda equina syndrome is present or evolving. Unfortunately, children and adolescents respond less favorably to nonoperative therapy compared with adults, and a significant percentage will require surgical intervention. Although patients with disc herniation may improve with reduction in the local inflammatory response around the nerve root, and also as the disc material loses water volume and shrinks, which eliminates mechanical compression, patients with symptomatic ring apophyseal separations have a bony fragment causing their symptoms and are much less likely to improve spontaneously.

The surgical technique involves removing a small area of the lamina via a posterior approach, called a **laminotomy**, which allows exposure of the neural elements and underlying disc. Any loose fragments are removed. A bulging disc may also be opened surgically to decompress the area compressing the neural elements, although a complete discectomy is inadvisable. The surgical approach is similar in the case of a slipped vertebral apophysis, in which fragments of bone and cartilage must also be removed. This often requires a bilateral laminotomy to completely address the pathology.

The initial results are excellent in the majority of patients. Up to one-third of patients may have recurrent herniations and resultant symptoms of back or leg pain with longer-term follow-up. These recurrences are initially treated nonoperatively. A spinal fusion may be required when there is instability, for example, a spondylolisthesis.

Bibliography is available at Expert Consult.

679.9 Tumors

R. Justin Mistovich and David A. Spiegel

Back pain may be the most common presenting complaint in children who have a tumor involving the vertebral column or the spinal cord. Other associated symptoms may include weakness of the lower extremities, scoliosis, and loss of sphincter control. The majority of tumors are benign (see Chapter 501), including osteoid osteoma, osteoblastoma, aneurysmal bone cyst, and eosinophilic granuloma. Malignant tumors involving the vertebral column may be osseous, such as osteosarcoma or Ewing sarcoma. The may involve the spinal cord and sympathetic or parasympathetic nerves, in cases of ganglioneuroma, ganglioneuroblastoma, neuroblastoma. Tumors from other primary sites can also metastasize to the spine.

In addition to high-quality plain radiographs, useful imaging modalities include bone scans, which help with localization and identification of other lesions; MRI, which is helpful to identify soft-tissue extension and neurologic compression; and CT, which provides excellent bony detail.

A biopsy is usually required to establish the diagnosis. Treatment of tumors of the spinal column may require a multidisciplinary approach. These cases should ideally be managed in centers with experience in the care patients with these lesions.

Chapter 680 The Neck

680.1 Torticollis

Patrick O'Toole and David A. Spiegel

Torticollis, literally meaning *twisted neck*, is not a diagnosis but rather a manifestation of a variety of underlying conditions (Table 680-1). Alternative names associated with this condition include *wry-neck* and *cock-robin* deformity.

CONGENITAL MUSCULAR TORTICOLLIS

Typically diagnosed during infancy, **congenital muscular torticollis (CMT)** is contracture of the sternocleidomastoid muscle, which results in tilting of the head and neck toward the side of the contracted muscle with rotation to the contralateral side. In the majority of cases (75%)

Table 680-1	Differential Diagnosis of Torticollis
CONGENITAL Muscular torticollis Positional deformation Vertebral anomalies (failure segmentation, formation or both) Unilateral atlantooccipital fusion Klippel-Feil syndrome Unilateral absence of sternocleidomastoid Pterygium colli	
TRAUMA Muscular injury (cervical muscles) Atlantooccipital subluxation Atlantoaxial subluxation C2-3 subluxation Rotary subluxation Fractures (C1, others)	
INFLAMMATION Cervical lymphadenitis Retropharyngeal abscess Cervical vertebral osteomyelitis or diskitis Juvenile idiopathic arthritis Grisel syndrome (nontraumatic rotary subluxation of the atlantoaxial joint caused by inflammation) Upper lobe pneumonia	
NEUROLOGIC Visual disturbances (nystagmus, superior oblique or lateral rectus paresis) Dystonic oculogyric drug reactions (phenothiazines, haloperidol, metoclopramide) Cervical cord tumor Posterior fossa brain tumor Acoustic neuroma Syringomyelia Wilson disease Dystonia musculorum deformans	
OTHER Acute cervical disk calcification Sandifer syndrome (gastroesophageal reflux, hiatal hernia) Benign paroxysmal torticollis Bone tumors (eosinophilic granuloma, osteoid osteoma) Soft-tissue tumor Psychogenic	

the right-hand sided sternocleidomastoid muscle is involved, causing the patient's face and chin to point to the left side.

CMT is thought to be the result of an intrauterine deformation and is more common in first pregnancies and in those with uterine compression syndrome or decreased amniotic fluid volume. CMT may be associated with the presence of a palpable mass (fibrous tissue) within the substance of the sternocleidomastoid muscle in approximately 50% of cases. The mass disappears during infancy and is replaced by a fibrous band. Information from muscle biopsies and magnetic resonance imaging has led to the suggestion that muscle injury from compression and/or stretch may create localized ischemia resulting in fibrosis and subsequent contracture: an intramuscular compartment syndrome. The condition may rarely be caused by hereditary muscle aplasia. Associated findings in CMT include plagiocephaly, facial asymmetry, and positional musculoskeletal deformities such as metatarsus adductus (15%) and calcaneovalgus feet. Hip dysplasia may be identified in 8-20% of CMT cases.

Although standards for screening in patients with a normal hip examination have not been established, as many as 15% of patients with CMT have developmental dysplasia of the hip based on screening ultrasound, some of whom required treatment. Consideration should be given to obtaining either an ultrasound scan (4 wks of age) or a plain radiograph of the hips (4-6 mo of age).

A muscle-stretching program should be successful in more than 90% of patients with CMT, especially when treatment is started within the 1st 3 mo of life. Although firm guidelines for imaging the cervical spine have not been established, consideration may be given to obtaining anteroposterior and lateral radiographs of the cervical spine when the typical clinical features associated with CMT are absent or if the deformity does not respond to treatment, as torticollis in infants may be a result of congenital vertebral anomalies. Surgical release of the sternocleidomastoid is considered in patients with persistent deformity despite nonoperative treatment. The muscle may be released at its insertion on the clavicle (unipolar release) or off both its origin and insertion (bipolar release). There is no agreement as to the most appropriate time for the surgical release, but surgical treatment is typically delayed until after 18 mo of age, and some even suggest waiting until the child is approaching school age. Although range of motion can be improved following surgical release even during the teenage years, remodeling of facial asymmetry and plagiocephaly may be less predictable in patients older than infancy. Surgical management results in adequate function and acceptable cosmesis in more than 90% of patients. However with early diagnosis and medical treatment, surgery should only be required in a minority of cases.

OTHER CAUSES OF TORTICOLLIS

The evaluation of torticollis becomes more complex when the typical findings associated with CMT are absent, the usual clinical response is not observed, or when the torticollis presents at a later age. In addition to a careful history and physical examination, consultation with an ophthalmologist and/or neurologist may be helpful. Plain radiographs should be obtained, and an MRI scan of the brain and cervical spine will be required in a subset of cases.

The differential diagnosis is extensive (see Table 680-1). **Neurogenic torticollis** is uncommon and results from tumors of the posterior fossa or brainstem, syringomyelia (see Chapter 606.3), and Arnold-Chiari malformation (see Chapter 591.11). In addition to the neurologic examination, MRI of the brain and cervical spine is required to establish the diagnosis. **Paroxysmal torticollis of infancy** is also uncommon and may be a result of vestibular dysfunction. Episodes may last from minutes to days, and the side of the deformity may alternate. The condition is self-limiting, and no specific treatment is required other than ruling out other treatable causes.

Torticollis may also be seen in association with discitis or vertebral osteomyelitis, juvenile idiopathic arthritis, cervical disc calcification, visual problems such as congenital nystagmus or paresis of the superior oblique or lateral rectus muscles, benign or malignant bone tumors, and in patients with cerebral palsy and chronic gastroesophageal reflux (Sandifer syndrome).

Atlantoaxial rotatory displacement represents a spectrum of rotational malalignment from subluxation to frank dislocation between the atlas (C1) and the axis (C2), and may best be described as a pathologic stickiness in the arc of joint motion. In some cases there is fixed malalignment between C1 and C2 (atlantoaxial rotary fixation) that results in a 50% loss of cervical rotation. The malalignment is often reducible initially but may become irreducible and fixed after weeks to months. As such, prompt diagnosis and treatment are essential. Atlantoaxial rotatory displacement may be diagnosed after infection or inflammation of the tissues of the upper airway, neck, and/or pharynx (**Grisel syndrome**), following traumatic injuries (usually minor), and as a complication of surgical procedures in the oropharynx, ear, or nose. The diagnosis is established using a dynamic rotational computerized tomography scan, in which axial images are obtained through the upper cervical spine with the head rotated maximally toward both the right and the left. If the patient is seen within a few days of the onset of symptoms, then a trial of analgesics and a soft collar may be attempted. Patients with symptoms for more than a week are often admitted to the hospital for analgesia, muscle relaxants, and a period of cervical traction. If this fails to reduce the displacement, then halo traction may be attempted. If the joint can be reduced, patients are typically immobilized for at least 6 wk in a halo vest. Patients with a fixed deformity may require a posterior atlantoaxial fusion to stabilize

the articulation. Most children with Grisel syndrome improve with supportive care (nonsteroidal antiinflammatory drugs, muscle relaxants) and treatment of their head and neck infections.

Bibliography is available at Expert Consult.

680.2 Klippel-Feil Syndrome

Patrick O'Toole and David A. Spiegel

Klippel-Feil syndrome (KFS) includes the classic triad of a low posterior hairline, short neck, and decreased cervical range of motion. These clinical findings are present in <50% of patients with KFS. Patients have a congenital fusion (failure of segmentation) of 1 or more cervical motion segments at the craniocervical junction or in the subaxial spine and often have associated congenital anomalies of the cervical spine and other organ systems (Fig. 680-1). Clinical problems are more common in adults and include pain and/or neurologic symptoms, from spinal instability and/or stenosis. The incidence has been estimated at 1:40,000-42,000 births; not every patient with the condition is diagnosed.

ETIOLOGY AND CLASSIFICATION

The etiology is felt to be sporadic when KFS is seen in isolation, but several candidate genes have been proposed in patients with associated anomalies. Additional findings in the cervical spine include occipitocervical synostosis, odontoid abnormalities, and basilar impression (proximal migration of the C2 vertebra). Other associations include **Sprengel's deformity** (congenital elevation of the scapula), congenital scoliosis, genitourinary anomalies (25-35%), sensorineural hearing loss (5%), and congenital heart disease (5-10%). Renal abnormalities include double collecting systems, renal aplasia, and horseshoe kidney. The cervical spine anomalies seen in patients with KFS may also be seen with Goldenhar syndrome, Mohr syndrome, VACTERL (vertebral defects, imperforate anus, congenital heart disease, tracheoesophageal fistula, renal and limb defects) syndrome, and fetal alcohol syndrome.

Traditionally, the classification of KFS has been based on the anatomic distribution of the cervical fusions and the kinematics of the cervical spine in flexion and extension. As more information regarding the genetics of this condition has become available, the classification system has incorporated these changes. KF 1 involves a fusion at C1 with or without a more caudal fusion level (autosomal recessive) and is associated with severe anomalies. KF 2 has a fusion of C2 and C3 with or without a more caudal fusion (autosomal dominant with 100% penetrance). KF 3 is an isolated fusion caudal to C1 and C2/3 (autosomal dominant or recessive). KF 4 (X-linked dominant) is synonymous with **Wildervanck syndrome**, which involves congenital cervical synostosis associated with hearing loss and the **Duane anomaly** (congenital rare type of strabismus).

CLINICAL PRESENTATION

KFS is present at birth but does not usually become clinically apparent until the 2nd or 3rd decades, when patients present with pain, loss of motion, and/or neurologic symptoms. Given that the same physiologic stresses are applied to a smaller number of mobile spinal segments, patients are at risk for the development of hypermobility and often instability, especially at motion segments adjacent to the fused vertebrae. Weakness or clumsiness may be the presenting symptoms. A complete history is essential, including a detailed family and birth history and review of systems.

PHYSICAL EXAMINATION

A comprehensive musculoskeletal and neurologic examination is required, given associated anomalies in the musculoskeletal and visceral systems. Scoliosis is present in more than 50% of patients with KFS, and congenital anomalies may be identified in other regions of the spine as well. The neurologic exam focuses on identifying any signs of radiculopathy or myelopathy. Spinal cord compression (myelopathy) may result from stenosis or instability, and may result in upper motor neuron signs such as hyperreflexia, Babinski's sign, and sustained clonus, with more than 3 beats considered pathologic. Nerve root compression (radiculopathy) may be from stenosis and is identified by weakness or decreased sensation in the muscles or dermatomes served by a particular nerve root, respectively.

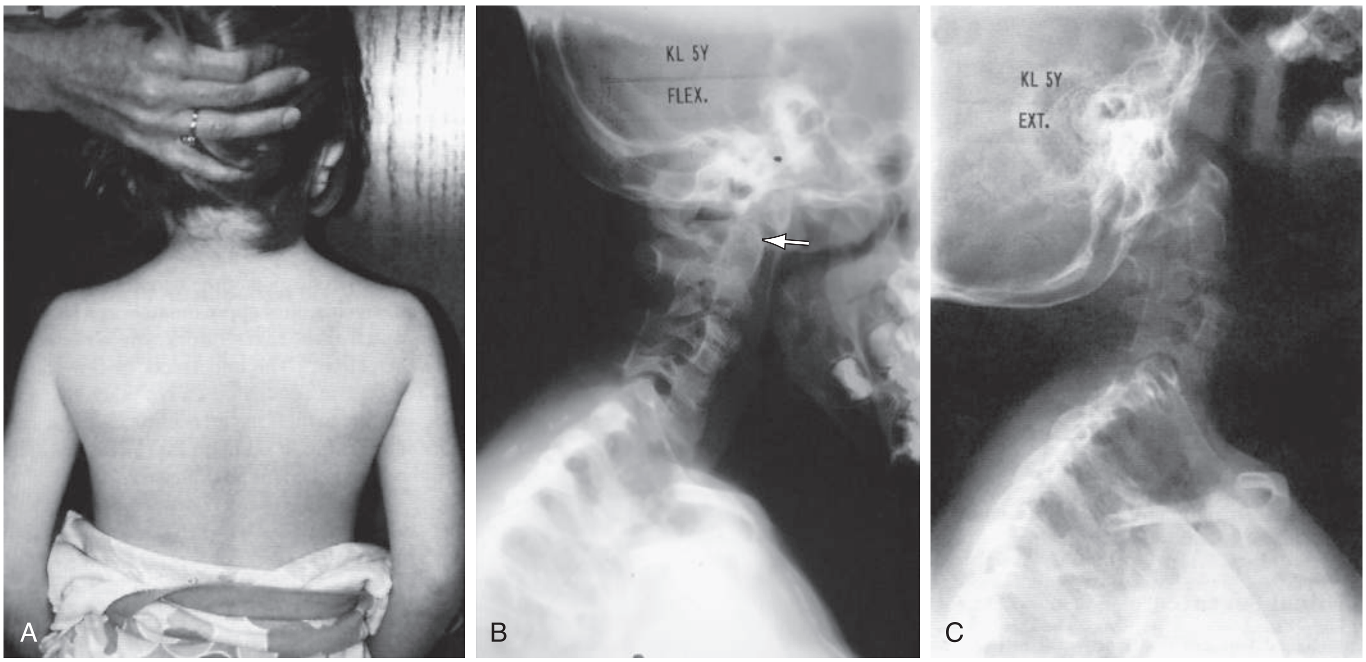

Figure 680-1 Clinical picture of a 5 yr old with Klippel-Feil syndrome. **A,** Note short neck and low hairline. **B** and **C,** Radiographs of the cervical spine (**B,** flexion; **C,** extension) demonstrate congenital fusion and evidence of spinal instability *(arrow)*. *(From Drummond DS: Pediatric cervical instability. RADIOGRAPHIC INVESTIGATION

Initial radiologic evaluation should include an anteroposterior, lateral, and oblique view of the cervical spine. The characteristic finding is a congenital fusion of 2 or more vertebrae (failure of segmentation); however, multiple vertebrae may be involved. Because congenital anomalies may exist in more than 1 region of the spine, radiographs of the thoracic and lumbosacral spine should be routinely obtained. Flexion–extension lateral views of the cervical spine may help to identify segments with excessive motion. Referral to an orthopedist is appropriate if the diagnosis is established. Patients with this condition usually undergo CT and MRI of the spine to accurately characterize the bony anomalies and also identify any coexisting neural pathology. A renal ultrasound is routinely obtained, and additional tests may be indicated.

TREATMENT

The 3 patterns commonly associated with instability include (1) C2/C3 fusion with occipitocervical synostosis, (2) extensive fusion over multiple levels with an abnormal occipitocervical junction, and (3) 2 fused segments separated by an open joint space. Pain may often be controlled by activity restriction, intermittent immobilization, or other nonoperative modalities. Patients who are chronically symptomatic and/or have instability with positive neurologic symptoms and/or findings, or are felt to be at increased risk for neurologic deterioration, are candidates for surgical treatment. Operative interventions include decompression of a nerve root(s) or the spinal cord, and/or spinal fusion to address spinal instability.

Bibliography is available at Expert Consult.

680.3 Cervical Anomalies and Instabilities

Patrick O'Toole and David A. Spiegel

One or more anomalies of the craniovertebral junction and/or lower cervical spine may be seen in isolation or in association with other conditions, including genetic syndromes, skeletal dysplasias, connective tissue disorders, and metabolic disorders. These anomalies may be congenital, resulting from a mutation in the homeobox genes, or developmental. Even though most anomalies remain asymptomatic and undiagnosed, a subset will place the patient at risk of neurologic injury as a result of instability or spinal canal stenosis. The most frequently encountered causes of cervical spine instability in children can be categorized etiologically (Table 680-2). Patients with conditions that have known associations involving the cervical spine should have a complete evaluation, including history, physical examination, and initial radiographic examination.

Patients may complain of neck pain and/or neurologic symptoms. Radicular symptoms include pain, weakness, and numbness within the distribution of a nerve root; myelopathic symptoms may include generalized weakness, gait disturbance, increased fatigue with ambulation, upper-extremity clumsiness, and abnormalities in bowel or bladder function. Physical findings may include a restriction in cervical mobility, cervical tenderness and/or spasm, and neurologic abnormalities.

The upper cervical spine has limited flexion and extension, with roughly 50% of cervical rotation occurring at the atlantoaxial (C1-2) joint. The main constraints to motion in the upper cervical spine are soft tissue (ligaments and joint capsules) rather than osseous, and excessive motion or instability may put neural tissues at risk, and result in compressive injury to the brainstem or spinal cord. Anomalies at the craniovertebral junction include congenital fusion of the occiput to C1 (occipitalization of the atlas), basilar impression and invagination (proximal migration of the C2 vertebra as the result of softening of the bones and with normal bones respectively), and accessory vertebrae. Aplasia or hypoplasia of the atlas or the axis may result in atlantoaxial instability.

Table 680-2 Causes of Pediatric Cervical Instability

CAUSES	SUBTYPES
Congenital	Cranio-occipital defects (occipital vertebrae, basilar impression, occipital dysplasias, condylar hypoplasia, occipitalized atlas) Atlantoaxial defects (aplasia of atlas arch, aplasia of odontoid process) Subaxial anomalies (failure of segmentation and/or fusion, spina bifida, spondylolisthesis) Syndromic disorders (i.e., Down syndrome, Klippel-Feil syndrome, 22q11.2 deletion syndrome, Larsen syndrome, Marfan syndrome, Ehlers-Danlos syndrome)
Acquired	Trauma Infection (pyogenic/granulomatous) Tumor (including neurofibromatosis) Inflammatory conditions (i.e., juvenile idiopathic arthritis) Osteochondrodysplasias (i.e., achondroplasia, diastrophic dysplasia, metatropic dysplasia, spondyloepiphyseal dysplasia) Storage disorders (i.e., mucopolysaccharidoses) Metabolic disorders (rickets) Miscellaneous (including osteogenesis imperfecta, postsurgery)

OS ODONTOIDEUM

Os odontoideum is the most common anomaly of the odontoid peg (dens) and radiographically appears as an oval-shaped, well-corticated, bony ossicle that is positioned cephalad to the body of the axis. There is a discontinuity in the midportion of the dens, and the upper portion of the dens moves with the ring of C1, narrowing the space available for the spinal cord and placing the spinal cord at risk for injury. The body of the dens is mesenchymal in origin and originates from the 1st cervical vertebra, subsequent separation allows it to then fuse with the C2 vertebra. It is formed by 2 separate ossification centers, 1 on either side of the midline, which fuse and are visible at birth. Three etiologies have been proposed: (1) that the os odontoideum represents a fracture nonunion of the odontoid peg; (2) that the os odontoideum represents damage to the epiphyseal plate that has occurred in the 1st yr of life; and (3) that the os odontoideum represents a congenital malformation of the dens itself. The most widely accepted etiology is that a fracture of the dens occurs and subsequently develops a nonunion.

The symptoms and physical findings vary with the location of compression or impingement. In a large series, the average age at presentation was 18.9 yr. The most common presenting symptom was neck pain followed by upper- and lower-limb paresthesia, while torticollis, neck stiffness, gait disturbance, and headaches were uncommon symptoms at presentation. Neurologic examination may reveal a combination of both upper and lower motor neuron signs. Some patients are completely asymptomatic with the anomaly noted incidentally on a lateral cervical spine radiograph.

The radiographic evaluation begins with anteroposterior, lateral, and open mouth (odontoid) views, which may be supplemented by flexion and extension lateral radiographs. CT provides the best bony detail and is useful in defining each anomaly. MRI, including dynamic images in flexion and extension, is best for evaluating neurologic impingement. Symptomatic treatment may be helpful; however, patients with cervical instability and/or neurologic impingement require surgical decompression with or without stabilization.

DOWN SYNDROME

Ligamentous hyperlaxity is a characteristic feature of Down syndrome and may result in hypermobility or instability at the occipitoatlantal or the atlantoaxial joints in 10-30% of patients (see Chapter 81). These patients may also have coexisting congenital or developmental

anomalies of the cervical spine such as occipitalization of the atlas, atlantal arch hypoplasia, basilar invagination, and os odontoideum.

Even though the natural history of this spectrum of pathology remains unknown, a subset of patients may develop or be at significant risk of developing neurologic dysfunction. The clinical diagnosis of neurologic dysfunction may be challenging, and subtle findings, such as decreased exercise tolerance and gait abnormalities, including increased tripping or falling, may be the earliest signs of myelopathy. In addition to a neurologic examination, focusing on the presence of long tract signs, imaging studies (plain films, MRI) are required to evaluate patients suspected of having neurologic involvement.

All patients require screening by history and physical examination (at regular intervals) and at least a single series of cervical spinal radiographs, including a lateral view in flexion and extension. Plain radiographs are the preliminary imaging modality used to evaluate for hypermobility or instability. The atlantodens interval (ADI) is used to evaluate the relationship between C1 and C2 (atlantoaxial joint) and is measured as the space between the dens and the anterior ring of C1 (ADI) on lateral radiographs in neutral, flexion, and extension (Fig. 680-2). Although the ADI should be 3 mm or less in the population without Down syndrome, a normal ADI in children with Down syndrome is <4.5 mm. Hypermobility is diagnosed as an ADI between 4.5 and 10 mm, while an ADI >10 mm represents instability and carries a significant risk of neurologic injury. MRI is indicated to detect neurologic involvement in patients with radiographic instability. Recommendations for surveillance of the cervical spine in children with Down syndrome remain varied. Routine clinical evaluations, including a neurologic examination, should be performed; the indications for repeating imaging studies in the absence of clinical symptoms or findings have not been defined. Surveillance helps to define the most appropriate level of physical activity and to identify the small subset of those with either progressive hyperlaxity or instability. Although the specific recommendations vary between states, both clinical and radiographic screenings are also required prior to participation in the Special Olympics. Patients with normal radiographs who are also neurologically normal may be allowed to participate in full activity. Those who are diagnosed with hypermobility may be restricted from contact sports and other high-risk activities that increase the risk of trauma to the cervical spine. Patients with C1-C2 instability with or without neurologic findings are candidates for an atlantoaxial fusion. The risks of a major complication are extremely high for a posterior cervical fusion in this population and include death, neurologic deterioration, and pseudarthrosis with or without graft resorption.

Although hypermobility at the occipitoatlantal joint is present in >50% of children with Down syndrome, most patients do not develop instability or neurologic symptoms. The relationships at this articulation are difficult to measure reliably on plain radiographs and an MRI in flexion and extension is required to evaluate any questionable radiographic findings, especially in the presence of symptoms. Involvement of the subaxial spine is less common and is typically encountered in the adult population of patients with Down syndrome, where degenerative changes and/or instability may result in pain, radiculopathy, and/or myelopathy.

22q11.2 DELETION SYNDROME

The chromosome abnormality deletion of 22q11.2 is a common genetic syndrome, with an overall prevalence of 1 in 5,950 births, and encompasses a wide spectrum of abnormalities. There are characteristic facial features, cleft palate, and cardiac anomalies. Cervical spine anomalies are also common phenotypic features of this syndrome.

At least 1 developmental variation of the occiput or cervical spine is noted in all patients. The occipital variations observed include platybasia (abnormal flattening of the base of the skull) and basilar impression. Variations in anatomy of C1 include dysmorphic shape, an open posterior arch, and occipitalization; axis variations include a dysmorphic dens and "C2 swoosh" (upswept lamina and posterior elements). A range of cervical vertebral fusions is noted in these patients, the most common being at the C2-3 level. Increased segmental motion in the cervical spine is noted in more than half of these patients, and more than a third of patients have increased segmental motion at more than 1 level. With frequent occurrence of upper cervical spine variations in the 22q11.2 deletion syndrome (Fig. 680-3), advanced imaging of the upper cervical spine and regular follow-up of patients to clarify their clinical course is recommended.

Chapter 681

The Upper Limb

Robert B. Carrigan

SHOULDER

The shoulder is a ball-and-socket joint. Although similar to the hip, the shoulder has a greater range of motion because of the size of the humeral head relative to the glenoid, as well as to the presence of scapulothoracic motion. The shoulder positions the hand along the surface of a theoretical sphere in space, with its center at the glenohumeral joint.

Brachial Plexus Birth Palsy

(See also Chapter 99.7.)

Injuries to the brachial plexus can occur in the peripartum time, usually as a result of a stretching mechanism. This palsy is often associated with large fetal size and shoulder dystocia. The incidence is 1-3 per 1,000 live births. The injury can range in severity from neurapraxia, to complete rupture of the nerve roots or avulsion of the nerve root from the spinal cord. More often, the upper roots (C5 and C6) of the brachial plexus are affected, rather than a complete brachial plexus palsy itself (C5-T1). Rarely, in isolation, is a lower plexus injury (C8 and T1) observed. The clinical appearance of a C5-C6 brachial plexus birth palsy (Erb-Duchenne palsy) is the waiter's tip position. The arm is held in a position of shoulder adduction and internal rotation, elbow extension, and wrist flexion.

Treatment

Occupational therapy should be instituted quickly after brachial plexus injury to maintain passive range of motion of the limb and encourage use of the arm. If the biceps muscle does not demonstrate evidence of recovery by 3 mo of age, or shows persistent weakness at 5 mo of age, a more severe nerve injury may be suspected. MRI and electrodiagnostic testing are not consistently reliable for delineation of nerve injury in this setting. Surgical exploration and nerve grafting of the brachial plexus are then indicated.

After complete or incomplete neurologic recovery shoulder dysplasia and dislocation (analogous to developmental dysplasia of the hip) can occur. This occurs as a result of muscle imbalances in the shoulder. In the typical Erb palsy a child may have a persistent internal rotation contracture of the shoulder as a result of the imbalance of the weak abductors and external rotators and stronger adductors and internal rotators. Infants and older children may require arthroscopic or open reduction of shoulder contractures. Older children with residual weakness in shoulder abduction and external rotation can benefit from muscle transfers. Osteotomies are reserved for children with severely deformed glenohumeral joints and functional impairment from persistent shoulder internal rotation contracture (Fig. 681-1).

Sprengel's Deformity

Sprengel's deformity, or congenital elevation of the scapula, is a disorder of development that involves a high scapula and limited scapulothoracic motion. The scapula originates in early embryogenesis at a level posterior to the 4th cervical vertebra, but it descends during development to below the 7th cervical vertebra. Failure of this descent, either unilateral or bilateral, is Sprengel's deformity. The severity of the deformity depends on the location of the scapula and associated anomalies. The scapula in mild cases is simply rotated, with a palpable or visible bump corresponding to the superomedial corner of the scapula in the region of the trapezius muscle. Function is generally good. In moderate cases, the scapula is higher on the neck and connected to the spine with an abnormal omovertebral ligament or even bone. Shoulder motion, particularly abduction, is limited. In severe cases, the scapula is small and positioned on the posterior neck, and the neck may be webbed. The majority of patients have associated anomalies of the musculoskeletal system, especially in the spine, making spinal evaluation important.

Treatment

In mild cases, treatment is generally unnecessary, although a prominent and unsightly superomedial corner of the scapula can be excised. In more severe cases, surgical repositioning of the scapula with rebalancing of parascapular muscles can significantly improve both function and appearance.

ELBOW

The elbow is the most congruent joint in the body. The stability of the elbow is imparted via this bony congruity as well as through the medial and radial collateral ligaments. Where the shoulder positions the hand along the surface of a theoretical sphere, the elbow positions the hand within that sphere. The elbow allows extension and flexion through the ulnohumeral articulation and pronation and supination through the radiocapitellar articulation.

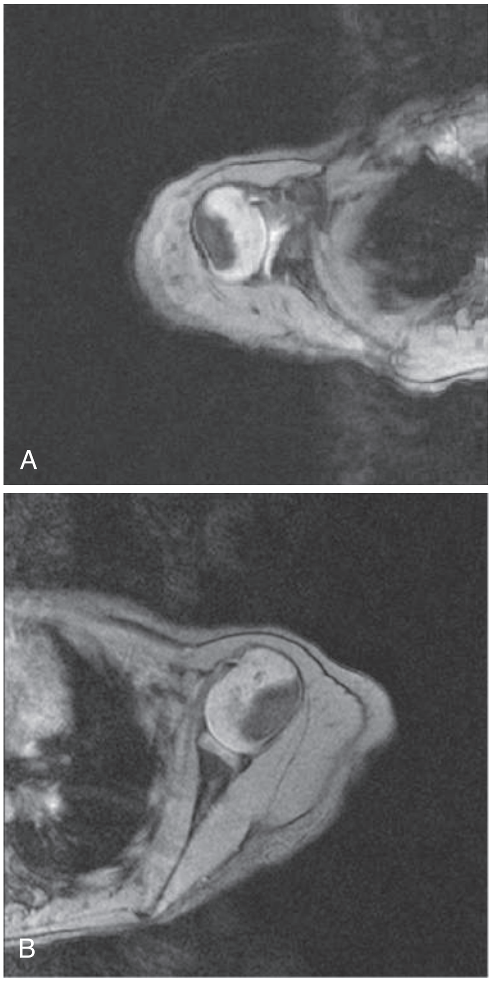

Figure 681-1 **A,** Shoulder MRI demonstrating glenohumeral dysplasia following brachial plexus birth palsy. **B,** Comparison MRI of uninvolved contralateral shoulder.

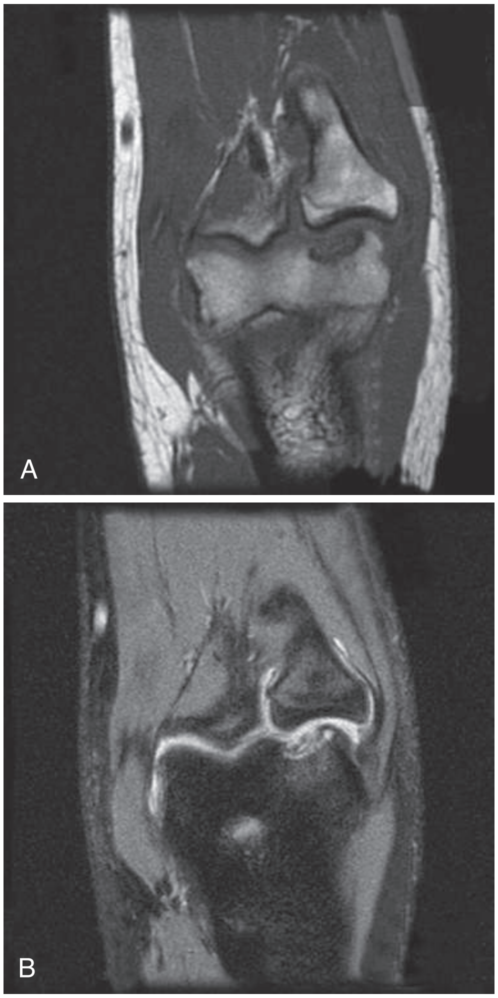

Figure 681-2 T1 **(A)** and T2 **(B)** coronal MRI images of the elbow depicting Panner disease of the elbow.

Panner Disease

Panner disease is a disruption of the blood flow to the articular cartilage and subchondral bone to the capitellum (Fig. 681-2). It typically occurs in boys between the ages of 5 and 13 yr. Presenting symptoms include lateral elbow pain, loss of motion, and, in advanced cases, mechanical symptoms of the elbow (loose bodies).

The mechanism of injury can be impaction or overloading of the joint, as seen with sports such as gymnastics and baseball. It can also be idiopathic. Radiographs of the elbow may be normal, but they may also show a small lucency within the subchondral bone of the capitellum. MRI is the study of choice to evaluate a suspected capitellar lesion. MRI can demonstrate the extent of the involvement in the subchondral bone as well as the integrity of the cartilage of the articular surface.

Treatment

Treatment is typically conservative. Rest, activity modification, and patient education are initial treatment options. In cases where the articular cartilage fragments and loose bodies form, arthroscopy of the elbow is warranted to remove the loose bodies. When the cartilage defect in the capitellum is large and symptomatic, procedures for restoration of the articular cartilage may be considered. These procedures include drilling of the subchondral bone (microfracture) to promote scar cartilage and osteochondral autograft transplantation.

Radial Longitudinal Deficiency

Radial longitudinal deficiency of the forearm comprises a spectrum of conditions and diseases that have resulted in hypoplasia or absence of the radius (Table 681-1). This process was formerly referred to as *radial club hand,* but the name has been changed to *radial longitudinal deficiency,* which better characterizes the condition. Clinical characteristics consist of a small, shortened limb with the hand and wrist in excessive radial deviation. Partial or complete absence of the radial structures of the forearm and hand are observed (Fig. 681-3).

Radial longitudinal deficiency can range in severity from mild to severe and has been classified into 4 types (Table 681-2). Radial longitudinal deficiency can be associated with other syndromes such as Holt-Oram and Fanconi anemia (see Table 681-1).

Treatment

The goals for the treatment of radial longitudinal deficiency include centralizing the hand and wrist on the forearm, balancing the wrist, and maintaining appropriate thumb and digital motion. Shortly after birth, parents are encouraged to passively stretch the wrist and hand to elongate the contracted radial soft tissues. Serial casting and splinting are ineffective at this time, because of the small size of the arm.

Surgery for correction of the wrist deformity remains controversial. Historically, for children with good elbow motion, centralization of the wrist on the forearm was performed. However recurrence of the deformity was often observed. For this reason some surgeons have elected to abandon this procedure.

When considering a centralization procedure, the preoperative plan begins with careful examination of the patient; considerations in regard to thumb and elbow function must be made before surgery. The surgery typically occurs when the child is 1 yr of age. Correction of the

radial deviation as well as centralization of the wrist can be accomplished with a variety of different surgical techniques. These techniques include open release, capsular reefing, and tendon rebalancing. External fixation techniques have also been described.

Nursemaid Elbow

Nursemaid elbow is a subluxation of a ligament rather than a subluxation or dislocation of the radial head. The proximal end of the radius, or radial head, is anchored to the proximal ulna by the annular ligament, which wraps like a leash from the ulna, around the radial head, and back to the ulna. If the radius is pulled distally, the annular ligament can slip proximally off the radial head and into the joint between the radial head and the humerus (Fig. 681-4). The injury is typically produced when a longitudinal traction force is applied to the arm, such as when a falling child is caught by the hand, or when a child is pulled by the hand. The injury usually occurs in toddlers and rarely occurs in children older than 5 yr of age. Subluxation of the annular ligament produces immediate pain and limitation of supination. Flexion and extension of the elbow are not limited, and swelling is generally absent. The diagnosis is made by history and physical examination, as radiographs are typically normal.

Treatment

The annular ligament is reduced by rotating the forearm into supination while holding pressure over the radial head. A palpable click or clunk can be felt. The child recovers active supination immediately and usually has immediate relief of discomfort. Immobilization is not required, but recurrent annular ligament subluxations can occur, and the parents should avoid activities that apply traction to the elbows. Parents can learn reduction maneuvers for recurrent episodes to avoid trips to the emergency department or pediatrician's office. Recurrent subluxation beyond 5 yr of age is rare. Irreducible subluxations tend to resolve spontaneously, with gradual resolution of symptoms over days to weeks; surgery is rarely indicated.

WRIST

The wrist is composed of the 2 forearm bones as well as the 8 carpal bones. The wrist allows flexion, extension, and radial and ulnar deviation through the radiocarpal and midcarpal articulations. Pronation and supination occur, at the wrist, through the distal radial ulnar joint. The wrist is a complex joint with numerous ligamentous and soft-tissue attachments. It has complex kinematics that allows for its generous range of motion, but when these kinematics are altered, significant dysfunction can occur.

Madelung Deformity

Madelung deformity is a deformity of the wrist that is characterized as radial and palmar angulations of the distal aspect of the radius (Fig. 681-5). Growth arrest of the palmar and ulnar aspect of the distal radial physis is the underlying cause of this deformity. Bony physeal lesions and an abnormal radiolunate ligament (Vicker's ligament) have been implicated. The deformity can be bilateral and affects girls more than boys.

Treatment

Treatment of Madelung's deformity is typically observation. Mild deformities can be observed until skeletal maturity. Moderate to severe deformities that either are painful or limit function may be candidates for surgical intervention. Surgical treatment for Madelung's deformity is often motivated by appearance. Patients and their families may be concerned about the palmar angulation of the wrist as well as the resulting prominent distal ulna.

There are a multitude of surgical options for treating Madelung's deformity. For the skeletally immature patient, resection of the tethering soft tissue (Vicker's ligament) and physiolysis (fat grafting of any bony lesion seen within the physis) is often the first option. When Madelung's deformity is encountered in skeletally mature patients, an osteotomy may be considered. Dorsal closing wedge, dome, and ulnar

shortening osteotomies may be used alone or in combination to achieve the desired result.

Long-term considerations of Madelung's deformity concern the incongruity of the distal radial ulnar joint and resulting premature distal radial ulnar joint arthritis.

Ganglion

As a synovial joint, the wrist articulation is lubricated with synovial fluid, which is produced by the synovial lining of the joint and maintained within the joint by the joint capsule. A defect in the capsule can allow fluid to leak from the joint into the soft tissues, resulting in a ganglion. The term *cyst* is a misnomer, because this extraarticular collection of fluid does not have its own true lining. The defect in the capsule can occur as a traumatic event, although trauma is rarely a feature of the presenting history. The fluid usually exits the joint in the interval between the scaphoid and lunate, resulting in a ganglion located at the dorsoradial aspect of the wrist. Ganglia can occur at other locations, such as the volar aspect of the wrist, or in the palm as a result of leakage of fluid from the flexor tendon sheaths. Pain is not commonly associated with ganglia in children, and when it is, it is unclear whether the cyst is the cause of the pain. The diagnosis is usually evident on physical examination, especially if the lesion transilluminates. Extensor tenosynovitis and anomalous muscles can mimic ganglion cysts, but radiography or MRI is not routinely required. Ultrasonography is an effective, noninvasive tool to support the diagnosis and reassure the patient and family.

Treatment

Regarding the treatment of ganglia in children, consider the vowels AEIOU.

Aspiration: Simple aspiration of the fluid has a high recurrence rate and is painful for children given the large-bore needle required to aspirate the gelatinous fluid. However, in older children who would like try and decompress the cyst before considering surgery, this may be reasonable.

Excision: Surgical excision, including excision of the stalk connecting the ganglion to its joint of origin, has a high success rate, although the ganglion can recur.

Injection: Aspiration of the cyst and a simultaneous injection of a corticosteroid have been shown to be effective in treating recurrence in children.

Observation: Up to 80% of ganglia in children younger than 10 yr of age resolve spontaneously within 1 yr of being noticed. If the ganglion is painful or bothersome and the child is older than 10 yr of age, treatment may be warranted.

Ultrasound: For children's parents who are concerned about the mass and want a radiographic study to confirm the diagnosis, ultrasound is a noninvasive test to confirm the diagnosis.

HAND

The hand and fingers allow complex and fine manipulations. An intricate balance among extrinsic flexors, extensors, and intrinsic muscles allow these complex motions to occur. Congenital anomalies of the hand and upper extremity rank just behind cardiac anomalies in incidence, and like cardiac anomalies, if they are not properly identified and remedied, they can have long-term consequences.

Camptodactyly

Camptodactyly is a nontraumatic flexion contracture of the proximal interphalangeal joint that is often progressive. The small and ring fingers are most often affected. Bilateralism is observed two-thirds of the time. The etiology of camptodactyly is varied. Several different hypotheses have been offered as to the cause of this condition. Camptodactyly can be divided into 3 different types (Table 681-3).

Treatment

Nonsurgical treatment is the primary treatment of camptodactyly. Mild contractures of <30 degrees are usually well tolerated and do not need treatment. Serial casting and static and dynamic splinting are the treatments of choice for preventing progression of contractures. This should be performed until the child is skeletally mature.

Surgical treatment is limited to the treatment of severe contractures. At the time of surgery, all contracted and anomalous structures are released. Results of contracture release for camptodactyly are mixed; often a loss of flexion results from an attempt to improve extension.

Clinodactyly

Angular deformity of the digit in the coronal plane, distal to the metacarpophalangeal joint is clinodactyly. The most commonly observed finding is a mild radial deviation of the small finger at the level of the distal interphalangeal joint. This is often because of a triangular or trapezoidal middle phalanx. In some cases, a disruption of the physis at the middle phalanx produces a longitudinal epiphysial bracket. This

Table 681-3 Classification of Camptodactyly

TYPE	CHARACTERISTICS
I	Congenital, no sex bias, small finger only
II	Acquired between ages 7 and 11 yr, typically progressive
III	Severe, significant contracture, bilateral, and associated with other musculoskeletal syndromes

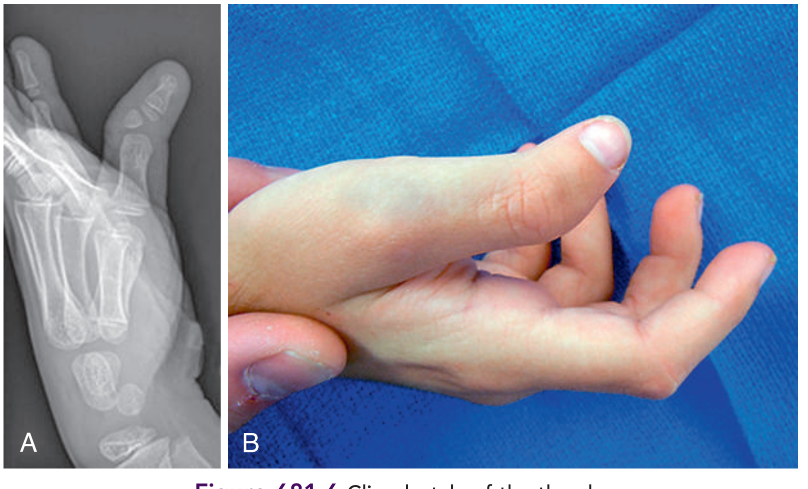

Figure 681-6 Clinodactyly of the thumb.

bracket is thought to be the underlying cause for the formation the "delta phalanx" that is often observed in clinodactyly. Clinodactyly has been observed in other fingers, including the thumb (Fig. 681-6) and ring finger.

Treatment

Often the treatment for clinodactyly is observation and not surgery. For severe deformities and for those affecting the thumb, surgery may be indicated. Surgery is technically demanding. Bracket resections, corrective osteotomies, and growth plate ablations are the most common procedures performed to correct the observed angular deformities. Results are good and recurrences are few when an appropriate procedure is performed.

Polydactyly

Polydactyly or duplication of a digit can occur either as a preaxial deformity (involving the thumb) or as a postaxial deformity (involving the small finger) (Table 681-4; Fig. 681-7). Each has an inherited and genetic component. Duplication of the thumb occurs more often in whites and Asians and is often unilateral, whereas duplication of the small finger occurs more frequently in African-Americans and may be bilateral. Transmission is typically in an autosomal dominant pattern and has been linked to defects in genes localized to chromosome 2.

Duplication of the thumb is subdivided on the basis of the degree of duplication. Table 681-5 lists the 7 types. Small finger duplication has been further subdivided into 2 types. Type A is a well-formed digit. Type B is a small, often underdeveloped supernumerary digit.

Treatment

Thumb and small finger duplication is typically treated with ablation of the supernumerary digit. Treatment options vary based on the

degree of involvement. Less-well-formed digits can be treated with suture ligation. Well-formed digits require reconstructive procedures that preserve important structures such as the collateral ligaments and nail folds (Fig. 681-8).

Thumb Hypoplasia

Hypoplasia of the thumb is a challenging condition for both the patient and the doctor. The thumb represents approximately 40% of hand function. A less-than-optimal thumb can severely limit a patient's function as the patient grows and develops. Hypoplasia of the thumb can range from being mild with slight shortening and underdeveloped musculature to complete absence of the thumb (Fig. 681-9). Radiographs are useful to help determine osseous abnormalities. The most important finding on physical exam is the presence or absence of a stable carpometacarpal joint. This finding helps guide surgical treatment.

Treatment

If the thumb has a stable carpometacarpal joint, reconstruction is advised. Key elements of thumb reconstruction include rebuilding the ulnar collateral ligament of the metacarpophalangeal joint, tendon transfers to aid thumb abduction, and procedures to deepen the web space.

If a stable carpometacarpal joint is not present or the thumb is completely absent, **pollicization** (surgical construction of a thumb from a finger) is the definitive treatment. Pollicization is a complex procedure rotating the index finger along its neurovascular pedicle to form a thumb. This procedure is typically performed at around 1 yr of age and may be followed by subsequent procedures to deepen the web space or augment abduction (Fig. 681-10).

Syndactyly

Failure of the individual digits to separate during development produces syndactyly. Syndactyly is one of the more common anomalies observed in the upper limb (Table 681-6). It is seen in 0.5 of 1,000 live births. Syndactyly can be classified as simple (skin attachments only), complicated (bone and tendon attachments), complete (fusion to the tips, including the nail), or incomplete (simple webbing).

Treatment

Division of the conjoined digits should be considered before the 2nd yr of life. Border digits should be divided earlier (3-6 mo) because of concern for tethered growth of digits of unequal length. Digits of similar size, such as the ring and middle, may wait until the child is older to consider separation. Reconstruction of the web space and nail folds as well as appropriate skin-grafting techniques must be used to ensure the best possible functional and cosmetic result (Fig. 681-11).

Fingertip Injuries

Young children are fascinated with doorjambs or car doors and other tight spaces, making crush injuries to the fingertips quite common.

Figure 681-9 Congenital absence of the thumb.

Figure 681-10 Postsurgical image after pollicization.

Injury can range from a simple subungual hematoma to complete amputation of part or the entire fingertip. Radiographs are important to rule out fractures. Physeal fractures associated with nail bed injuries are **open fractures** with a high risk of osteomyelitis, growth arrest, and deformity if not treated promptly with formal surgical debridement and reduction. Tuft fractures involving the very distal portion of the distal phalanx are common and require little specific treatment other than that for the soft-tissue injury.

The treatment of the soft-tissue injury depends on the type of injury. For suture repairs, only absorbable sutures should be used, because suture removal from a young child's fingertip can require sedation or general anesthesia. If a subungual hematoma exists but the nail is normal and no displaced fracture exists, the nail need not be removed for nail bed repair. If the nail is torn or avulsed, the nail should be removed, the nail bed and skin should be repaired with absorbable sutures, and the nail (or a piece of foil if the nail is absent) should be replaced under the eponychial fold to prevent scar adhesion of the eponychial fold to the nail bed that can prevent nail regrowth.

If the fingertip is completely amputated, treatment depends on the level of amputation and the age of the child. Distal amputations of skin and fat in children younger than 2 yr of age can be replaced as a composite graft with a reasonable chance of surviving. Similar amputations in older children can heal without replacing the skin as long as no bone is exposed and the amputated area is small. A variety of coverage procedures exist for amputations through the mid-portion of the nail. Amputations at or proximal to the proximal edge of the fingernail should be referred emergently to a replant center for consideration for microvascular replantation. When referring, all amputated parts should be saved, wrapped in saline-soaked gauze, placed in a watertight bag, and then placed in ice water. Ice should never directly contact the part, because it can cause severe osmotic and thermal injury.

Trigger Thumb and Fingers

The flexor tendons for the thumb and fingers pass through fibrous tunnels made up of a series of pulleys on the volar surface of the digits. These tunnels, for reasons that are not well understood, can become tight at the most proximal or first annular pulley. Swelling of the underlying tendon occurs, and the tendon no longer glides under the pulley. In children, the most common digit involved is the thumb. It has classically been thought to be a congenital problem, but prospective screening studies of large numbers of neonates have failed to find a single case in a newborn child. The incidence of trigger thumb is approximately 3 per 1,000 children at 1 yr of age. Trauma is rarely a feature of the history, and the condition is often painless. Overall function is rarely impaired. A trigger thumb typically manifests with the inability to fully extend the thumb interphalangeal joint. A palpable nodule can be felt in the flexor pollicis longus tendon at the base of the thumb metacarpal phalangeal joint volarly. Other conditions can mimic trigger thumb, including the thumb-in-palm deformity of cerebral palsy. Similar findings in the fingers (index through small) are much less common and may be associated with inflammatory conditions such as juvenile rheumatoid arthritis (Fig. 681-12).

Treatment

Trigger thumbs spontaneously resolve in up to 30% of children in whom they are diagnosed before 1 yr of age. Spontaneous resolution beyond that age is not common. Corticosteroid injections are effective in adults but are not effective in children and risk injury to the nearby digital nerves. Surgical release of the first annular pulley is curative and is generally performed between 1 and 3 yr of age. Treatment of trigger fingers other than the thumb in children involves evaluation and treatment of any underlying inflammatory process and in some cases surgical decompression of the flexor sheath and possible flexor tendon partial excision.

Chapter 682

Arthrogryposis

Helen M. Horstmann, Christine M. Conroy, and Richard S. Davidson

Arthrogryposis multiplex congenita refers to a heterogeneous group of muscular, neurologic, and connective tissue anomalies that present with 2 or more joint contractures at birth as well as muscle weakness. It is associated with abnormal contraction of muscle fibers, causing reduced mobility with a decreased active and passive arc of motion. Arthrogryposis is not a specific diagnosis but a descriptive term with various etiologies and complex clinical features, including multiple congenital contractures of various limb joints. It is associated with 200-300 different disorders encompassing malformations, malfunction, and neurologic deficiencies.

Approximately 1% of all births show some form of contractures of the joints ranging from unilateral clubfoot to pervasive, crippling contractures due to amyoplasia. Overall incidents of arthrogryposis have been reported to be 1 in 5,000-10,000 live births with equal gender ratios.

Although children with arthrogryposis have many other problems, such as micrognathia, nutrition issues, and sucking issues, here we focus on the orthopedic problems frequently seen in this group of children. In the absence of central nervous system lesions, many children have normal intelligence.

ETIOLOGY

In humans, both the intrinsic and extrinsic causes of arthrogryposis are categorized into 6 groups (Fig. 682-1), including a multitude of disorders (Table 682-1).

Neurologic Abnormalities

As one of the most common causes of arthrogryposis, neurologic abnormalities are present in 70-80% of cases. Patchy damage to the anterior horn cells of the spinal cord can lead to characteristic limb posturing of arthrogryposis. Neurologic disorders, such as spinal muscular atrophy and anterior horn disease, including Werdnig-Hoffmann disease, are associated with arthrogryposis; however, the type of anterior horn cell involvement is usually not from spinal muscular atrophy syndrome (Werdnig-Hoffman disease). Other, less-common neurologic disorders include neonatal myasthenia and myotonic dystrophy.

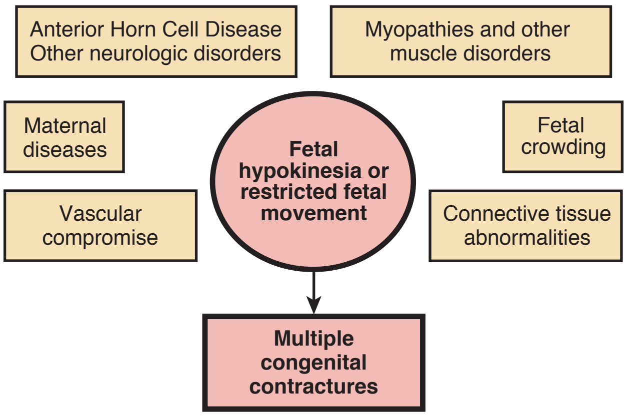

Figure 682-1 Etiology of arthrogryposis. *(Modified from Hall JG: Arthrogryposis multiplex congenital: Etiology, genetics, classification, diagnostic approach, and general aspects.* J Pediatr Orthop B *6:159–166, 1996.)*

Table 682-1 Associated Etiologies of Arthrogryposis

ARTHROGRYPOSIS CAUSED BY NERVOUS SYSTEM DISORDERS • Focal anterior horn cell deficiency • Generalized anterior horn cell deficiency • Structural brain disorder/damage • Uncertain location (Spastic conditions are excluded)
DISTAL ARTHROGRYPOSIS SYNDROMES • Type I dominant distal • Type IIa dominant distal (Gordon syndrome) • Type IIe distal • Digitotalar dysmorphism • Trismus pseudocamptodactyly • Distal distribution, type not specified
PTERYGIUM SYNDROMES • Multiple pterygium syndrome • Lethal multiple pterygium syndrome • Popliteal pterygium syndrome • Ptosis, scoliosis, pterygia • Antecubital webbing syndrome (Liebenberg)
MYOPATHIES • Emery-Dreifuss muscular dystrophy • Hypotonia, myopathy, mild contractures
ABNORMALITIES OF JOINTS AND CONTIGUOUS TISSUE • Congenital contractural arachnodactyly • Freeman-Sheldon syndrome • Laxity or hypertonicity with intrauterine dislocation and contractures • Larsen syndrome • Spondyloepimetaphyseal dysplasia with joint laxity • Trisomy 18, extended breech position with bilateral hip dislocation • Siblings with bifid humeri, hypertelorism, and hip and knee joint dislocations
SKELETAL DISORDERS • Diastrophic dysplasia • Parastremmatic dysplasia • Kniest dysplasia • Metatropic dysplasia • Campomelic dysplasia • Schwartz syndrome • Fetal alcohol syndrome with synostoses • Osteogenesis imperfecta with bowing/contractures
INTRAUTERINE/MATERNAL FACTORS • Fetal alcohol syndrome with contractures • Infections • Untreated maternal systemic lupus erythematosus • Intrauterine fetal constraint • Deformity (pressure) • Amniotic fluid leakage • Multiple pregnancies • Intrauterine tumors • Disruption (bands)
MISCELLANEOUS • Pseudotrisomy 18 with contractures • Roberts pseudothalidomide syndrome • Deafness with distal contractures • VACTERL association • Multiple abnormalities and contractures not otherwise specified • ARC
SINGLE JOINT • Campomelia • Symphalangism • "Trigger" finger

ARC, arthrogryposis, renal tubular acidosis, cholestasis; VACTERL, vertebral defects, imperforate anus, congenital heart disease, tracheoesophageal fistula, renal and limb defects.

Muscular Abnormalities

These rare abnormalities affect the function and structure of the muscles. Some muscular diseases associated with arthrogryposis are muscular dystrophies, congenital muscular dystrophies (central core, nemaline, centronuclear), intrauterine myositis and mitochondrial diseases.

Limited Intrauterine Spacing

With a less than 0.1% occurrence rate, uterine constraint is rarely the primary cause of arthrogryposis. Maternal uterine anomalies will occasionally increase contractures of fetal limbs with arthrogryposis already existing. Other known causes are lack of amniotic fluid within the uterus and tumors, such as fibroids that can impinge on uterine space, preventing movement.

Connective Tissue Abnormalities

When the tendons, bones, joints, and joint lining develop atypically, decrease in fetal movement causes congenital contractures. Diseases such as diastrophic dysplasia and metatropic dwarfism result from connective tissue not developing properly. These are specific diagnoses resulting in limited joint motion and not true distal arthrogryposis. Other cases show that individuals who lack normal joint movement have distal joint involvement because the connective tissue develops normally but does not attach to the proper location around a joint bone or joint.

Maternal Diseases

Maternal diseases, such as multiple sclerosis, diabetes mellitus, myasthenia gravis, maternal hyperthermia, infection, drugs, and trauma, are associated with an increased incidence of arthrogryposis. In approximately 10% of neonates born to mothers with myasthenia gravis, maternal antibodies enter the fetal circulation through the placenta, causing transient myasthenia gravis; this inhibits fetal acetylcholine receptors, which leads to damaged fetal muscles.

Intrauterine Vascular Compromise

Inadequate vascular supply to the fetus causes fetal hypoxia resulting in anterior horn cell death, which decreases neurologic and myopathic function, resulting in fetal akinesia and secondary joint contractures. Multiple congenital contractures have been reported in individuals after bleeding throughout pregnancy or after a failed attempt at terminating the pregnancy.

CLASSIFICATION

Arthrogryposis multiplex congenita is divided into subgroups with different signs, symptoms, and causes as a practical way to make a differential diagnosis. Disorders involving primarily limbs such as **amyoplasia** and **distal arthrogryposis** are the most common subgroups (Table 682-2). Disorders involving limbs *and* other body parts typically represent a form of *multiple pterygium,* which is characterized by a web-like membrane that forms across joints affecting a child's ability to extend and causing fixed flexion. Disorders with limb involvement and abnormal neurologic function are caused by atypical central nervous system, peripheral nervous system, and damaged or absent anterior horn cells.

Amyoplasia, also known as *classic arthrogryposis,* is a sporadic symmetric disorder that causes fibrotic replacement of the muscles. Symptoms include internally rotated and adducted shoulders, extended elbows, pronated forearms, flexed fingers and wrists, dislocated hips, feet with severe equinovarus contractures, and extended knees. Involved muscles are hypoplastic and fibrotic. Often patients have midfacial hemangioma. Intelligence is usually normal (Figs. 682-2 and 682-3).

Distal arthrogryposis is an autosomal dominant disorder that primarily affects the distal joints of the limbs. Characteristics of the upper limbs are medially overlapping fingers, clenched fists, ulnar deviation of fingers, camptodactyly, and hypoplasia. Lower limbs show talipes equinovarus, calcaneovalgus, vertical talus, or metatarsus varus (Fig. 682-4).

Ten different types of distal arthrogryposis have been categorized based on specific traits they share with each other.

MANAGEMENT OF ORTHOPEDIC PROBLEMS OF ARTHROGRYPOSIS

When a child is born with arthrogryposis, the many stiff or dislocated joints pose issues of timing and best practices of management.

Table 682-2 Current Labels and OMIM Numbers for the Distal Arthrogryposis Syndromes

SYNDROME	OMIM NUMBER
Distal arthrogryposis type 1	108120
Distal arthrogryposis type 2A (Freeman-Sheldon syndrome)	193700
Distal arthrogryposis type 2B (Sheldon-Hall syndrome)	601680
Distal arthrogryposis type 3 (Gordon syndrome)	114300
Distal arthrogryposis type 4 (scoliosis)	609128
Distal arthrogryposis type 5 (ophthalmoplegia, ptosis)	108145
Distal arthrogryposis type 6 (sensorineural hearing loss)	108200
Distal arthrogryposis type 7 (trismus-pseudocamptodactyly)	158300
Distal arthrogryposis type 8 (autosomal dominant multiple pterygium syndrome)	178110
Distal arthrogryposis type 9 (congenital contractural arachnodactyly)	121050
Distal arthrogryposis type 10 (congenital plantar contractures)	187370

Figure 682-5 Child with stiff elbows, wrists, knees, and clubfeet.

Figure 682-6 Infant with splints to extend metatarsophalangeal joints, wrists, and knees.

Typically a child can have stiff elbows, dislocated hips, dislocated, hyperextended or contracted knees, and clubfeet (Fig. 682-5). The stiffness and deformity need to be aggressively addressed through a combination of modalities. A team of clinicians including therapists for the upper and lower extremities, orthotists, and orthopedic surgeons will be involved.

Initially, passive range-of-motion exercises and judicious splinting directed and assisted by physical and occupational therapy will help to address the various deformities. Splinting and casting can be augmented by a taping program which can be taught to the family so that the taping can be redone frequently to take advantage of improved range of motion. The ingenuity of the therapists and/or orthotist to create the right splints and braces using appropriate thermoplastics, neoprene, Velcro, and other materials can be simple yet effective (Fig. 682-6).

The therapeutic and orthopedic goal for the child with arthrogrypotic limb deformities is to achieve maximal joint motion and to optimize joint position for function. In the lower extremities, the foot needs to be plantigrade. The knees need to have optimal motion for sitting and standing. Hips need to be stabilized especially if the child has walking potential. In the upper extremities, the goals should

Figure 682-7 Clubfeet in infant with arthrogryposis.

include positioning of 1 arm for feeding and the other for toileting in cases where there is extreme stiffness. Two-handed activities require some symmetry, which can be a challenging goal with extreme contractures and limited muscle strength.

Although scoliosis is common, it usually does not become a problem until adolescence.

FOOT PROBLEMS

Clubfoot deformities are the most commonly seen deformities with arthrogryposis (Fig. 682-7). A clubfoot has components of hindfoot equinus, midfoot varus, and forefoot adduction. Feet in arthrogryposis tend to be resistant to improvement but the traditional methods of treatment are nevertheless employed. Casting is begun shortly after birth in a method known as the Ponseti method. Casts are changed weekly until a plateau is reached and heel cord lengthening is needed. Other deformities such as vertical talus are also seen and are addressed in a similar approach although with appropriately differing techniques.

Persistent stiffness often leads to more comprehensive soft tissue releases. This is typically done around age 6-12 mo and is followed by 3 mo of further casting and additional bracing as needed, especially as the foot is growing. When deformities are not corrected in early childhood, additional bony surgery may be needed later. Some of the approaches to this involve bony wedge osteotomies, lateral column lengthening, bone decancellation or talectomy. Ilizarov ring or multiaxial monolateral external fixation with or without osteotomies are used in late correction of residual deformities.

Children with significant deformities are often in ankle foot orthoses through much of their lives to avoid deformity recurrence and to augment the standing base due to weak leg muscles. A plantigrade, pain free, stable foot is the goal of foot management. Foot stiffness is anticipated and unavoidable in arthrogryposis involving the foot.

KNEE PROBLEMS

Knee issues, including knee extension or flexion, subluxation, and stiffness, respond well to therapy and splinting. Knee flexion is more common in arthrogryposis. Infrequently it can structurally be complex and associated with skin webbing known as pterygiums. Pterygiums are resistant to nonsurgical intervention and require plastic Z lengthenings. In the case of a flexion contracture, the quadriceps musculature is often deficient and weak. Sometimes the casting and splinting of the knee contractures is insufficient. Hamstring lengthenings with additional posterior knee capsular releases are often needed.

In the case of knee hyperextension, the quadriceps are sometimes fibrotic and weak in spite of seeming to overpower the hamstrings. Casting and splinting should begin shortly after birth, which can be done in conjunction with clubfoot casting following the principles of Ponseti. If splinting and therapy fail, lengthening of the quadriceps can be achieved through release of the lateral medial quadriceps, with proximal detachment of the rectus femoris, lengthening of the quadriceps either percutaneously or through a mini open procedure which may minimize scarring.

Long-standing stiffness may lead to joint surface flattening permanently reducing the arc of motion. Repositioning the arc of motion may improve sitting or standing, a choice to be made by the patient, family and physician. Follow up bracing can help to compensate for weak, fibrotic muscles of the legs.

HIP PROBLEMS

Teratologic hip dislocations are common within the spectrum of arthrogryposis and usually require open reduction of the hip. Hips in a child with less upper-extremity involvement and more supple hips that are not pathologically stiff *may* respond to early treatment with a Pavlik harness. Knee hyperextension can often be treated with physical therapy and serial casting. Careful observation of the hip during knee flexion as tightening of the quadriceps and hip flexors can push the hip into posterior dislocation. Once some knee flexion has been achieved, the Pavlik harness can be useful in further flexing the knee and maintaining hip stability in the infant. Most often the hips are stiff and not reducible closed. For these, open reduction with pelvic reconstruction and femoral osteotomy are commonly required, typically at 1 yr of age. There is some controversy about reducing bilateral hip dislocations as a high failure rate can result in asymmetry of the pelvis, pain, leg length inequality, and stiffness. If a child has little ambulation potential, he may do as well retaining the bilateral hip dislocations and positioning the hips for sitting. Management judgment should be made in conjunction with the family guided by a pediatric hip surgeon.

Ambulation

As would be expected walking is more difficult for children with arthrogryposis due to the muscle weakness and limited joint motion. Children with arthrogryposis who walk have lower activity levels and take fewer steps than their peers. Not surprisingly muscle fatigue and pain on exertion was noted in a study that included adults with distal arthrogryposis.

UPPER-EXTREMITY PROBLEMS

If splinting and a movement exercise program do not result in optimally functional upper extremities, surgical management may improve use of the arms of the child with arthrogryposis. A typical child with arthrogrypotic involvement of the upper extremities has internally rotated arms, extended elbows, flexed wrists, and thumb in palm or clasp thumb deformities (see Figs. 682-2 and 682-3).

Treatment is geared toward optimizing use of the arms and hands particularly for critical activities of daily living, such as feeding and toileting. Therapy to improve motion of the joints is started immediately after birth. Pediatric hand therapists are the optimal leaders of the mobility treatment program. Therapy is augmented by use of splints so that less-extensive surgery will be required. The elbow is the critical length adjuster of the arm, allowing the arm to reach out as is necessary for toileting or to approach the mouth for feeding. If necessary, lack of these motions can be compensated by modified silverware and other adaptive equipment, including arm extenders for grabbing.

Surgery of the Upper Extremity

Surgical correction of arthrogrypotic upper extremity contractures should be started after 1-3 mo and completed by age 12 mo so that the child can optimize his or her motor development. This allows for improved results optimizing the joint growth remodeling plasticity. One-stage procedures yield the best results. Delays in surgery result in more problems of intraarticular adhesions as well as fixed joint incongruity.

Shoulder

Because of the rotational capacity of the shoulder derotation osteotomy of the humerus is only occasionally needed. This is usually done in later childhood.

Elbow

A stiff elbow that does not respond to therapy requires surgical intervention starting with soft tissue and capsular release. Capsulotomy of the posterior elbow combined with a V-Y or Z reconstructive lengthening of the triceps allows improved elbow flexion. The triceps may need to be lengthened. Muscle transfer to the forearm can permit active elbow flexion. Each child needs individual assessment as to available flexor source. Most commonly available is the triceps. An elbow with some flexion is extremely important for arm function. Use of the triceps can create elbow flexion overpowering and contracture.

Wrist

Wrist flexion deformity is improved with soft-tissue balancing as well as partial carpectomies. The carpectomies need to be trapezoidal with more removed from the dorsum and the radial side to balance the wrist flexion contracture as well as the tendency for ulnar deviation. Thumb adduction may require an adductor release with an opponensplasty. Tendon transfers such as transfer of the extensor indicis pollicis to the extensor pollicis longus is helpful for improved function of the thumb in clasp thumb deformity.

Finger stiffness and wrist contractures often respond to therapy and bracing without need for surgery.

Scoliosis

Scoliosis is frequent in arthrogrypotic children, although the reported incidence of between 28% and 66% is probably skewed upward in reports as they reflect the experience of scoliosis surgeons. Scoliosis can be congenital or paralytic. The scoliosis is often accompanied by hip contractures associated with hip dislocation and compensatory lumbar lordosis. Curves <30 degrees can be treated initially with bracing in a thoracolumbar spinal orthosis (TLSO brace). After 40 degrees, spinal fusion is warranted.

Surgical Staging

At Children's Hospital of Philadelphia, surgical treatment of the lower limbs usually begins distally and works proximally. The feet are corrected around 6 mo of age, the knees around 8 mo of age, and the hips around 12 mo of age as pelvic osteotomy is often needed to stabilize the hips properly.

The upper extremities are corrected during infancy when the child is seen early. Hand, physical, and occupational therapy are a critical part of the team to optimize function and function prior to and after surgery. Further surgery as a child may be needed to tweak and optimize functional use of the upper and lower extremities.

Chapter 683
Common Fractures

Keith D. Baldwin, Lawrence Wells, and John P. Dormans

Trauma is a leading cause of death and disability in children older than 1 yr of age (see Chapter 5.1). Several factors make fractures of the immature skeleton different from those involving the mature skeleton. The anatomy, biomechanics, and physiology of the pediatric skeletal system are different from those of adults. This results in different fracture patterns (Fig. 683-1), diagnostic challenges, and management techniques specific to children to preserve growth and function.

Epiphyseal lines, rarefaction, dense growth lines, congenital fractures, and pseudofractures appear on radiographs, which could confuse the interpretation of a fracture. Although most fractures in children heal well with indifferent treatment, some fractures terminate disastrously if handled with inexpertise. The differences in the pediatric skeletal system predispose children to injuries different from those of adults. The important differences are the presence of periosseous cartilage, physes, and a thicker, stronger, more osteogenic periosteum that produces new bone, called *callus*, more rapidly and in greater amounts. The pediatric bone has low density and more porosity. The low density is from lower mineral content and the increased porosity is the result of an increased number of haversian canals and vascular channels. These differences result in a comparatively lower modulus of elasticity and lower bending strength. The bone in children can fail either in tension or in compression; because the fracture lines do not propagate as in adults, there is less chance of comminuted fractures. Hence, pediatric bone can crush, splinter, and break incompletely, as opposed to adult bone which generally breaks like glass and may comminute.

A common teaching is that joint injuries, dislocation, and ligament disruptions are infrequent in children. Although this is generally true, MRI studies show that ligament damage in ankle injuries may not be as unusual as once thought. Damage to a contiguous physis is more likely. Interdigitating mammillary bodies and the perichondrial ring enhance the strength of the physes. Biomechanically, the physes are not as strong as the ligaments or metaphyseal bone. The physis is most resistant to traction and least resistant to torsional forces. The periosteum is loosely attached to the shaft of bone and adheres densely to the physeal periphery. The periosteum is usually injured in all fractures, but it is less likely to have complete circumferential rupture, because of its loose attachment to the shaft. This intact hinge or sleeve of periosteum lessens the extent of fracture displacement and assists in reduction and maintenance of reduction. The thick periosteum can also act as an impediment to closed reduction, particularly if the fracture has penetrated the periosteum, or in reduction of displaced growth plate.

683.1 Unique Characteristics of Pediatric Fractures

Keith D. Baldwin, Lawrence Wells, and John P. Dormans

FRACTURE REMODELING

Remodeling is the third and final phase in biology of fracture healing, preceded by the inflammatory and reparative phases. This occurs from a combination of appositional bone deposition on the concavity of deformity, resorption on the convexity, and asymmetric physeal growth. Thus, reduction accuracy is somewhat less important than it is in adults (Fig. 683-2). The 3 major factors that have a bearing on the potential for angular correction are skeletal age, distance to the joint, and orientation to the joint axis. The rotational deformity and angular deformity not in the axis of the joint motion are less likely to remodel. Remodeling is best when the fracture occurs close to the physis, the child has more growth remaining, has less deformity to remodel, and is adjacent to a rapidly growing physis (i.e., the proximal humerus). Remodeling typically occurs over the next several months following injury throughout skeletal maturity. Skeletal maturity is reached in girls between 13 and 15 yr of age, and in boys between 14 and 17 yr of age.

OVERGROWTH

Physeal stimulation from the hyperemia associated with fracture healing causes overgrowth. It is usually prominent in long bones such as the femur. The growth acceleration is usually present for 6 mo to 1 yr following the injury. Femoral fractures in children younger than 10 yr of age often overgrow by 1-3 cm. If external fixation or casting is employed, bayonet apposition of bone may be preferred to

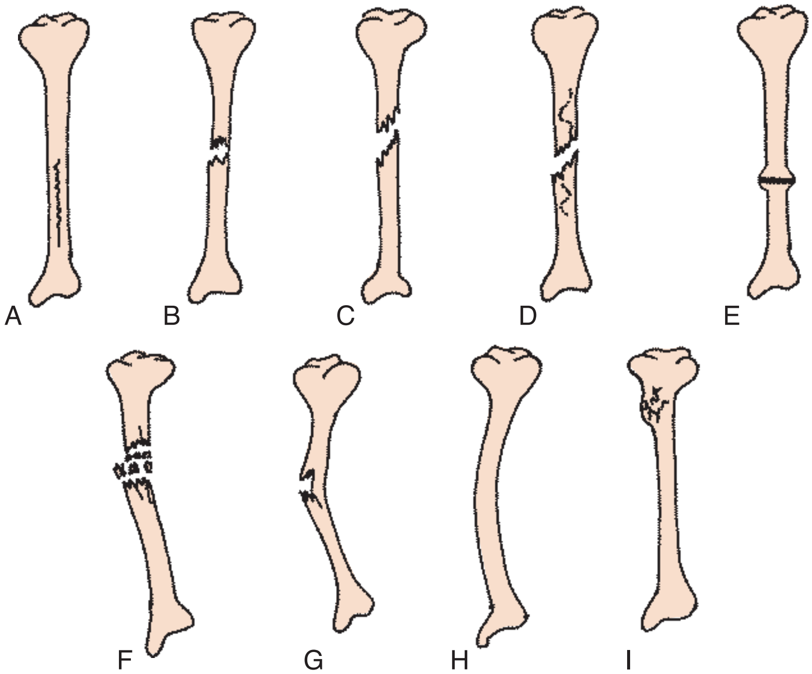

Figure 683-1 Illustration of fracture patterns. **A,** Longitudinal fracture line parallel to bony axis. **B,** Transverse fracture line perpendicular to bony axis. **C,** Oblique fracture line at angle to bony axis. **D,** Spiral fracture line runs a curvilinear course to the bony axis. **E,** Impacted fractured bone ends compressed together. **F,** Comminuted fragmentation of bone into 3 or more parts. **G,** Greenstick bending of bone with incomplete fracture of convex side. **H,** Bowing bone plastic deformation. **I,** Torus buckling fracture. *(From White N, Sty R: Radiological evaluation and classification of pediatric fractures,* Clin Pediatr Emerg Med *3:94–105, 2002.)*

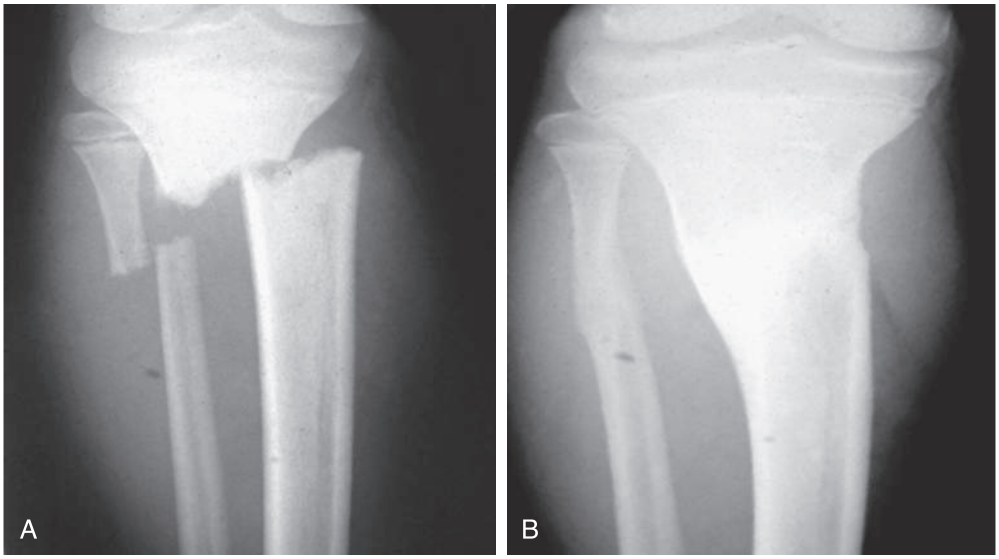

Figure 683-2 Remodeling in children is often extensive, as in this proximal tibial fracture **(A)** and as seen 1 yr later **(B).** *(From Dormans JP:* Pediatric orthopedics: introduction to trauma, *Philadelphia, 2005, Mosby, p. 38.)*

compensate for the expected overgrowth. This overgrowth phenomenon will result in equal or near equal limb lengths at the conclusion of fracture remodeling if the fracture shortens less than 2 cm. After 10 yr of age, overgrowth is less of a problem and anatomic alignment is recommended. In physeal injuries, growth stimulation is associated with use of implants or fixation hardware that can cause chronic stimulus for longitudinal growth.

PROGRESSIVE DEFORMITY

Injuries to the physes can be complicated by progressive deformities with growth. The most common cause is complete or partial closure of the growth plate. This can be common in fractures of the distal ulna, distal femur, and proximal tibia. An MRI can be helpful to diagnose percent of physeal closure after such an injury. Harris growth arrest lines may be observed in the setting of asymmetric growth and will point toward the area of growth arrest (Fig. 683-3). As a consequence, angular deformity, shortening, or both, can occur. The partial arrest may be peripheral, central, or combined. The magnitude of deformity depends on the physis involved and the amount of growth remaining.

RAPID HEALING

Children's fractures heal more quickly than adults as a result of children's growth potential and thicker, more active periosteum. As

Figure 683-3 **A,** Harris growth arrest lines on either side of the femur pointing centrally in the femur indicating a central growth arrest. **B,** Corresponding MRI image showing central growth arrest. *(**A** courtesy of Keith D. Baldwin, MD, MPH, Children's Hospital of Philadelphia.)*

children approach adolescence and maturity, the rate of healing slows and becomes similar to that of an adult.

Bibliography is available at Expert Consult.

683.2 Pediatric Fracture Patterns

Keith D. Baldwin, Lawrence Wells, and John P. Dormans

The different pediatric fracture patterns are the reflection of a child's characteristic skeletal system. The majority of pediatric fractures can be managed by closed methods and heal well.

PLASTIC DEFORMATION

Plastic deformation is unique to children. It is most commonly seen in the ulna and occasionally the fibula. The fracture results from a force that produces microscopic failure on the tensile side of bone and does not propagate to the concave side (Fig. 683-4). The concave side of bone also shows evidence of microscopic failure in compression. The bone is angulated beyond its elastic limit, but the energy is insufficient to produce a fracture. Thus, no fracture line is visible radiographically (Fig. 683-5). The plastic deformation is permanent, and a bend in the ulna of <20 degrees in a 4 yr old child is expected to correct with growth.

BUCKLE OR TORUS FRACTURE

A compression failure of bone usually occurs at the junction of the metaphysis and diaphysis, especially in the distal radius (Fig. 683-6). This injury is referred to as a *torus fracture* because of its similarity to the raised band around the base of a classic Greek column. They are inherently stable and heal in 3-4 wk with simple immobilization.

GREENSTICK FRACTURE

These fractures occur when the bone is bent, and there is failure on the tensile (convex) side of the bone. The fracture line does not propagate to the concave side of the bone (Fig. 683-7). The concave side shows evidence of microscopic failure with plastic deformation. It is necessary to break the bone on the concave side because the plastic deformation recoils it back to the deformed position.

COMPLETE FRACTURES

Fractures that propagate completely through the bone are called *complete fractures*. These fractures may be classified as spiral, transverse, or oblique, depending on the direction of the fracture lines. A rotational force usually creates the spiral fractures, and reduction is easy because of the presence of an intact periosteal hinge. Oblique fractures are in the diaphysis at 30 degrees to the axis of the bone and are inherently unstable. The transverse fractures occur following a 3-point

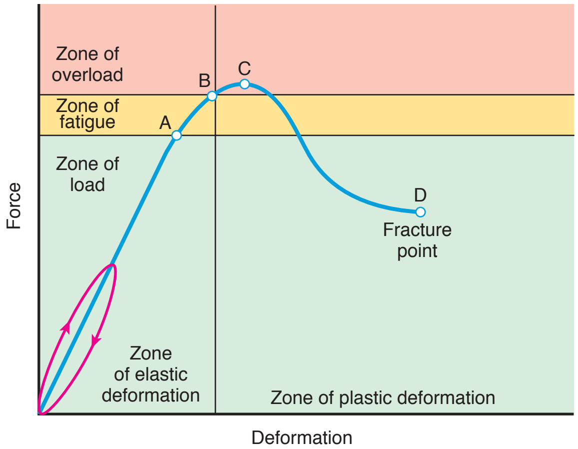

Figure 683-4 Graphic relation of bony deformation (bowing) and force (longitudinal compression) showing that the limit of an elastic response is not a fracture but plastic deformation. If the force continues, a fracture results. **A,** Reversible bowing with stress; **B,** microfractures occur; **C,** point of maximal strength; between **C** and **D,** bowing fractures; **D,** linear fracture occurs. *(Modified from Borden S IV: Roentgen recognition of acute plastic bowing of the forearm in children,* Am J Roentgenol Radium Ther Nucl Med *125:524–530, 1975.)*

Figure 683-5 Plastic deformation is a microfailure in tension without a visible fracture line. *(Courtesy of Dr. John Flynn, Children's Hospital, Philadelphia.)*

bending force and are easily reduced by using the intact periosteum from the concave side.

EPIPHYSEAL FRACTURES

The injuries to the epiphysis involve the growth plate. There is always a potential for deformity to occur, and hence long-term observation is

necessary. The distal radial physis is the most commonly injured physis. Salter and Harris (SH) classified epiphyseal injuries into 5 groups (Table 683-1 and Fig. 683-8). This classification helps to predict the outcome of the injury and offers guidelines in formulating treatment. SH types I and II fractures usually can be managed by closed reduction techniques and do not require perfect alignment, because they tend to remodel with growth. SH type II fractures of the distal femoral epiphysis need anatomic reduction. The SH type III and IV epiphyseal fractures involve the articular surface and require anatomic alignment (<2 mm displacement) to prevent any step off and realign the growth cells of the physis. SH type V fractures are usually not diagnosed initially. They manifest in the future with growth disturbance. Other injuries to the epiphysis are avulsion injuries of the tibial spine and muscle attachments to the pelvis. Osteochondral fractures are also defined as physeal injuries that do not involve the growth plate.

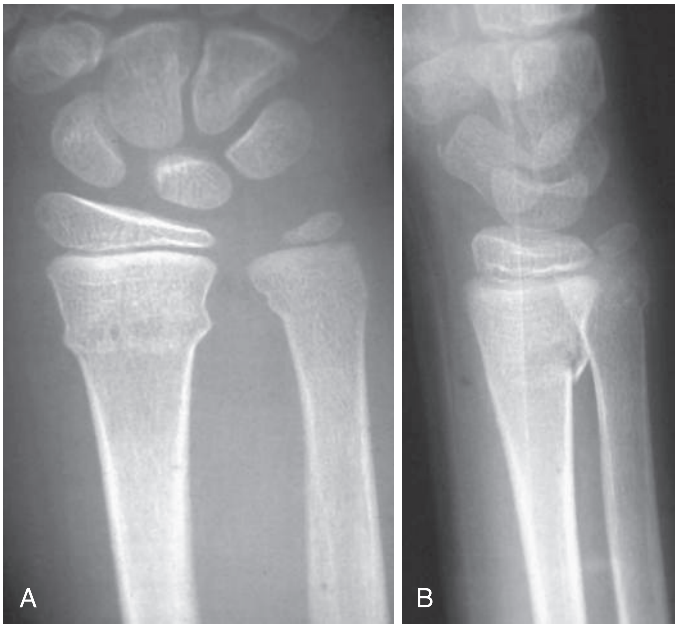

Figure 683-6 Buckle fracture is a partial failure in compression: anteroposterior **(A)** and lateral **(B)** radiographs of the distal radius. *(From Dormans JP: Pediatric orthopedics: introduction to trauma, Philadelphia, 2005, Mosby, p. 37.)*

Figure 683-7 This displaced distal radius fracture has an ulna fracture that is a greenstick (complete failure on the tensile side with microscopic failure on the compression side).

CHILD ABUSE

(See also Chapter 40.)

Fractures are the second most common manifestation of child abuse after skin injury (bruises, burns/abrasions). The orthopedic surgeon sees 30-50% of physically abused children. Child abuse should be expected in nonambulatory children with lower-extremity long-bone fractures. No fracture pattern or types are pathognomonic for child abuse; any type of fracture can result from nonaccidental trauma. The fractures that suggest nonaccidental injury include femur fractures in nonambulatory children (younger than age18 months), distal femoral metaphyseal corner fractures, posterior rib fractures, scapular spinous process fractures, and proximal humeral fractures. Fractures that were unwitnessed or carry a suspicious or changing story also warrant investigation. A full skeletal survey (as opposed to a "babygram") is essential in every suspected case of child abuse, because it can demonstrate other fractures in different stages of healing. Radiographically, some systemic diseases mimic signs of child abuse, such as osteogenesis imperfecta, osteomyelitis, Caffey disease, and fatigue fractures. Many hospitals have a multidisciplinary team to evaluate and treat patients who are victims of child abuse, these teams are critical to engage early and preferably in the emergency room setting, as difficulty arises managing these emotionally charged issues in a clinic setting. Dedicated teams are most well equipped to identify and manage these issues. It is mandatory to report these cases to social welfare agencies.

683.3 Upper Extremity Fractures

Keith D. Baldwin, Lawrence Wells, and John P. Dormans

PHALANGEAL FRACTURES

The different phalangeal fracture patterns in children include physeal, diaphyseal, and tuft fractures. The mechanism of injury is a direct blow to the finger or a finger trapped in a door (see Chapter 681). Crush injuries of the distal phalanx manifest with severe comminution of the underlying bone (tuft fracture), disruption of the nail bed, and significant soft-tissue injury. These injuries are best managed with antibiotics, tetanus prophylaxis, and irrigation. A mallet finger deformity is the inability to extend the distal portion of the digit and is caused by a hyperextension injury. It represents an avulsion fracture of the physis of the distal phalanx. The treatment is splinting the digit in extension for 3-4 wk. The physeal injuries of the proximal and middle phalanx are similarly treated with splint immobilization. Diaphyseal fractures may be oblique, spiral, or transverse in fracture geometry. They are assessed for angular and rotational deformity with the finger in flexion. The patient should be asked to make a fist. All fingers should point toward the scaphoid. If they do not, a malrotation is suspected, even in the presence of x-rays which appear minimally displaced. Any malrotation or angular deformity requires correction for optimal functioning of the hand. These deformities are corrected with closed reduction, and if unstable, they need stabilization.

FOREARM FRACTURES

Fractures of the wrist and forearm are very common fractures in children, accounting for nearly half of all fractures seen in the skeletally immature. The most common mechanism of injury is a fall on the outstretched hand. Eighty percent of forearm fractures involve the distal radius and ulna, 15% involve the middle third, and the rest are rare fractures of the proximal third of the radius or ulnar shaft. The majority of forearm fractures are torus or greenstick fractures. The torus fracture is an impacted fracture, and there is minimal soft-tissue swelling or hemorrhage. They are best treated in a short arm (below the elbow) cast and usually heal within 3-4 wk. Wrist buckle fractures have also been successfully treated with a removable splint. Impacted greenstick fractures of the forearm tend to be intrinsically stable (no cortical disruption) and may be managed with a soft bandage rather than casting.

Diaphyseal fractures can be more difficult to treat because the limits of acceptable reduction are much more stringent than for distal radial fractures. A significant malunion of a forearm diaphyseal fracture can lead to a permanent loss of pronation and supination, leading to functional difficulties. This is particularly true with malrotation of the fragments. Diaphyseal fractures are vulnerable to rotational malalignment due to insertion of the pronator muscle groups and the supinator groups. This malalignment is particularly hard to assess because the deformity is in the axial plane and is evaluated with anteroposterior (AP) and lateral radiographs (Fig. 683-9). The physical examination focuses on soft-tissue injuries and ruling out any neurovascular involvement. The AP and lateral radiographs of the forearm and wrist confirm the diagnosis. Displaced and angulated fractures require manipulative closed reduction under general anesthesia or conscious sedation. They are immobilized in an above-elbow cast for at least 6 wk. Both bone fractures in older children and adolescents (<10 yr of age) must be followed carefully as they are vulnerable to loss of reduction. Loss of reduction and unstable fractures require open reduction and internal fixation. Fixation may be with intramedullary nails or plate fixation, which yield equivalent results.

Figure 683-9 **A rotationally malaligned forearm fracture that initially had good alignment but lost reduction in the cast.** Note that the radial styloid is visible, but the biceps tuberosity is not. The 2 should normally be 180 degrees from one another. These landmarks are sometimes hard to appreciate in children but were visible on other views in this child.

DISTAL HUMERAL FRACTURES

Fractures around the elbow receive more attention because more aggressive management is needed to achieve a good result. Many injuries are intraarticular, involve the physeal cartilage, and can result in rare malunion or nonunion. As the distal humerus develops from a series of ossification centers, these ossification centers can be mistaken for fractures by inexperienced eyes. Careful radiographic evaluation is an essential part of diagnosing and managing distal humeral injuries. Observation of soft-tissue swelling and tenderness is critical to pick up subtle injuries. Common fractures include separation of the distal humeral epiphysis (transcondylar fracture), supracondylar fractures of the distal humerus, and epiphyseal fractures of the lateral condyle or medial epicondyle. The mechanism of injury is a fall on an outstretched arm. The physical examination includes noting the location and extent of soft-tissue swelling, ruling out any neurovascular injury, specifically anterior interosseous nerve involvement or evidence of compartment syndrome. A transcondylar fracture in neonates should raise suspicion of child abuse. AP and lateral radiographs of the involved extremity are necessary for the diagnosis. If the fracture is not visible, but there is an altered relationship between the humerus and the radius and ulna or the presence of a posterior fat pad sign, a transcondylar fracture or an occult fracture should be suspected. Imaging studies such as oblique radiographs, CT, MRI, and ultrasonography may be required for further confirmation. Displaced supracondylar fractures may be associated with concomitant neurovascular injury (Fig. 683-10) or, rarely, a compartment syndrome. Neurologic injury may also appear in the postoperative period. Careful neurologic examination of the hand before and after are needed to document and treat nerve injury. Preoperative nerve injury requires immediate attention and treatment of the fracture.

In general, distal humeral fractures need good restoration of anatomic alignment. This is necessary to prevent deformity and to allow for normal growth and development. Closed reduction alone, or in

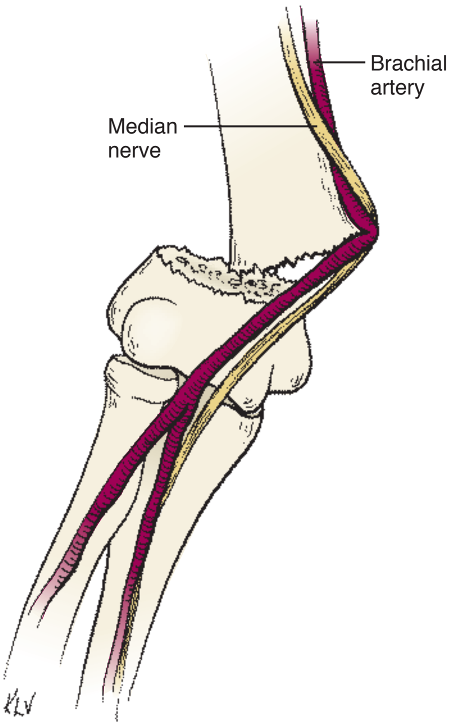

Figure 683-10 **Posterolaterally displaced type III (extension-type) supracondylar humeral fracture.** The proximal fragment displaces anteromedially. Thus placing the brachial artery and median nerve at risk. *(From Herring JA, Ho C: Upper extremity injuries. In Herring JA, editor:* Tachdjian's pediatric orthopaedics, *ed 5, Philadelphia, 2014, WB Saunders, Fig. 33-36, p. 1268.)*

association with percutaneous fixation, is the preferred method. Open reduction is indicated for fractures that cannot be reduced by closed methods, fractures with vascular compromise following closed reduction, open fractures, or interarticular fractures, particularly in older children. Inadequate reductions can lead to loss of motion, cubitus varus, cubitus valgus, and rare nonunion or elbow instability. Elbow stiffness is not as common as in adult fractures, but may occur with fractures which are severe or intra-articular.

PROXIMAL HUMERUS FRACTURES

Fractures of the proximal humerus account for <5% of fractures in children. They usually result from a fall onto an outstretched arm. The fracture pattern tends to vary with the age group. Children younger than 5 yr of age have an SH I injury, those 5-10 yr of age have metaphyseal fractures, and children older than 11 yr of age have SH II injury. Examination includes a thorough neurologic evaluation, especially of the axillary nerve. The diagnosis is made on AP radiographs of the shoulder. An axillary view is obtained to rule out any dislocation. Many children are too uncomfortable to tolerate this view. In this case, a Velpeau axillary can be obtained while the arm remains in a sling. SH I injuries do not require reduction because they have excellent remodeling capacity, and simple immobilization in a sling for 2-3 wk is sufficient. The proximal humerus contributes 80% of the growth to the humerus. The metaphyseal fractures usually do not need reduction unless the angulation is >50 degrees. A closed reduction with sling immobilization adequately treats this fracture. SH II fractures with <30 degrees of angulation and <50% displacement are managed in a sling. Displaced fractures are treated with closed reduction and further stabilization if unstable. Occasionally, open reduction is required because of button-holing of the fracture spike through the deltoid or interposition of the tendon of biceps. The majority of longitudinal growth of the limb comes from the proximal humeral physis. Additionally, the glenohumeral joint is capable of a large amount of motion. As such this area is extremely tolerant to deformity. Indications for open reduction are rare. However, as adolescents approach adulthood, these fractures will remodel less.

CLAVICULAR FRACTURES

Neonatal fractures occur as a result of direct trauma during birth, most often through a narrow pelvis or following shoulder dystocia. They can be missed initially and can appear with pseudoparalysis. Childhood fractures are usually the result of a fall on the affected shoulder or direct trauma to the clavicle. The most common site for fracture is the junction of the middle and lateral 3rd clavicle. Tenderness over the clavicle will make the diagnosis. A thorough neurovascular examination is important to diagnose any associated **brachial plexus injury.** Biceps function is important to assess as it is a prognostic indicator for future function.

An AP radiograph of the clavicle demonstrates the fracture and can show overlap of the fragments. Physeal injuries occur through the medial or lateral growth plate and are sometimes difficult to differentiate from dislocations of the acromioclavicular or sternoclavicular joint. Further imaging such as a CT scan may be necessary to further define the injury. Posterior medial clavicular physeal injuries are particularly problematic due to their proximity to the great vessels and the trachea. Closed vs open reduction with a cardiac/thoracic team on standby is necessary. This can be delayed if there is no sign of vascular or respiratory compromise.

The treatment of most clavicle fractures consists of an application of a figure-of-eight clavicle strap or a simple sling. A figure-of-eight strap will extend the shoulders and minimize the amount of overlap of the fracture fragments. Evidence exists for adults — that fractures that are shortened or displaced result in strength loss of the shoulder without anatomic reduction and fixation. Many centers are extending that indication to older adolescents, though the data are currently not as strong as for adults. If a fracture is tenting the skin, or open or resulting in neurovascular compromise, surgery is indicated. The physeal fractures are treated with simple sling immobilization without any reduction attempt. Often, anatomic alignment is not achieved, nor is it necessary. The fractures heal rapidly usually in 3-6 wk. A palpable mass of callus is usually visible in thin children. This remodels satisfactorily in 6-12 mo. Complete restoration of shoulder motion and function is uniformly achieved.

Bibliography is available at Expert Consult.

683.4 Fractures of Lower Extremity

Keith D. Baldwin, Lawrence Wells, and John P. Dormans

HIP FRACTURE

Hip fractures in children account for <1% of all children's fractures. These injuries result from high-energy trauma and are often associated with injury to the chest, head, or abdomen. Treatment of hip fractures in children entails a complication rate of up to 60%, an overall avascular necrosis rate of 50%, and a malunion rate of up to 30%. The unique blood supply to the femoral head accounts for the high rate of avascular necrosis. Fractures are classified by the Delbet classification as transphyseal separations, transcervical fractures, cervicotrochanteric fractures, and intertrochanteric fractures. The management principle includes urgent anatomic reduction (either open or closed), stable internal fixation (avoiding the physis if possible), and spica casting. Urgent management has been associated with a lower rate of avascular necrosis and superior overall outcomes. Capsular decompression also has been advocated as decreasing overall pressure on the epiphyseal vessels, and has been demonstrated experimentally. The clinical results have been mixed.

Figure 683-11 A spiral fracture of the tibia in a 3 yr old (toddler fracture). The mechanism was a twisting fall.

TODDLER FRACTURE

Toddler fractures occur in young ambulatory children. The age range for this fracture is typically from around 1-4 yr (Fig. 683-11). The injury often occurs after a seemingly harmless twist or fall and is often unwitnessed. The children in this age group are usually unable to articulate the mechanism of injury clearly or to describe the area of injury well. The radiographs may show no fracture; the diagnosis is made by physical examination. The classic symptom is refusal to bear weight, which can manifest as pulling up the affected extremity or florid display of protest. The AP and lateral views of the tibia–fibula might show a nondisplaced spiral fracture of the distal tibial metaphysis. An oblique view is often helpful because the fracture line may be visible in only 1 of the 3 views. Inflammatory markers may be ordered to rule out infectious processes if the diagnosis is in doubt. Bone scans were employed in the past but impart a large amount of radiation to the child. The fracture is treated with an above-knee cast for approximately 3 wk.

PROXIMAL TIBIA FRACTURES

Proximal tibia fractures can be physeal injuries, metaphyseal injuries, or avulsion injuries of the tibial spine or tubercle. Physeal injuries can be either isolated or as part of tibial tubercle fracture. If the distal segment is displaced posteriorly the trifurcation of the popliteal vessels may be involved. Careful neurovascular examination is warranted both pre- and postreduction. Anatomic reduction and pin fixation is preferred with unstable fractures or displaced Salter-Harris III or IV fractures.

Proximal tibial metaphyseal fractures, or the so-called cozen fracture, are most common in the 3-6 yr old age group. They result in a late valgus deformity even if anatomically reduced. This deformity remodels within 1-2 yr but can cause great distress to parents and treating clinicians.

Tibial eminence fractures are fractures of the bony prominence that is the attachment of the anterior cruciate ligament. The mechanism of injury is similar to that of an anterior cruciate ligament tear in an adult. Displaced fractures require surgical reduction and fixation. This may be done either open or arthroscopically.

Tibial tubercle fractures are common in patients with Osgood-Schlatter syndrome. Care must be taken to observe for compartment syndrome as the injury is associated with injury of the recurrent anterior tibial artery. The injury may be treated non operatively if the fracture is displaced <2 mm and the patient has no extensor lag (rare). Open reduction and internal fixation is preferred otherwise.

TIBIA AND FIBULA SHAFT FRACTURES

The tibia is the most commonly fractured bone of the lower limb in children. This fracture generally results from a direct injury. Most tibial fractures are associated with a fibular fracture, and the mean age of presentation is 8 yr. The child has pain, swelling, and deformity of the affected leg and is unable to bear weight. Distal neurovascular examination is important in assessment. The AP and lateral radiographs should include the knee and ankle. Closed reduction and immobilization are the standard method of treatment. Most fractures heal well, and children usually have excellent results. Open fractures need to undergo irrigation and debridement, and antibiotic treatment. The tibia is a subcutaneous bone. Severe soft-tissue loss may necessitate plastic surgery consultation. Definitive external fixation vs internal fixation and simultaneous soft-tissue coverage are alternate treatment strategies to minimize infection. Tibia fractures are associated with compartment syndrome. Vigilance is necessary to avoid disastrous outcomes in the setting of missed compartment syndrome. Emergent fasciotomy is indicated as soon as compartment syndrome is diagnosed. Several return trips to the operating room are often necessary to close, vs cover, the fasciotomy wounds.

FEMORAL SHAFT FRACTURES

Fractures of the femur in children are common. All age groups, from early childhood to adolescence, can be affected. The mechanism of injury varies from low-energy twisting type injuries to high-velocity injuries in vehicular accidents. Femur fractures in children younger than age 2 yr should raise the concern for child abuse. A thorough physical examination is necessary to rule out other injuries and assess the neurovascular status. In the case of high-energy trauma, any signs of hemodynamic instability should prompt the examiner to look for other sources of bleeding. AP and lateral radiographs of the femur demonstrate the fracture. An AP radiograph of the pelvis is obtained to rule out any associated pelvic fracture. Treatment of shaft fractures varies with the age group, as described in Table 683-2.

TRIPLANE AND TILLAUX FRACTURES

Triplane and Tillaux fracture patterns occur at the end of the growth period and are based on relative strength of the bone–physis junction and asymmetric closure of the tibial physis. The triplane fractures are so named because the injury has coronal, sagittal, and transverse components (Fig. 683-12). The Tillaux fracture is an avulsion fracture of the anterolateral aspect of the distal tibial epiphysis. Radiographs and further imaging with CT and 3-dimensional reconstructions are necessary to analyze the fracture geometry. The triplane fracture involves the articular surface and hence anatomic reduction is necessary. The reduction is further stabilized with internal fixation. The Tillaux fracture is treated by closed reduction. Open reduction is recommended if a residual intraarticular step-off persists.

METATARSAL FRACTURES

Metatarsal fractures are common in children. They usually result from direct trauma to the dorsum of the foot. High-energy trauma or

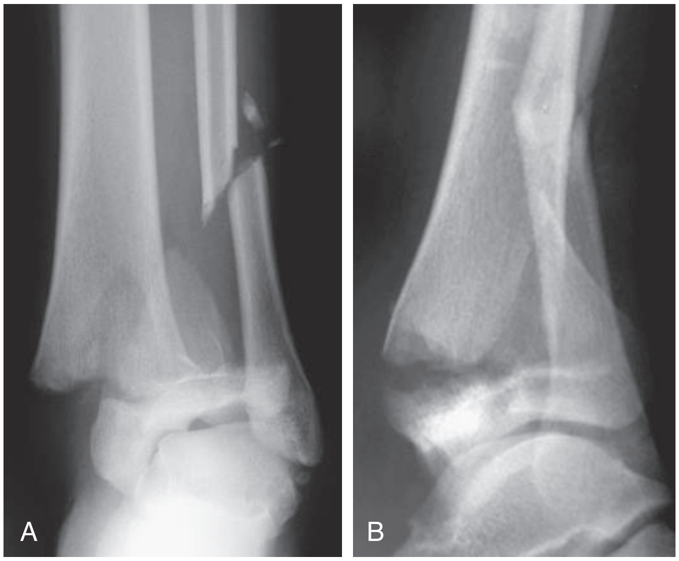

Figure 683-12 The triplane fracture is a transitional fracture: anteroposterior **(A)** and lateral **(B)** radiographs. *(From Dormans JP:* Pediatric orthopedics: introduction to trauma, *Philadelphia, 2005, Mosby, p. 38.)*

multiple fractures of the metatarsal base are associated with significant swelling. A high index for compartment syndrome of the foot must be maintained and compartment pressures must be measured if indicated. Diagnosis is obtained by AP, lateral, and oblique radiographs of the foot. Most metatarsal fractures can be treated by closed methods in a below-knee cast. Weight bearing is allowed as tolerated. Displaced fractures can require closed or open reduction with internal fixation. Percutaneous, smooth Kirschner wires generally provide sufficient internal fixation for these injuries. If the compartment pressure is increased, complete release of all compartments in the foot is necessary.

TOE PHALANGEAL FRACTURES

Fractures of the lesser toes are common and are usually secondary to direct blows. They commonly occur when the child is barefoot. The toes are swollen, ecchymotic, and tender. There may be a mild deformity. Diagnosis is made radiographically. Bleeding suggests the possibility of an open fracture. The lesser toes usually do not require closed reduction unless significantly displaced. If necessary, reduction can usually be accomplished with longitudinal traction on the toe. Casting is not usually necessary. Buddy taping of the fractured toe to an adjacent stable toe usually provides satisfactory alignment and relief of symptoms. Crutches and heel walking may be beneficial for several days until the soft-tissue swelling and the discomfort decrease.

Bibliography is available at Expert Consult.

683.5 Operative Treatment

Keith D. Baldwin, Lawrence Wells, and John P. Dormans

Surgery is required for 4-5% of pediatric fractures. The common indications for operative treatment in children and adolescents include displaced physeal fractures, displaced intraarticular fractures, unstable fractures, multiple injuries, open fractures, failure to achieve adequate reduction in older children, failure to maintain an adequate reduction, and certain pathologic fractures.

The aim of operative intervention is to obtain anatomic alignment and relative stability. Rigid fixation is not necessary as it is in adults for early mobilization. The relatively stable construct can be supplemented with external immobilization. SH types III and IV injuries require anatomic alignment, and if they are unstable, internal fixation is used (smooth Kirschner wires, preferably avoiding the course across the growth plate). Multiple closed reductions of an epiphyseal fracture are contraindicated because they can cause permanent damage to the germinal cells of the physis.

Table 683-3	Common Indications for External Fixation in Pediatric Fractures
Grades II and III open fractures Fractures associated with severe burns Fractures with soft-tissue loss requiring free flaps or skin grafts Fractures requiring distractions such as those with significant bone loss Unstable pelvic fractures Fractures in children with associated head injuries and spasticity Fractures associated with vascular or nerve repairs or reconstruction	

SURGICAL TECHNIQUES

It is important to take great care with soft tissues and skin. The other indications for open reduction and internal fixation are unstable fractures of the spine, ipsilateral fractures of the femur, neurovascular injuries requiring repair, and, occasionally, open fractures of the femur and tibia. Closed reduction and minimally invasive fixation are specifically used for supracondylar fractures of the distal humerus, phalangeal fractures. Failure to obtain anatomic alignment by closed means is an indication for an open reduction. Percutaneous techniques such as intramedullary fixation and minimally invasive plate osteosynthesis are increasingly popular as well.

As children become older and more similar to adults, techniques become more similar to adult techniques. The classic example of this is the femoral shaft fracture. Newborns may be treated with a soft dressing or Pavlik harness; young children may have a spica cast; older children will often be treated with flexible nails. Adolescents will frequently be treated with rigid intramedullary fixation similar to their adult counterparts.

Table 683-3 summarizes the main indications for external fixation. The advantages of external fixation include rigid immobilization of the fractures, access to open wounds for continued management, and easier patient mobilization for treatment of other injuries and transportation for diagnostic and therapeutic procedures. The majority of complications with external fixation are pin tract infections, chronic osteomyelitis, and refractures after pin removal.

Bibliography is available at Expert Consult.

683.6 Complications of Fractures in Children

Keith D. Baldwin, Lawrence Wells, and John P. Dormans

Complications of fractures in children can be as the result of the injury itself, of treatment, or of late effects of the injury on growth and development of the limb.

The fracture itself may cause growth arrest; this is most common in the proximal tibia, distal femur, and distal ulna. Fractures about the hip may cause avascular necrosis or premature physeal closure. Unacceptable alignment may cause loss of motion or limb malalignment. Fracture healing may cause cosmetically unappealing bumps or curves in the limb. Injuries to the limbs may cause neurovascular compromise or compartment syndrome. Nonunions are rare in children.

Treatment may complicate fractures. Cast immobilization can result in cast ulcers, either from inadequate padding of bony prominences or from patients placing objects in the cast. Casts that are too tight can cause neurovascular compromise. Patients can get cast saw burns from using cast saws that are too dull to remove the cast. Improperly placed casts can promote fracture displacement. Improper follow-up of fractures can result in malunited fractures. Surgical treatment can be complicated by blood loss, neurovascular compromise, iatrogenic physeal damage and hardware complications such as infection or hardware failure.

Late effects of trauma can be from partial or complete closure of the physis. This can lead to limb angular deformity or shortening. Angular deformities can be treated by hemiepiphysiodesis or osteotomy. Reflex sympathetic dystrophy is another poorly understood late effect of trauma but can be debilitating. Physical and occupational therapists are very helpful in managing this condition. Some evidence exists that vitamin C may be useful in the acute setting of high-risk injuries to prevent this complication.

Chapter **684**

Osteomyelitis

Sheldon L. Kaplan

Bone infections in children are relatively common. Early recognition of osteomyelitis in young patients is of critical importance; prompt institution of appropriate medical and surgical therapy before extensive infection develops will minimize permanent damage. The risk is greatest if the physis (the growth plate of bone) is damaged.

ETIOLOGY

Bacteria are the most common pathogens in acute skeletal infections. *Staphylococcus aureus* (see Chapter 181.1) is the most common infecting organism in osteomyelitis among all age groups, including newborns. Community-acquired methicillin-resistant *S. aureus* (CA-MRSA) isolates account for more than 50% of *S. aureus* isolates recovered from children with osteomyelitis in some reports. The USA300 clone of *S. aureus* is the most common among CA-MRSA isolates in the United States and is more likely to cause venous thrombosis in children with acute osteomyelitis than other *S. aureus* clones or other bacteria for reasons that are not known.

Group B streptococcus (see Chapter 184) and Gram-negative enteric bacilli (*Escherichia coli,* see Chapter 200) are also prominent pathogens in neonates; group A streptococcus (see Chapter 183) constitutes <10% of all cases. After 6 yr of age, most cases of osteomyelitis are caused by *S. aureus,* streptococcus, or *Pseudomonas aeruginosa* (see Chapter 205). Cases of *Pseudomonas* infection are related almost exclusively to puncture wounds of the foot, with direct inoculation of *P. aeruginosa* from the foam padding of the shoe into bone or cartilage, which develops as osteochondritis. *Salmonella* species (see Chapter 198) and *S. aureus* are the 2 most common causes of osteomyelitis in children with sickle cell anemia (see Chapter 462.1). *Streptococcus pneumoniae* (see Chapter 182) most commonly causes osteomyelitis in children younger than 24 mo of age and in children with sickle cell anemia, but its frequency has declined because of pneumococcal conjugate vaccines. *Bartonella henselae* (see Chapter 209.2) can cause osteomyelitis of any bone, but especially in pelvic and vertebral bones.

Kingella kingae (see Chapter 193) may be the second most common cause of osteomyelitis in children younger than 5 yr of age in some parts of the world. The organism is increasingly recognized as a cause of osteomyelitis, spondylodiskitis, and septic arthritis, especially when polymerase chain reaction testing is employed. Nearly 90% of identified *K. kingae* infections have been in young children.

Infection with atypical mycobacteria (see Chapter 217), *S. aureus,* or *Pseudomonas* can occur after penetrating injuries. These organisms as well as coagulase-negative staphylococci or Gram-negative enteric bacteria may cause bone infection related to implanted materials such as spinal instrumentation or any orthopedic hardware. Fungal infections usually occur as part of multisystem disseminated disease; *Candida* (see Chapter 234) osteomyelitis sometimes complicates fungemia in neonates with or without indwelling vascular catheters.

A microbial etiology is confirmed in approximately 60% of cases of osteomyelitis. Blood cultures are positive in approximately 50% of patients. Prior antibiotic therapy and the inhibitory effect of pus on microbial growth might explain the low bacterial yield.

EPIDEMIOLOGY

The median age of children with musculoskeletal infections is approximately 6 yr. Bone infections are more common in boys than girls; the behavior of boys might predispose them to traumatic events. Except for the increased incidence of skeletal infection in patients with sickle cell disease, there is no predilection for osteomyelitis based on race.

The majority of osteomyelitis cases in previously healthy children are hematogenous. Minor closed trauma is a common preceding event in cases of osteomyelitis, occurring in approximately 30% of patients. Infection of bones can also follow penetrating injuries or open fractures. Bone infection following orthopedic surgery is unusually associated with an implanted surgical device. Impaired host defenses also increase the risk of skeletal infection. Table 684-1 lists other risk factors.

PATHOGENESIS

The unique anatomy and circulation of the ends of long bones result in the predilection for localization of bloodborne bacteria. In the metaphysis, nutrient arteries branch into nonanastomosing capillaries

Table 684-1 Microorganisms Isolated from Patients with Osteomyelitis and Their Clinical Associations

MOST COMMON CLINICAL ASSOCIATION	MICROORGANISM
Frequent microorganism in any type of osteomyelitis	*Staphylococcus aureus* (susceptible or resistant to methicillin)
Foreign body–associated infection	Coagulase-negative staphylococci, other skin flora, atypical mycobacteria, fungi
Common in nosocomial infections	*Enterobacteriaceae, Pseudomonas aeruginosa, Candida* spp.
Decubitus ulcer	*S. aureus*, streptococci, Gram-negative enterics, and/or anaerobic bacteria; polymicrobial infections are common
Sickle cell disease	*Salmonella* spp., *S. aureus*, or *Streptococcus pneumoniae*
Exposure to kittens	*Bartonella henselae*
Human or animal bites	*Pasteurella multocida* or *Eikenella corrodens*
Immunocompromised patients	*Aspergillus* spp., *Candida albicans,* or *Mycobacteria* spp.
Populations in which tuberculosis is prevalent	*Mycobacterium tuberculosis*
Populations in which these pathogens are endemic	*Brucella* spp., *Coxiella burnetii*, fungi found in specific geographic areas (coccidioidomycosis, blastomycosis, histoplasmosis)

Modified From Lew DP, Waldvogel FA: Osteomyelitis, Lancet *364:369–379, 2004.*

under the physis, which make a sharp loop before entering venous sinusoids draining into the marrow. Blood flow in this area is thought to be "sluggish," predisposing to bacterial invasion. Once a bacterial focus is established, phagocytes migrate to the site and produce an inflammatory exudate (metaphyseal abscess). The generation of proteolytic enzymes, toxic oxygen radicals, and cytokines results in decreased oxygen tension, decreased pH, osteolysis, and tissue destruction. As the inflammatory exudate progresses, pressure increases spread through the porous metaphyseal space via the haversian system and Volkmann canals into the subperiosteal space. Purulence beneath the periosteum may lift the periosteal membrane of the bony surface, further impairing blood supply to the cortex and metaphysis.

In newborns and young infants, transphyseal blood vessels connect the metaphysis and epiphysis, so it is common for pus from the metaphysis to enter the joint space. This extension through the physis has the potential to result in abnormal growth and bone or joint deformity. During the latter part of the 1st yr of life, the physis forms, obliterating the transphyseal blood vessels. Joint involvement, once the physis forms, can occur in joints where the metaphysis is intra-articular (hip, ankle, shoulder, and elbow), and subperiosteal pus ruptures into the joint space.

In later childhood, the periosteum becomes more adherent, favoring pus to decompress through the periosteum. Once the growth plate closes in late adolescence, hematogenous osteomyelitis more often begins in the diaphysis and can spread to the entire intramedullary canal. Septic arthritis contiguous with a site of osteomyelitis is also seen in older children with *S. aureus* osteomyelitis, which may be related to simultaneous hematogenous inoculation of bone and joint space.

CLINICAL MANIFESTATIONS

The earliest signs and symptoms of osteomyelitis, often subtle and nonspecific, are generally highly dependent on the age of the patient. Neonates might exhibit **pseudoparalysis** or pain with movement of the affected extremity (e.g., diaper changes). Half of neonates do not have fever and might not appear ill. Older infants and children are more likely to have pain, fever, and localizing signs such as edema, erythema, and warmth. With involvement of the lower extremities, limp or refusal to walk is seen in approximately half of patients.

Focal tenderness over a long bone can be an important finding. Local swelling and redness with osteomyelitis can mean that the infection has spread out of the metaphysis into the subperiosteal space, representing a secondary soft-tissue inflammatory response. Pelvic osteomyelitis can manifest with subtle findings such as hip, thigh, or abdominal pain. Back pain with or without tenderness to palpation overlying the vertebral processes is noted in vertebral osteomyelitis.

Long bones are principally involved in osteomyelitis (Table 684-2); the femur and tibia are equally affected and together constitute almost half of all cases. The bones of the upper extremities account for 25% of all cases. Flat bones are less commonly affected.

Usually only a single site of bone or joint is involved, although multiple sites of osteomyelitis may be noted in up to 20% of children with *S. aureus* infections. In neonates, 2 or more bones are involved in almost half of the cases. Children with subacute symptoms and focal findings in the metaphyseal area (usually of tibia) might have a **Brodie abscess,** with radiographic lucency and surrounding reactive bone. Typically the contents of Brodie abscesses are sterile (Fig. 684-1).

Table 684-2 Sites of Osteomyelitis in Children

BONE	PERCENT (%)	BONE	PERCENT (%)
Femur	23-28	Carpal bone	<1
Tibia	20-26	Rib	<1

Skull	~1		

Modified from Gafur OA, Copley LA, Hollmig ST, et al: The impact of the current epidemiology of pediatric musculoskeletal infection on evaluation and treatment guidelines, J Pediatr Orthop *28(7):777–785, 2008.*

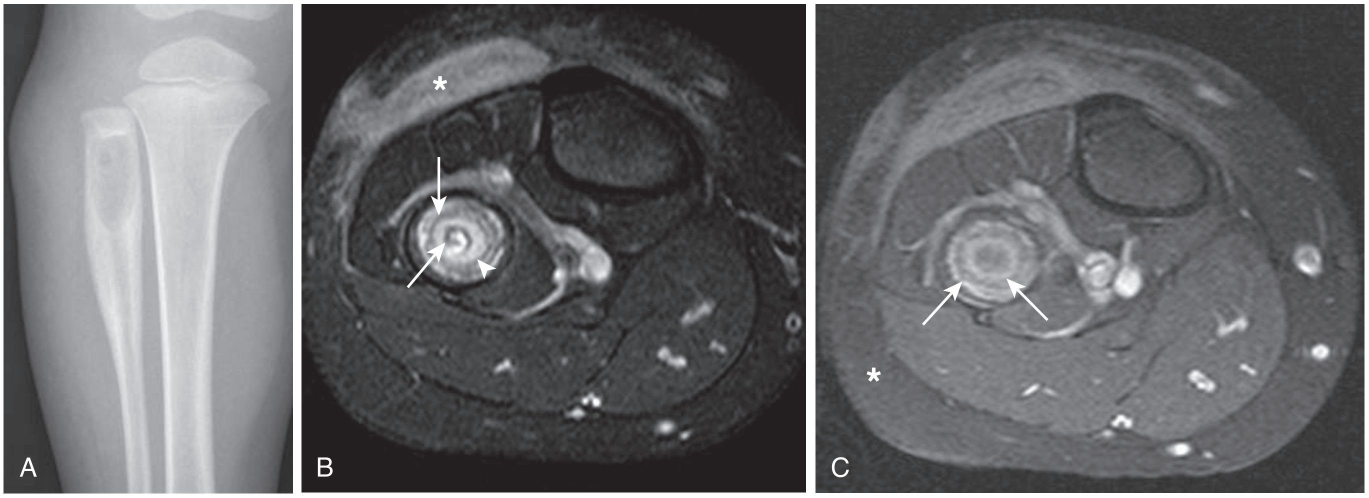

Figure 684-1 A, Radiograph demonstrates a lytic lesion in the proximal fibula with laminated thick periostitis. T2-weighted fat-saturated axial **(B)** and T1-weighted fat-saturated postgadolinium axial **(C)** magnetic resonance images demonstrate a Brodie abscess with sclerotic outer rim *(asterisk)* and inner granulation tissue with enhancement *(arrowhead).* Note the nonenhancing central abscess, which contains a small sequestrum *(arrows)* that is only seen on the T2-weighted fat-saturated sequence. *(From Kan JH, Azouz EM: Musculoskeletal infections. In Coley BD, editor:* Caffey's pediatric diagnostic imaging, *ed 12, Philadelphia, 2013, WB Saunders,* Fig. 138-15, *p. 1477.)*

Some patients with an adjacent deep venous thrombosis develop septic pulmonary emboli and are more acutely ill than those with a more insidious onset.

DIAGNOSIS

The diagnosis of osteomyelitis is clinical; **blood cultures should be performed in all suspected cases.** Depending on the results of imaging studies (see later) aspiration or biopsy of bone or subperiosteal abscess for Gram stain, culture, and possibly bone histology provides the optimal specimen for culture to confirm the diagnosis. These specimens are often obtained by the interventional radiologist or at the time of surgical drainage by the orthopedic surgeon. Direct inoculation of clinical specimens into aerobic blood culture bottles can improve the recovery of *K. kingae,* particularly if held for 1 wk. Polymerase chain reaction appears to be the most sensitive technique to detect *K. kingae*, even up to 6 days after antibiotics are initiated.

There are no specific laboratory tests for osteomyelitis. The white blood cell count and differential, erythrocyte sedimentation rate (ESR), or C-reactive protein (CRP) are generally elevated in children with bone infections but are nonspecific and not helpful in distinguishing between skeletal infection and other inflammatory processes. The leukocyte count and ESR may be normal during the 1st few days of infection, and normal test results do not preclude the diagnosis of skeletal infection. However, most children with acute hematogenous osteomyelitis have elevations in the ESR and/or CRP. Monitoring elevated ESR and CRP may be of value in assessing response to therapy or identifying complications.

RADIOGRAPHIC EVALUATION

Radiographic studies play a crucial role in the evaluation of osteomyelitis. Conventional radiographs, MRI, ultrasonography, CT, and radionuclide studies can all contribute to establishing the diagnosis. Plain radiographs are often used for initial evaluation to exclude other causes such as trauma and foreign bodies. The sequence of radionuclide studies or MRI is often determined by age, site, and clinical presentation.

Plain Radiographs

Within 72 hr of onset of symptoms of osteomyelitis, plain radiographs of the involved site using soft-tissue technique and compared to the opposite extremity, if necessary, can show displacement of the deep muscle planes from the adjacent metaphysis caused by deep-tissue edema. Lytic bone changes are not visible on radiographs until 30-50% of the bony matrix is destroyed. Tubular long bones do not show lytic changes for 7-14 days after onset of infection. Infection in flat and irregular bones can take longer to appear.

Computed Tomography and Magnetic Resonance Imaging

CT can demonstrate osseous and soft-tissue abnormalities and is ideal for detecting gas in soft tissues. In selected children who cannot remain still or tolerate sedation, CT is a valuable imaging modality. **MRI is more sensitive than CT or radionuclide imaging in acute osteomyelitis and is the best radiographic imaging technique for identifying abscesses and for differentiating between bone and soft-tissue infection.** MRI provides precise anatomic detail of subperiosteal pus and accumulation of purulent debris in the bone marrow and metaphyses for possible surgical intervention. In acute osteomyelitis, purulent debris and edema appear dark, with decreased signal intensity on T1-weighted images, with fat appearing bright (Figs. 684-2 and 684-3). The opposite is seen in T2-weighted images. The signal from fat can be diminished with fat-suppression techniques to enhance visualization. Gadolinium administration can also enhance MRI. Cellulitis and sinus tracts appear as areas of high signal intensity on T2-weighted images. Short tau inversion recovery MRI is a rapid imaging modality for osteomyelitis (Fig. 684-4). MRI can also demonstrate a contiguous or isolated septic arthritis, pyomyositis, or venous thrombosis.

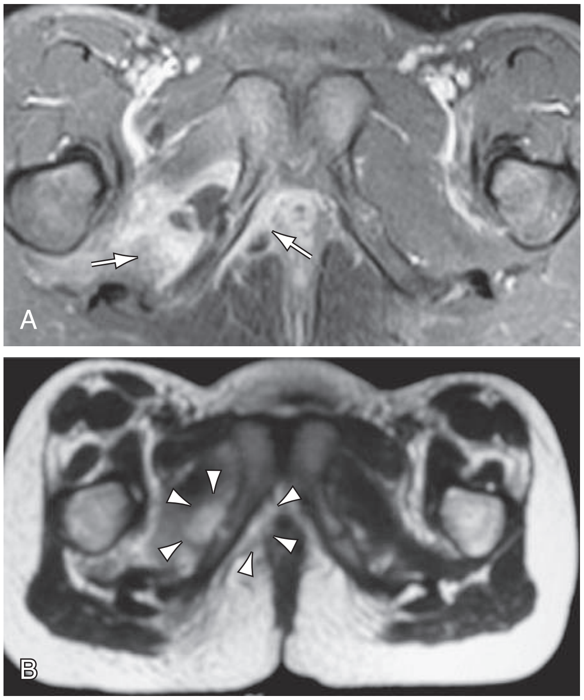

Figure 684-2 **MRI of an 8 yr old girl with acute pelvic hematogenous osteomyelitis. A,** Axial T1-weighted contrast-enhanced MRI with fat saturation reveals a nonenhancing fluid collection adjacent to the inflamed pubic synchondrosis. **B,** The fluid collection appears hyperintense on the corresponding T2-weighted image *(arrowheads).* In addition, a contrast enhancement within the adjacent internal obturator muscle is seen *(arrow),* indicating pelvic acute pelvic hematogenous osteomyelitis with complicating adjacent abscess formation and soft-tissue inflammation. *(From Weber-Chrysochoou C, Corti N, Goetschel P, et al: Pelvic osteomyelitis: a diagnostic challenge in children,* J Pediatr Surg *42:553–557, 2007.)*

Radionuclide Studies

Radionuclide imaging can be valuable in suspected bone infections, especially early in the course of infection and/or if multiple foci are suspected or an unusual site is suspected, as in the pelvis. Technetium-99 methylene diphosphonate (^{99m}Tc), which accumulates in areas of increased bone turnover, is the preferred agent for radionuclide bone imaging (3-phase bone scan). Osteomyelitis causes increased vascularity, inflammation, and increased osteoblastic activity, resulting in an increased concentration of ^{99m}Tc. Any areas of increased blood flow or inflammation can cause increased uptake of ^{99m}Tc in the 1st and 2nd phases, but osteomyelitis causes increased uptake of ^{99m}Tc in the 3rd phase (4-6 hr). Three-phase imaging with ^{99m}Tc has excellent sensitivity (84-100%) and specificity (70-96%) in hematogenous osteomyelitis and can detect osteomyelitis within 24-48 hr after onset of symptoms. The sensitivity in neonates is much lower, because of poor bone mineralization. Advantages include infrequent need for sedation, lower cost, and the ability to image the entire skeleton for detection of multiple foci.

DIFFERENTIAL DIAGNOSIS

Distinguishing osteomyelitis from cellulitis or trauma (accidental or abuse) is the most common clinical circumstance. Myositis or pyomyositis can also appear similar to osteomyelitis with fever, warm and swollen extremities, and limping; tenderness to palpation of the affected soft-tissue area is generally more diffuse than noted in acute osteomyelitis. Nevertheless, distinguishing myositis and pyomyositis from osteomyelitis clinically may be difficult. Myositis and pyomyositis may be isolated but are often found adjacent to an osteomyelitis on MRI. Pyomyositis is most often caused by *S. aureus* followed by group A streptococcus. The pelvic muscles are a common site of pyomyositis

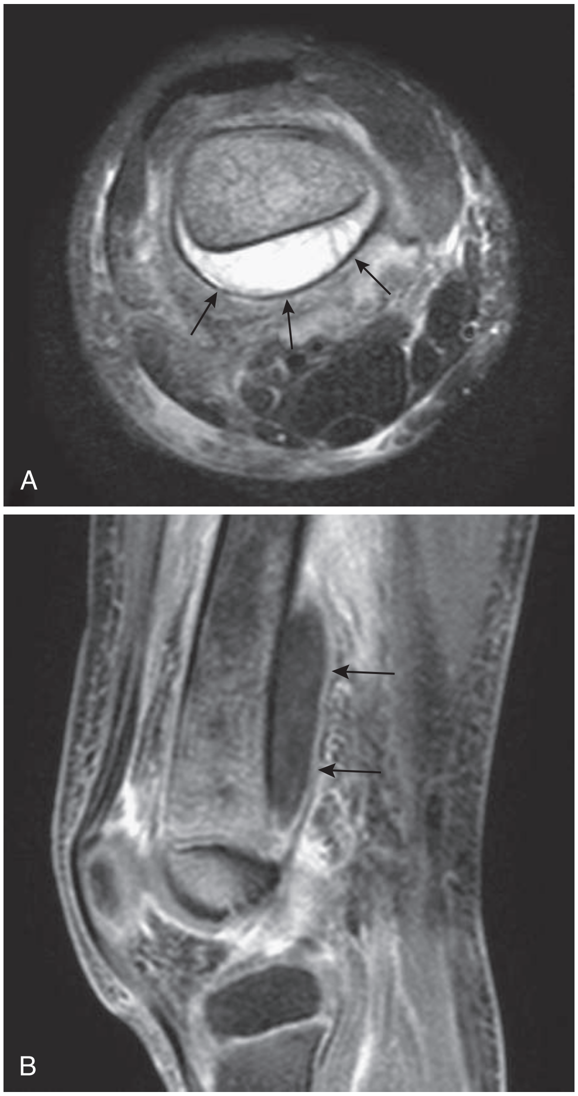

Figure 684-3 Acute osteomyelitis of the distal femur in a 5 yr old boy. **A,** T2-weighted fat-saturated axial MRI shows a large subperiosteal abscess *(arrows)* at the posterior aspect of the femur. Increased signal is seen within the bone, and there is adjacent soft-tissue edema. **B,** T1-weighted fat-saturated postgadolinium sagittal MRI shows the longitudinal extent of the subperiosteal abscess with enhancing wall *(arrows). (From Kan JH, Azouz EM: Musculoskeletal infections. In Coley BD, editor:* Caffey's pediatric diagnostic imaging, *ed 12, Philadelphia, 2013, WB Saunders,* Fig. 138-13, *p. 1476.)*

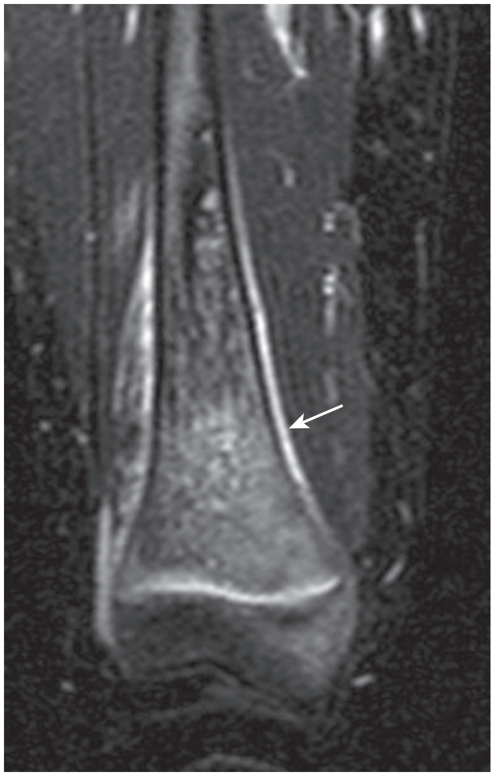

Figure 684-4 Short tau inversion (STIR) recovery coronal magnetic resonance image demonstrates a salt-and-pepper appearance to marrow edema and periosteal reaction *(arrow). (From Kan JH, Azouz EM: Musculoskeletal infections. In Coley BD, editor:* Caffey's pediatric diagnostic imaging, *ed 12, Philadelphia, 2013, WB Saunders,* Fig. 138-14, *p. 1477.)*

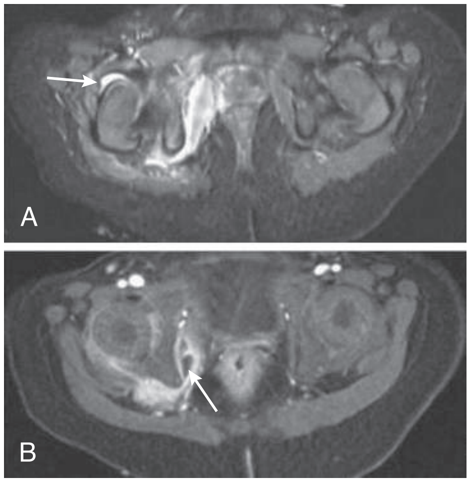

Figure 684-5 **A,** Axial short tau inversion recovery (STIR) MR demonstrates high signal in the left internal obturator muscle. **B,** Postcontrast fast multiplanar spoiled gradient recalled MR demonstrates a small abscess *(arrow).* This child had *Staphylococcus aureus* pyomyositis and responded to intravenous antibiotic treatment. *(From Karmazyn B, Loder RT, Kleiman MB, et al: The role of pelvic magnetic resonance in evaluating nonhip sources of infection in children with acute nontraumatic hip pain.* J Pediatr Orthop *27:158–164, 2007, Fig. 1, p. 160.)*

and can mimic a pelvic osteomyelitis. MRI is the definitive study to identify and localize pelvic pyomyositis (Fig. 684-5). An iliopsoas abscess can manifest with thigh pain, limp, and fever and must be considered in the differential diagnosis of osteomyelitis. The iliopsoas abscess may be primary (hematogenous: *S. aureus*) or secondary to infection in adjacent bone (*S. aureus*), kidney (*E. coli*) or intestine (*E. coli*, *Bacteroides* spp.). *Mycobacterium tuberculosis* has been reported in patients with HIV infection. Any child with negative bone imaging and a negative hip aspiration, who presents with fever, limp, and elevated inflammatory marks should be evaluated for pyomyositis.

Appendicitis, urinary tract infection, and gynecologic disease are among the conditions in the differential diagnosis of pelvic osteomyelitis. Children with leukemia commonly have bone pain or joint pain as an early symptom. Neuroblastoma with bone involvement may be mistaken for osteomyelitis. Primary bone tumors need to be considered, but fever and other signs of illness are generally absent except in Ewing sarcoma. In patients with sickle cell disease, distinguishing bone infection from infarction may be challenging.

Chronic recurrent multifocal osteomyelitis (CRMO) is a nonpyrogenic, sterile inflammatory bone disease that is considered an autoinflammatory disorder (see Chapter 163). It is also associated with a family history of autoimmune disease; the affected patient may also

Figure 684-6 MRI in a patient with chronic recurrent multifocal osteomyelitis. **A,** Whole-body image showing multiple foci of osteomyelitis, some of which are distributed symmetrically. **B,** Image of the ankle showing inflammatory metaphyseal and epiphyseal lesions. **C,** Image of the left femur showing involvement of the diaphysis with a soft-tissue reaction. *(From Wipff J, Adamsbaum C, Kahan A, Job-Deslandre C: Chronic recurrent multifocal osteomyelitis.* Joint Bone Spine *78:555–560, 2011, Fig. 3, p. 557.)*

have other inflammatory diseases such as Crohn disease, Sweet syndrome, psoriasis, and palmer plantar pustulosis. CRMO in children has many similarities with synovitis, acne, pustulosis, hyperostosis, and osteitis seen in adults. In addition, CRMO has similarities to Majeed syndrome, an autosomal recessive disorder with a microcytic dyserythropoietic anemia and with a deficiency of interleukin-1 receptor antagonist, an autosomal recessive autoinflammatory disease.

In contrast to infectious osteomyelitis, CRMO is multifocal, recurrent, and may involve bones not typical of osteomyelitis (spine, pelvis, clavicle, mandible, calcaneus). Plain radiographs reveal osteolytic lesions or sclerosis; whole-body short tau inversion recovery MRI imaging is the diagnostic study of choice (Fig. 684-6), followed by bone scan.

Pain in CRMO is usually insidious, noted at night; fever is not always present. The mean age of onset is 10 yr. The ESR and CRP may be elevated but are not as high as in bacterial osteomyelitis. Pain usually responds to nonsteroidal antiinflammatory drug agents or, in more severe cases, a short course of prednisone.

TREATMENT

Optimal treatment of skeletal infections requires collaborative efforts of pediatricians, orthopedic surgeons, and radiologists. Obtaining material for culture (blood, periosteal abscess, bone) **before** antibiotics are given is essential. Because most patients with osteomyelitis have an indolent, non–life-threatening condition, optimally cultures should be obtained, even if there is a delay of a few hours in initiating antibiotics.

Antibiotic Therapy

The initial empirical antibiotic therapy is based on knowledge of likely bacterial pathogens at various ages, the results of the Gram stain of aspirated material, and additional considerations. In neonates, an antistaphylococcal penicillin, such as nafcillin or oxacillin (150-200 mg/kg/24 hr divided q6h IV), and a broad-spectrum cephalosporin, such as cefotaxime (150-225 mg/kg/24 hr divided q8h IV), provide coverage for the methicillin-susceptible *S. aureus,* group B streptococcus, and Gram-negative bacilli. If methicillin-resistant *Staphylococcus* is suspected, vancomycin is substituted for nafcillin. If the neonate is a small premature infant or has a central vascular catheter, the possibility of nosocomial bacteria (Gram-negative enteric, *Pseudomonas,* or *S. aureus*) or fungi *(Candida)* should be considered. In older infants and children, the principal pathogens are *S. aureus* and streptococcus.

A major factor influencing the selection of empirical therapy is the rate of methicillin resistance among community *S. aureus* isolates. **If methicillin-resistant *S. aureus* (MRSA) accounts for ≥10% of community *S. aureus* isolates, including an antibiotic effective against CA-MRSA in the initial empirical antibiotic regimen is suggested.** Vancomycin (60 mg/kg/24 hr divided q6h IV) is the gold standard agent for treating invasive MRSA infections, especially when the child is critically ill. Clindamycin (40 mg/kg/24 hr q8hr) is also recommended when the rate of clindamycin resistance is ≤10% among community *S. aureus* isolates, the child is not severely ill and bacteremia is not a concern or blood cultures are known to be negative. Cefazolin (100 mg/kg/24 hr divided q8h IV) or nafcillin (150-200 mg/kg/24 hr divided q6h) is the agent of choice for parenteral treatment of osteomyelitis caused by methicillin-susceptible *S. aureus*. Penicillin is first-line therapy for treating osteomyelitis caused by susceptible strains of *S. pneumoniae* as well as all group A streptococci. Cefotaxime or ceftriaxone is recommended for pneumococcal isolates with resistance to penicillin and for most *Salmonella* spp.

Special situations dictate deviations from the usual empirical antibiotic selection. In patients with sickle cell disease with osteomyelitis, Gram-negative enteric bacteria *(Salmonella)* are common pathogens as well as *S. aureus,* so a broad-spectrum cephalosporin such as cefotaxime (150-225 mg/kg/24 hr divided q8h) is used in addition to vancomycin or clindamycin. Clindamycin (40 mg/kg/24 hr divided q6h IV) is a useful alternative drug for patients allergic to β-lactam drugs. In addition to good antistaphylococcal activity, clindamycin has broad activity against anaerobes and is useful for treating infections secondary to penetrating injuries or compound fractures. For immunocompromised patients, combination therapy is usually initiated, such as with vancomycin and ceftazidime, or with piperacillin-tazobactam and an aminoglycoside. *K. kingae* usually responds to β-lactam antibiotics, including cefotaxime. Although the efficacy of treating osteomyelitis

caused by *B. henselae* is uncertain, azithromycin plus rifampin may be considered.

When the pathogen is identified and antibiotic susceptibilities are determined, appropriate adjustments in antibiotics are made as necessary. If a pathogen is not identified and a patient's condition is improving, therapy is continued with the initially selected antibiotic. This selection is more complicated currently owing to the presence of MRSA isolates in the community. If a pathogen is not identified and a patient's condition is not improving, reaspiration or biopsy and the possibility of a noninfectious condition should be considered.

Duration of antibiotic therapy is individualized depending on the organism isolated and clinical course. For most infections including those caused by *S. aureus*, the minimal duration of antibiotics is 21-28 days, provided that the patient shows prompt resolution of signs and symptoms (within 5-7 days) and the CRP and ESR have normalized; a total of 4-6 wk of therapy may be required. For group A streptococcus, *S. pneumoniae,* or *Haemophilus influenzae* type b, treatment duration maybe shorter. A total of 7-10 postoperative days of treatment is adequate for *Pseudomonas* osteochondritis when thorough curettage of infected tissue has been performed. Immunocompromised patients generally require prolonged courses of therapy, as do patients with mycobacterial or fungal infection.

Changing antibiotics from the intravenous route to oral administration when a patient's condition clearly has improved and the child is afebrile for ≥48-72 hr may be considered. For the oral antibiotic regimen with β-lactam drugs for susceptible staphylococcal or streptococcal infection, cephalexin (80-100 mg/kg/24 hr q8h) or oral clindamycin (30-40 mg/kg/24 hr q8h) can be used to complete therapy for children with clindamycin-susceptible CA-MRSA or for patients who are seriously allergic or cannot tolerate β-lactam antibiotics. The oral regimen decreases the risk of complications related to prolonged intravenous therapy, is more comfortable for patients, and permits treatment outside the hospital if adherence to treatment can be ensured. Outpatient intravenous antibiotic therapy via a central venous catheter can be used for completing therapy at home, as an alternative; however, catheter-related complications, including infection or mechanical problems, can lead to readmission or emergency department visits.

In children with venous thrombosis complicating osteomyelitis, anticoagulants generally are administered under the supervision of a hematologist until the thrombus has resolved.

Surgical Therapy

When frank pus is obtained from subperiosteal or metaphyseal aspiration or is suspected based on MRI findings, a surgical drainage procedure is usually indicated. Surgical intervention is also often indicated after a penetrating injury and when a retained foreign body is possible. In selected cases, catheter drainage performed by an interventional radiologist is adequate.

Treatment of chronic osteomyelitis consists of surgical removal of sinus tracts and sequestrum, if present. Antibiotic therapy is continued for several months or longer until clinical and radiographic findings suggest that healing has occurred. Monitoring the CRP or ESR is not helpful in most cases of chronic osteomyelitis.

Physical Therapy

The major role of physical medicine is a preventive one. If a child is allowed to lie in bed with an extremity in flexion, limitation of extension can develop within a few days. The affected extremity should be kept in extension with sandbags, splints, or, if necessary, a temporary cast. Casts are also indicated when there is a potential for pathologic fracture. After 2-3 days, when pain is easing, passive range of motion exercises are started and continued until the child resumes normal activity. In neglected cases with flexion contractures, prolonged physical therapy is required.

PROGNOSIS

When pus is drained and appropriate antibiotic therapy is given, the improvement in signs and symptoms is rapid. Failure to improve or worsening by 72 hr requires review of the appropriateness of the antibiotic therapy, the need for surgical intervention, or the correctness of the diagnosis. Acute-phase reactants may be useful as monitors. The serum CRP typically normalizes within 7 days after start of treatment, whereas the ESR typically rises for 5-7 days, and then falls slowly, dropping sharply after 10-14 days. Failure of either of these acute-phase reactants to follow the usual course should raise concerns about the adequacy of therapy. Recurrence of disease and development of chronic infection after treatment occur in <10% of patients.

Because children are in a dynamic state of growth, sequelae of skeletal infections might not become apparent for months or years; therefore, long-term follow-up is necessary with close attention to range of motion of joints and bone length. Although firm data about the impact of delayed treatment on outcome are not available, it appears that initiation of medical and surgical therapy within 1 wk of onset of symptoms provides a better prognosis than delayed treatment.

Chapter 685
Septic Arthritis

Sheldon L. Kaplan

Without early recognition and prompt institution of appropriate medical and surgical therapy, septic arthritis in infants and children has the potential to damage to the synovium, adjacent cartilage, and bone, and cause permanent disability.

ETIOLOGY

Historically, *Haemophilus influenzae* type b (see Chapter 194) accounted for more than half of all cases of bacterial arthritis in infants and young children. Since the development of the conjugate vaccine, it is now a rare cause; *Staphylococcus aureus* (see Chapter 181.1) is now the most common infection in all age groups. Methicillin-resistant *S. aureus* accounts for a high proportion (>25%) of community *S. aureus* isolates in many areas of the United States and throughout the world. Group A streptococcus (see Chapter 183) and *Streptococcus pneumoniae* (pneumococcus; see Chapter 182) historically cause 10-20%; *S. pneumoniae* is most likely in the 1st 2 yr of life, but its frequency has declined since the introduction of the pneumococcal conjugate vaccines. *Kingella kingae* is recognized as a relatively common etiology with improved culture and polymerase chain reaction methods in children younger than 5 yr old (see Chapters 193 and 684). In sexually active adolescents, gonococcus (see Chapter 192) is a common cause of septic arthritis and tenosynovitis, usually of small joints or as a monoarticular infection of a large joint (knee). *Neisseria meningitidis* (see Chapter 191) can cause either a septic arthritis that occurs in the 1st few days of illness or a reactive arthritis that is typically seen several days after antibiotics have been initiated. Group B streptococcus (see Chapter 184) is an important cause of septic arthritis in neonates.

Fungal infections usually occur as part of multisystem disseminated disease; *Candida* arthritis can complicate systemic infection in neonates with or without indwelling vascular catheters. Primary viral infections of joints are rare, but arthritis accompanies many viral (parvovirus, mumps, rubella live vaccines) syndromes, suggesting an immune-mediated pathogenesis.

A microbial etiology is confirmed in approximately 65% of cases of septic arthritis. Prior antibiotic therapy and the inhibitory effect of synovial fluid on microbial growth might explain the low bacterial yield. Additionally, some cases treated as bacterial arthritis are actually postinfectious (gastrointestinal or genitourinary) reactive arthritis (see Chapter 157) rather than primary infection. Lyme disease produces an arthritis more like a rheumatologic disorder and not typically suppurative.

EPIDEMIOLOGY

Septic arthritis is more common in young children. Half of all cases occur by 2 yr of age and three-fourths of all cases occur by 5 yr of age. Adolescents and neonates are at risk of gonococcal septic arthritis.

The majority of infections in otherwise healthy children are of hematogenous origin. Infection of joints can follow penetrating injuries or procedures such as trauma, arthroscopy, prosthetic joint surgery, intraarticular steroid injection, and orthopedic surgery, although this is uncommon. Immunocompromised patients and those with rheumatologic joint disease are also at increased risk of joint infection.

PATHOGENESIS

Septic arthritis primarily occurs as a result of hematogenous seeding of the synovial space. Less often, organisms enter the joint space by direct inoculation or extension from a contiguous focus. The synovial membrane has a rich vascular supply and lacks a basement membrane, providing an ideal environment for hematogenous seeding. The presence of bacterial products (endotoxin or other toxins) within the joint space stimulates cytokine production (tumor necrosis factor-α, interleukin-1) within the joint, triggering an inflammatory cascade. The cytokines stimulate chemotaxis of neutrophils into the joint space, where proteolytic enzymes and elastases are released by neutrophils, damaging the cartilage. Proteolytic enzymes released from the synovial cells and chondrocytes also contribute to destruction of cartilage and synovium. Bacterial hyaluronidase breaks down the hyaluronic acid in the synovial fluid, making the fluid less viscous and diminishing its ability to lubricate and protect the joint cartilage. Damage to the cartilage can occur through increased friction, especially for weight-bearing joints. The increased pressure within the joint space from accumulation of purulent material can compromise the vascular supply and induce pressure necrosis of the cartilage. Synovial and cartilage destruction results from a combination of proteolytic enzymes and mechanical factors.

CLINICAL MANIFESTATIONS

Most septic arthritides are monoarticular. The signs and symptoms of septic arthritis depend on the age of the patient. Early signs and symptoms may be subtle, particularly in neonates. Septic arthritis in neonates and young infants is often associated with adjacent osteomyelitis caused by transphyseal spread of infection, although osteomyelitis contiguous with an infected joint can be seen at any age (see Chapter 684).

Older infants and children might have fever and pain, with localizing signs such as swelling, erythema, and warmth of the affected joint. With involvement of joints of the pelvis and lower extremities, limp or refusal to walk is often seen.

Erythema and edema of the skin and soft tissue overlying the site of infection are seen earlier in septic arthritis than in osteomyelitis, because the bulging infected synovium is usually more superficial, whereas the metaphysis is located more deeply. Septic arthritis of the hip is an exception because of the deep location of the hip joint.

Joints of the lower extremity constitute 75% of all cases of septic arthritis (Table 685-1). The elbow, wrist, and shoulder joints are involved in approximately 25% of cases, and small joints are uncommonly infected. Suppurative infections of the hip, shoulder, elbow, and ankle in older infants and children may be associated with an adjacent osteomyelitis of the proximal femur, proximal humerus, proximal radius, and distal tibia because the metaphysis extends intraarticularly.

Table 685-1 Anatomic Distribution of Septic Arthritis

BONE	PERCENT (%)	BONE	PERCENT (%)
Knee	~40	Interphalangeal	<1
Hip	22-40	Metatarsal	<1
Ankle	4-13	Sacroiliac	<1
Elbow	8-12	Acromioclavicular	<1
Wrist	1-4	Metacarpal	<1
Shoulder	~3	Toe	~1

Modified from Gafur OA, Copley LA, Hollmig ST, et al: The impact of the current epidemiology of pediatric musculoskeletal infection on evaluation and treatment guidelines, J Pediatr Orthop *28:777–785, 2008.*

DIAGNOSIS

Blood cultures should be performed in all cases of suspected septic arthritis. Aspiration of the joint fluid for Gram stain and culture when the history and physical findings indicate septic arthritis remains the definitive diagnostic technique and provides the optimal specimen for culture to confirm the diagnosis. Most large joint spaces are easy to aspirate, but the hip can pose technical problems; ultrasound guidance facilitates aspiration. Aspiration of joint pus provides the best specimen for bacteriologic culture of infection. If gonococcus is suspected, cervical, anal, and throat cultures should also be obtained. In addition to prompt inoculation onto solid media, inoculation of the specimen in blood culture bottles can increase recovery of *K. kingae.* Polymerase chain reaction appears to be the most sensitive method for detecting *K. kingae* in joint fluid.

Synovial fluid analysis for cell count, differential, protein, and glucose has limited usefulness because noninfectious inflammatory diseases, such as rheumatic fever (see Chapter 183.1) and rheumatoid arthritis (see Chapter 155), can also cause exuberant reaction with increased cells and protein and decreased glucose. Nevertheless, cell counts >50,000-100,000 cells/mm^3 generally indicate an infectious process. Synovial fluid characteristics of septic arthritis can suggest infection but are not sufficiently specific to exclude infection. When the joint aspiration is negative, pyomyositis, especially of pelvic muscles, must be excluded by MRI (see Chapter 684).

The white blood cell count and differential, erythrocyte sedimentation rate (ESR), and C-reactive protein (CRP) are generally elevated in children with joint infections but are nonspecific and might not be helpful in distinguishing between infection and other inflammatory processes. The leukocyte count and ESR may be normal during the 1st few days of infection, and normal test results do not preclude the diagnosis of septic arthritis. Monitoring elevated ESR and CRP may be of value in assessing response to therapy or identifying complications. In one study of *S. aureus* septic arthritis, risk features for a site of osteomyelitis contiguous with septic arthritis included a CRP >10 mg/dL at the time of admission, positive blood cultures or more than 2 days of fever following admission.

Radiographic Evaluation

Radiographic studies play a crucial role in evaluating septic arthritis. Conventional radiographs, ultrasonography, CT, MRI, and radionuclide studies can all contribute to establishing the diagnosis (Fig. 685-1).

Plain Radiographs

Plain films of septic arthritis can show widening of the joint capsule, soft-tissue edema, and obliteration of normal fat lines. Plain films of the hip can show medial displacement of the obturator muscle into the pelvis (the obturator sign), lateral displacement or obliteration of the gluteal fat lines, and elevation of Shenton's line with a widened arc.

Ultrasonography

Ultrasonography is particularly helpful in detecting joint effusion and fluid collection in the soft-tissue and subperiosteal regions. Ultrasonography is highly sensitive in detecting joint effusion, particularly for the hip joint, where plain radiographs are normal in more than 50% of cases of septic arthritis of the hip. Ultrasonography can serve as an aid in performing hip aspiration.

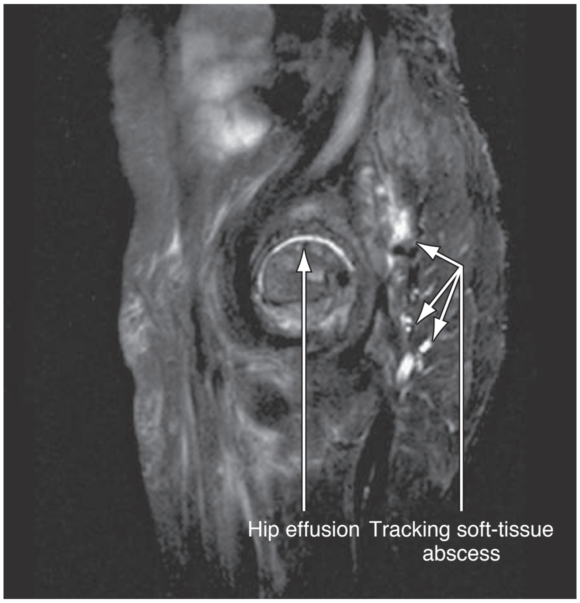

Figure 685-1 MRI of staphylococcal septic arthritis of left hip, with fluid collections between planes of gluteal muscles. *Arrows* indicate fluid collection. *(From Matthews CJ, Weston VC, Jones A, et al: Bacterial septic arthritis in adults,* Lancet *375:846–854, 2010.)*

Magnetic Resonance Imaging and Computed Tomography

MRI and CT may be useful in confirming the presence of joint fluid in patients with suspected osteoarthritis infections. MRI may be useful in excluding adjacent osteomyelitis.

Radionuclide Imaging

Radionuclide imaging compared to radiographs is more sensitive in providing supportive evidence of the diagnosis of septic arthritis; a scan may be positive within 2 days of the onset of symptoms. Three-phase imaging with technetium-99 methylene diphosphonate shows symmetric uptake on both sides of the joint, limited to the bony structures adjacent to the joint. Radionuclide imaging is also useful for evaluating the sacroiliac joint.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of septic arthritis depends on the joint or joints involved and the age of the patient. For the hip, toxic synovitis, pyomyositis, Legg-Calvé-Perthes disease, slipped capital femoral epiphysis, psoas abscess, and proximal femoral, pelvic, or vertebral osteomyelitis as well as diskitis should be considered. For the knee, distal femoral or proximal tibial osteomyelitis, pauciarticular rheumatoid arthritis, and referred pain from the hip should be considered. Knee or thigh pain may be referred from the hip. Other conditions such as trauma, cellulitis, pyomyositis, sickle cell disease, hemophilia, and Henoch-Schönlein purpura can mimic purulent arthritis. When several joints are involved, serum sickness, collagen vascular disease, rheumatic fever, and Henoch-Schönlein purpura should be considered. Arthritis is one of the extraintestinal manifestations of inflammatory bowel disease. Reactive arthritis following a variety of bacterial (gastrointestinal or genital) and parasitic infections, streptococcal pharyngitis, or viral hepatitis can resemble acute septic arthritis (see Chapter 157).

TREATMENT

Optimal treatment of septic arthritis requires cooperation of pediatricians, orthopedic surgeons, and radiologists to benefit the patient.

Antibiotic Therapy

The initial empirical antibiotic therapy is based on knowledge of likely bacterial pathogens at various ages, the results of the Gram stain of aspirated material, and additional considerations. In neonates, an antistaphylococcal penicillin, such as nafcillin or oxacillin (150-200 mg/kg/24 hr divided q6h IV), and a broad-spectrum cephalosporin, such as cefotaxime (150-225 mg/kg/24 hr divided q8h IV), provide coverage for the *S. aureus,* group B streptococcus, and Gram-negative bacilli. If methicillin-resistant *S. aureus* (MRSA) is a concern, vancomycin is selected in stead of nafcillin or oxacillin. If the neonate is a small premature infant or has a central vascular catheter, the possibility of nosocomial bacteria (*S. aureus*, Gram-negative enterics, or *Pseudomonas aeruginosa*) or fungi *(Candida)* should be considered.

In older infants and children with septic arthritis, empirical therapy to cover for *S. aureus*, streptococci, and *K. kingae* includes cefazolin (100-150 mg/kg/24 hr divided q8h) or nafcillin (150-200 mg/kg/24 hr divided q6h).

In areas where methicillin resistance is noted in ≥10% of community-acquired methicillin-resistant *S. aureus* strains (CA-MRSA), including an antibiotic that is effective against CA-MRSA isolates is suggested. Clindamycin (40 mg/kg divided q8h) and vancomycin (15 mg/kg q6 IV) are alternatives when treating CA-MRSA infections. For immunocompromised patients, combination therapy is usually initiated, such as with vancomycin and ceftazidime or with extended-spectrum penicillins and β-lactamase inhibitors with an aminoglycoside. Adjunct therapy with dexamethasone for 4 days with antibiotic therapy appeared to benefit children with septic arthritis in one study but has not been studied in children with CA-MRSA septic arthritis.

When the pathogen is identified, appropriate changes in antibiotics are made, if necessary. If a pathogen is not identified and a patient's condition is improving, therapy is continued with the antibiotic selected initially. If a pathogen is not identified and a patient's condition is not improving, reaspiration or the possibility of a noninfectious condition should be considered.

Duration of antibiotic therapy is individualized depending on the organism isolated and the clinical course. Ten to 14 days is usually adequate for streptococci, *S. pneumoniae*, and *K. kingae;* longer therapy may be needed for *S. aureus* and Gram-negative infections. Normalization of ESR and CRP in addition to a normal examination supports discontinuing antibiotic therapy. In selected patients, obtaining a plain radiograph of the joint before completing therapy can provide evidence (typically periosteal new bone) of a previously unappreciated contiguous site of osteomyelitis that would likely prolong antibiotic treatment. Oral antibiotics can be used to complete therapy once the patient is afebrile for 48-72 hr and is clearly improving.

Surgical Therapy

Infection of the hip is generally considered a surgical emergency because of the vulnerability of the blood supply to the head of the femur. For joints other than the hip, daily aspirations of synovial fluid may be required. Generally, 1 or 2 subsequent aspirations suffice. If fluid continues to accumulate after 4-5 days, arthrotomy or video-assisted arthroscopy is needed. At the time of surgery, the joint is flushed with sterile saline solution. Antibiotics are not instilled because they are irritating to synovial tissue, and adequate amounts of antibiotic are achieved in joint fluid with systemic administration.

PROGNOSIS

When pus is drained and appropriate antibiotic therapy is given, the improvement in signs and symptoms is rapid. Failure to improve or worsening by 72 hr requires review of the appropriateness of the antibiotic therapy, the need for surgical intervention, and the correctness of the diagnosis. Acute-phase reactants may be useful as monitors. Failure of either of these acute-phase reactants to follow the usual course should raise concerns about the adequacy of therapy. Recurrence of disease and development of chronic infection after treatment occur in <10% of patients.

Because children are in a dynamic state of growth, sequelae of skeletal infections might not become apparent for months or years; therefore, long-term follow-up is necessary, with close attention to range of motion of joints and bone length. Although firm data about the impact of delayed treatment on outcome are not available, it appears that initiation of medical and surgical therapy within 1 wk of onset of symptoms provides a better prognosis than delayed treatment.

Section 2

Sports Medicine

Chapter 686

Epidemiology and Prevention of Injuries

Gregory L. Landry

The Centers for Disease Control and Prevention recommend moderate to vigorous physical activity on a regular basis for all adolescents. Physical activity has favorable effects on hypertension, obesity, and serum lipid levels in youths and is associated with lower rates of cardiovascular disease, type 2 diabetes mellitus, osteoporosis, and colon and breast cancer among adults.

Pediatricians should promote physical activity to their patients, especially those with lower rates of physical activity and sports participation, including children with special healthcare needs (see Chapter 717) and those from lower socioeconomic groups. Physicians also have the responsibility of providing medical clearance for participation in physical activity and sports and for diagnosis and rehabilitation of injuries.

Approximately 30 million children and adolescents participate in organized sports in the United States. Approximately 3 million injuries occur annually if injury is defined as time lost from the sport. Deaths in sports are rare, with the majority of nontraumatic deaths caused by cardiac diseases (see Chapter 436). Nonetheless, approximately 30% of life-threatening injuries in children presenting to an emergency room are sports related. Overall, injury rates and injury severity in sports increase with age and pubertal development, related to the greater speed, strength, and intensity of competition.

Identifying mechanisms of injury and establishing and enforcing rules that reduce the likelihood of that mechanism of injury, including penalizing dangerous play, have reduced catastrophic injury rates. Injury rates also have been reduced by removing environmental hazards, such as trampolines in gymnastics and stationary (vs breakaway) bases in softball, and by modifying heat injury rates in soccer tournaments by adding water breaks and reducing the playing time. Wearing equipment such as mouth guards can reduce dental injuries. A common reason for reinjury is lack of rehabilitation of old injuries; appropriate rehabilitation reduces injury rates. Preseason training for high school athletes, with an emphasis on speed, agility, jump training, and flexibility, is associated with lower injury rates in soccer and fewer serious knee injuries in female athletes. Traditional stretching maneuvers or massage have not been demonstrated to reduce the risk of injury or muscle soreness, but ankle taping is helpful particularly to prevent reinjury of the ankle. One setting for implementing some of these prevention strategies and for detecting unrehabilitated injuries and medical problems that could affect participation in sports is the preparticipation sports examination.

Table 686-1	Objectives of the Preparticipation Sports Examination

- Determination of the general health of the athlete
- Disclosure of defects that may limit participation
- Detection of conditions that may predispose the athlete to injury
- Determination of optimal level of performance
- Classification of the athlete according to individual qualifications
- Fulfillment of legal and insurance requirements for organized athletic programs
- Evaluation of size and level of maturation of younger athletes
- Improvement of fitness and performance
- Provision of opportunities for students to compete who have either physiologic or pathologic health conditions that may preclude blanket approval
- Provision of the opportunity to counsel youths and answer health and personal questions
- Entry of the athlete into the local sports medicine system establishing a doctor-patient relationship that continues

From Sanders B, Blackburn TA, Boucher B: Preparticipation screening-the sports physical therapy perspective. Int J Sports Phys Ther *8(2):180–193, 2013, Table 1.*

PREPARTICIPATION SPORTS EXAMINATION

The preparticipation sports examination (PSE) is performed with a directed history and a directed physical examination, including a screening musculoskeletal examination. It identifies possible problems in 1-8% of athletes and excludes fewer than 1% from participation. The PSE is not a substitute for the recommended comprehensive annual evaluation, which looks at behaviors that are potentially harmful to teens, such as sexual activity, drug use, and violence, and assesses for depression and suicidal ideation and addresses broader issues of prevention. Table 686-1 identifies the purposes of the PSE. If possible, the PSE should be combined with the comprehensive annual health visit with emphasis on preventive healthcare (see Chapters 5 and 16).

State requirements for how often a youth needs a PSE differ, ranging from annually to entry to a new school level (middle school, high school, college). At a minimum, a focused, annual interim evaluation should be done on an otherwise healthy young athlete. The PSE is optimally performed 3-6 wk before the start of practice.

History and Physical Examination

The essential components of the PSE are the history and focused medical and musculoskeletal screening examinations. Identified problems require more investigation (Tables 686-2 and 686-3). In the absence of symptoms, no screening laboratory tests are required.

Seventy-five percent of significant findings are identified by the history; a standardized questionnaire given to the parent and athlete is important because the young athlete might not know or might forget important aspects of his or her history. The questionnaire should include questions about previous medical, surgical, cardiac, pulmonary, neurologic, dermatologic, visual, psychologic, musculoskeletal, and menstrual problems, as well as about heat illness, medications, allergies, immunizations, and diet. The most commonly identified problems are **unrehabilitated injuries.** An investigation of previous injuries, including diagnostic tests, treatment, and present functional status, is indicated.

Sudden death during sports can result from undetected cardiac disease such as hypertrophic or other cardiomyopathies (see Chapter 439), anomalous coronary vessels (see Chapter 432.2), or a ruptured aorta in Marfan syndrome (see Chapter 702). In many cases, the underlying heart disease is not suspected, and death is the first sign of heart disease (see Chapter 436). However, in approximately 25-50% of cases,

Text continued on p. 3335

Table 686-2 Preparticipation Sports Examination

COMPONENT OF THE PHYSICAL EXAMINATION	CONDITION TO BE DETECTED
Vital signs	Hypertension, cardiac disease, brady- or tachycardia
Height and weight	Obesity, eating disorders, malabsorption
Vision and pupil size	Legal blindness, absent eye, anisocoria, amblyopia
Lymph node	Infectious diseases, malignancy
Cardiac (performed standing and supine)	Heart murmur, prior surgery, dysrhythmia
Pulmonary	Recurrent and exercise-induced bronchospasm, chronic lung disease
Abdomen	Organomegaly, abdominal mass
Skin	Contagious diseases (impetigo, herpes, staphylococcal, streptococcal)
Genitourinary	Varicocele, undescended testes, tumor, hernia
Musculoskeletal	Acute and chronic injuries, physical anomalies (scoliosis)

Table 686-3 Medical Conditions and Sports Participation

CONDITION	MAY PARTICIPATE	EXPLANATION
Atlantoaxial instability (instability of the joint between cervical vertebrae 1 and 2)	Qualified yes	Athlete (particularly if the athlete has Down syndrome or juvenile rheumatoid arthritis with cervical involvement) needs evaluation to assess the risk of spinal cord injury during sports participation, especially when using a trampoline
Bleeding disorder	Qualified yes	Athlete needs evaluation
Diabetes mellitus	Yes	All sports can be played with proper attention and appropriate adjustments to diet (particularly carbohydrate intake), blood glucose concentrations, hydration, and insulin therapy Blood glucose concentrations should be monitored before exercise, every 30 min during continuous exercise, 15 min after completion of exercise, and at bedtime
Eating disorders	Qualified yes	Athlete with an eating disorder needs medical and psychiatric assessment before participation
Fever	No	Elevated core temperature can indicate a pathologic medical condition (infection or disease) that is often manifest by increased resting metabolism and heart rate. Accordingly, during the athlete's usual exercise regimen, fever can result in greater heat storage, decreased heat tolerance, increased risk of heat illness, increased cardiopulmonary effort, reduced maximal exercise capacity, and increased risk of hypotension because of altered vascular tone and dehydration. On rare occasions, fever accompanies myocarditis or other conditions that can make usual exercise dangerous
Heat illness, history of	Qualified yes	Because of the likelihood of recurrence, the athlete needs individual assessment to determine the presence of predisposing conditions and behavior and to develop a prevention strategy that includes sufficient acclimatization (to the environment and to exercise intensity and duration), conditioning, hydration, and salt intake, as well as other effective measures to improve heat tolerance and to reduce heat injury risk (e.g., protective equipment and uniform configurations)
HIV infection	Yes	Because of the apparent minimal risk to others, all sports may be played as athlete's state of health allows (especially if viral load is undetectable or very low) For all athletes, skin lesions should be covered properly, and athletic personnel should use universal precautions when handling blood or body fluids with visible blood Certain sports (such as wrestling and boxing) can create a situation that favors viral transmission (likely bleeding plus skin breaks); if viral load is detectable, then athletes should be advised to avoid such high-contact sports
Malignant neoplasm	Qualified yes	Athlete needs individual assessment
Musculoskeletal disorders	Qualified yes	Athlete needs individual assessment

Continued

Table 686-3 Medical Conditions and Sports Participation—cont'd

CONDITION	MAY PARTICIPATE	EXPLANATION
Myopathies	Qualified yes	Athlete needs individual assessment
Obesity	Yes	Because of the increased risk of heat illness and cardiovascular strain, obese athletes particularly need careful acclimatization (to the environment and to exercise intensity and duration), sufficient hydration, and potential activity and recovery modifications during competition and training.
Organ transplant recipient (and those taking immunosuppressive medications)	Qualified yes	Athlete needs individual assessment for contact, collision, and limited-contact sports In addition to potential risk of infections, some medications (e.g., prednisone) increase tendency for bruising
Skin infections, including herpes simplex, molluscum contagiosum, verrucae (warts), staphylococcal and streptococcal infections (furuncles [boils], carbuncles, impetigo, methicillin-resistant *Staphylococcus aureus* [cellulitis and/or abscesses]), scabies, and tinea	Qualified yes	During contagious periods, participation in gymnastics or cheerleading with mats, martial arts, wrestling, or other collision, contact, or limited-contact sports is not allowed
Spleen, enlarged	Qualified yes	If the spleen is acutely enlarged, then participation should be avoided because of risk of rupture If the spleen is chronically enlarged, then individual assessment is needed before collision, contact, or limited-contact sports are played
CARDIOVASCULAR		
Carditis (inflammation of the heart)	No	Carditis can result in sudden death with exertion
Hypertension (high blood pressure)	Qualified yes	Those with hypertension >5 mm Hg above the 99th percentile for age, sex, and height should avoid heavy weightlifting and power lifting, bodybuilding, and high-static component sports Those with sustained hypertension (>95th percentile for age, sex, and height) need evaluation The National High Blood Pressure Education Program Working Group report defined prehypertension and stage 1 and stage 2 hypertension in children and adolescents younger than 18 yr of age
Congenital heart disease (structural heart defects present at birth)	Qualified yes	Consultation with a cardiologist is recommended Those who have mild forms may participate fully in most cases; those who have moderate or severe forms or who have undergone surgery need evaluation The 36th Bethesda Conference defined mild, moderate, and severe disease for common cardiac lesions
Heart murmur	Qualified yes	If the murmur is innocent (does not indicate heart disease), full participation is permitted; otherwise, athlete needs evaluation (see structural heart disease, especially hypertrophic cardiomyopathy and mitral valve prolapse)
Dysrhythmia (Irregular Heart Rhythm)		
Long-QT syndrome	Qualified yes	Consultation with a cardiologist is advised. Those with symptoms (chest pain, syncope, near-syncope, dizziness, shortness of breath, or other symptoms of possible dysrhythmia) or evidence of mitral regurgitation on physical examination need evaluation; all others may participate fully
Malignant ventricular arrhythmias	Qualified yes	
Symptomatic Wolff-Parkinson-White syndrome	Qualified yes	
Advanced heart block	Qualified yes	
Family history of sudden death or previous sudden cardiac event	Qualified yes	
Implantation of a cardioverter-defibrillator	Qualified yes	
Structural or Acquired Heart Disease		
Hypertrophic cardiomyopathy	Qualified no	Consultation with a cardiologist is recommended. The 36th Bethesda Conference provided detailed recommendations. Most of these conditions carry a significant risk of sudden cardiac death associated with intense physical exercise. Hypertrophic cardiomyopathy requires thorough and repeated evaluations, because disease can change manifestations during later adolescence. Marfan syndrome with an aortic aneurysm also can cause sudden death during intense physical exercise. An athlete who has ever received chemotherapy with anthracyclines may be at increased risk for cardiac problems owing to the cardiotoxic effects of the medications, and resistance training in this population should be approached with caution; strength training that avoids isometric contractions may be permitted. Athlete needs evaluation
Coronary artery anomalies	Qualified no	
Arrhythmogenic right ventricular cardiomyopathy	Qualified no	
Acute rheumatic fever with carditis	Qualified no	
Ehlers-Danlos syndrome, vascular form	Qualified no	
Marfan syndrome	Qualified yes	
Mitral valve prolapse	Qualified yes	
Anthracycline use	Qualified yes	
Vasculitis, vascular disease	Qualified yes	
Kawasaki disease (coronary artery vasculitis)	Qualified yes	Consultation with a cardiologist is recommended. Athlete needs individual evaluation to assess risk on the basis of disease activity, pathologic changes, and medical regimen
Pulmonary hypertension	Qualified yes	

Table 686-3 Medical Conditions and Sports Participation—cont'd

CONDITION	MAY PARTICIPATE	EXPLANATION
EYES		
Functionally 1-eyed athlete	Qualified yes	A functionally 1-eyed athlete is defined as having best-corrected visual acuity worse than 20/40 in the poorer-seeing eye. Such an athlete would suffer significant disability if the better eye were seriously injured, as would an athlete with loss of an eye. Specifically, boxing and full-contact martial arts are not recommended for functionally 1-eyed athletes, because eye protection is impractical and/or not permitted. Some athletes who previously underwent intraocular eye surgery or had a serious eye injury may have increased risk of injury because of weakened eye tissue. Availability of eye guards approved by the American Society for Testing and Materials and other protective equipment might allow participation in most sports, but this must be judged on an individual basis
Loss of an eye	Qualified yes	
Detached retina or family history of retinal detachment at young age	Qualified yes	
High myopia	Qualified yes	
Connective tissue disorder, such as Marfan or Stickler syndrome	Qualified yes	
Previous intraocular eye surgery or serious eye injury	Qualified yes	
Conjunctivitis, infectious	Qualified no	Athlete with active infectious conjunctivitis should be excluded from swimming
GASTROINTESTINAL		
Malabsorption syndromes (celiac disease or cystic fibrosis)	Qualified yes	Athlete needs individual assessment for general malnutrition or specific deficits resulting in coagulation or other defects; with appropriate treatment, these deficits can be treated adequately to permit normal activities
Short-bowel syndrome or other disorders requiring specialized nutritional support, including parenteral or enteral nutrition	Qualified yes	Athlete needs individual assessment for collision, contact, or limited-contact sports Central or peripheral indwelling venous catheter might require special considerations for activities and emergency preparedness for unexpected trauma to the device(s)
Hepatitis, infectious (primarily hepatitis C)	Yes	All athletes should receive hepatitis B vaccination before participation. Because of the apparent minimal risk to others, all sports may be played as the athlete's state of health allows For all athletes, skin lesions should be covered properly, and athletic personnel should use universal precautions when handling blood or body fluids with visible blood
Liver, enlarged	Qualified yes	If the liver is acutely enlarged, participation should be avoided because of risk of rupture If the liver is chronically enlarged, individual assessment is needed before collision, contact, or limited-contact sports are played Patients with chronic liver disease can have changes in liver function that affect stamina, mental status, coagulation, or nutritional status
Diarrhea, infectious	Qualified no	Unless symptoms are mild and athlete is fully hydrated, no participation is permitted, because diarrhea can increase risk of dehydration and heat illness (see fever)
GENITOURINARY		
Kidney, absence of one	Qualified yes	Athlete needs individual assessment for contact, collision, and limited-contact sports Protective equipment can reduce risk of injury to the remaining kidney sufficiently to allow participation in most sports, providing such equipment remains in place during the activity
Ovary, absence of one	Yes	Risk of severe injury to remaining ovary is minimal
Pregnancy and postpartum period	Qualified yes	Athlete needs individual assessment As pregnancy progresses, modifications to usual exercise routines become necessary; activities with high risk of falling or abdominal trauma should be avoided Scuba diving and activities posing risk of altitude sickness should also be avoided during pregnancy After the birth, physiologic and morphologic changes of pregnancy take 4-6 wk to return to baseline
Testicle, undescended or absence of 1	Yes	Certain sports require a protective cup
NEUROLOGIC		
Cerebral palsy	Qualified yes	Athlete needs evaluation to assess functional capacity to perform sports-specific activity
History of serious head or spine trauma or abnormality, including craniotomy, epidural bleeding, subdural hematoma, intracerebral hemorrhage, second-impact syndrome, vascular malformation, and neck fracture	Qualified yes	Athlete needs individual assessment for collision, contact, or limited-contact sports
History of simple concussion (mild traumatic brain injury), multiple simple concussions, and/or complex concussion	Qualified yes	Athlete needs individual assessment Research supports a conservative approach to concussion management, including no athletic participation while symptomatic or when deficits in judgment or cognition are detected, followed by graduated return to full activity
Recurrent headaches	Yes	Athlete needs individual assessment
Seizure disorder, well controlled	Yes	Risk of seizure during participation is minimal

Continued

Table 686-3 Medical Conditions and Sports Participation—cont'd

CONDITION	MAY PARTICIPATE	EXPLANATION
Seizure disorder, poorly controlled	Qualified yes	Athlete needs individual assessment for collision, contact, or limited-contact sports The following noncontact sports should be avoided: archery, riflery, swimming, weightlifting, power lifting, strength training, and sports involving heights; in these sports, a seizure during activity can pose a risk to self or others
Recurrent plexopathy (burner or stinger) and cervical cord neurapraxia with persistent defects	Qualified yes	Athlete needs individual assessment for collision, contact, or limited-contact sports; regaining normal strength is an important benchmark for return to play
RESPIRATORY		
Pulmonary compromise, including cystic fibrosis	Qualified yes	Athlete needs individual assessment but, generally, all sports may be played if oxygenation remains satisfactory during graded exercise test Athletes with cystic fibrosis need acclimatization and good hydration to reduce risk of heat illness
Asthma	Yes	With proper medication and education, only athletes with severe asthma need to modify their participation For those using inhalers, recommend having a written action plan and using a peak flowmeter daily Athletes with asthma might encounter risks when scuba diving
Acute upper respiratory infection	Qualified yes	Upper respiratory obstruction can affect pulmonary function Athlete needs individual assessment for all except mild disease (see fever)
RHEUMATOLOGIC		
Juvenile rheumatoid arthritis	Qualified yes	Athletes with systemic or polyarticular juvenile rheumatoid arthritis and history of cervical spine involvement need radiographs of C1 and C2 to assess risk of spinal cord injury Athletes with systemic or HLA-B27–associated arthritis require cardiovascular assessment for possible cardiac complications during exercise For those with micrognathia (open bite and exposed teeth), mouth guards are helpful If uveitis is present, risk of eye damage from trauma is increased; ophthalmologic assessment is recommended In visually impaired athletes, guidelines for functionally 1-eyed athletes should be followed
Juvenile dermatomyositis, idiopathic myositis Systemic lupus erythematosus Raynaud phenomenon	Qualified yes Qualified yes Qualified yes	Athlete with juvenile dermatomyositis or systemic lupus erythematosus with cardiac involvement requires cardiology assessment before participation. Athletes receiving systemic corticosteroid therapy are at higher risk for osteoporotic fractures and avascular necrosis, which should be assessed before clearance; those receiving immunosuppressive medications are at higher risk for serious infection. Sports activities should be avoided when myositis is active. Rhabdomyolysis during intensive exercise can cause renal injury in athletes with idiopathic myositis and other myopathies. Because of photosensitivity with juvenile dermatomyositis and systemic lupus erythematosus, sun protection is necessary during outdoor activities. With Raynaud phenomenon, exposure to the cold presents risk to hands and feet
SICKLE CELL		
Sickle cell disease	Qualified yes	Athlete needs individual assessment In general, if illness status permits, all sports may be played; however, any sport or activity that entails overexertion, overheating, dehydration, or chilling should be avoided Participation at high altitude, especially when not acclimatized, also poses risk of sickle cell crisis
Sickle cell trait	Yes	Athletes with sickle cell trait generally do not have increased risk of sudden death or other medical problems during athletic participation under normal environmental conditions; however, when high exertional activity is performed under extreme conditions of heat and humidity or increased altitude, such catastrophic complications have occurred rarely Athletes with sickle cell trait, like all athletes, should be progressively acclimatized to the environment and to the intensity and duration of activities and should be sufficiently hydrated to reduce the risk of exertional heat illness and/or rhabdomyolysis According to National Institutes of Health management guidelines, sickle cell trait is not a contraindication to participation in competitive athletics, and there is no requirement for screening before participation More research is needed to fully assess potential risks and benefits of screening athletes for sickle cell trait

This table is intended for use by medical and nonmedical personnel. "Needs evaluation" means that a physician with appropriate knowledge and experience should assess the safety of a given sport for an athlete with the listed medical condition. Unless otherwise noted, this need for special consideration is because of variability in the severity of the disease, the risk of injury for the specific sports, or both.

Figure 686-1 **Classification of sports according to cardiovascular demands (based on combined static and dynamic components).** This classification is based on peak static and dynamic components achieved during competition. The higher values may be reached during training. The increasing dynamic component is defined in terms of the estimated percentage of maximal oxygen uptake (Max O_2) achieved and results in increasing cardiac output. The increasing static component is related to the estimated percentage of maximal voluntary contraction (MVC) reached and results in increasing blood pressure load. Activities with the lowest total cardiovascular demands (cardiac output and blood pressure) are shown in box IA, and those with the highest demands are shown in box IIIC. Boxes IIA and IB depict activities with low to moderate total cardiovascular demands; boxes IIIA, IIB, and IC depict activities with moderate total cardiovascular demands; and boxes IIIB and IIC depict high-moderate total cardiovascular demands. These categories progress diagonally across the graph from lower left to upper right. [a]Danger of bodily collision. [b]Increased risk if syncope occurs. [c]Participation is not recommended by the American Academy of Pediatrics. [d]The American Academy of Pediatrics classifies cricket in the IB box (low static component and moderate dynamic component). *(From Mitchell JH, Haskell W, Snell P, et al: 36th Bethesda conference. Task force 8: classification of sports.* J Am Coll Cardiol *45:1364–1367, 2005.)*

in retrospect there were preceding symptoms of dizziness, chest pain, syncope, palpitations, shortness of breath, and/or a family history of early, unexpected death. Chest radiographs, electrocardiograms, and echocardiograms are not recommended as routine screening tests. If there is a **suspicion** of heart disease, such as a history of syncope, presyncope, palpitations, or excessive dyspnea with exercise, or a family history of a condition such as hypertrophic cardiomyopathy or prolonged QT or Marfan syndrome, the evaluation should be complete and include a 12-lead electrocardiogram, an echocardiogram, Holter or event-capture monitoring, and a stress test with electrocardiographic monitoring. Recommendations for participation with identified cardiac disease should be made in consultation with a cardiologist.

Disqualification and limitations for sports participation among various medical conditions are available from the American Academy of Pediatrics (see Table 686-3). Sports may also be classified by intensity (Fig. 686-1) and contact (Table 686-4). Athletes may seek to participate in sports against medical advice and have done so successfully for professional sports. Section 504(a) of the Rehabilitation Act of 1973 prohibits discrimination against disabled athletes if they have the capabilities or skills required to play a competitive sport. This was reinforced through the Americans with Disabilities Act of 1990. An amateur athlete has no absolute right to decide whether to participate in competitive sports. Participation in competitive sports is considered a privilege, not a right. *Knapp v Northwestern University* established that "difficult medical decisions involving complex medical problems can be made by responsible physicians exercising prudent judgment (which will be necessarily conservative when definitive scientific evidence is lacking or conflicting) and relying on the recommendations of specialist consultants or guidelines established by a panel of experts."

Chapter 687

Management of Musculoskeletal Injury

Kevin P. Murphy and Aaron M. Karlin

MECHANISM OF INJURY

Acute Injuries

Sprains, strains, and contusions account for the majority of musculoskeletal injuries. A **sprain** is an injury to a ligament or joint capsule. Most sprains are grades I-III. A *grade I* sprain is defined as mild damage to a ligament or ligaments without instability of the affected joint. A *grade II* sprain is considered a partial tear to the ligament, stretched to the point that it becomes loose. *Grade III is a complete tear of the ligament with instability to the affected joint.* A **strain** is an injury to a muscle or tendon and these, too, are graded I-III. *Grade I* muscle strains involve disruption of only a few muscle fibers, pain is mild to moderate and range of motion and strength are at or near normal. *Grade II* strains represent a more significant partial tear of the muscle and frequently involve loss of range of motion and strength. *Grade III* strains are defined as complete rupture of the musculotendinous unit. A **contusion** is a crush injury to any soft tissue. The history of the injury is especially helpful in assessing musculoskeletal trauma. More severe injuries, indicating internal derangement, can have acute signs and symptoms such as immediate swelling, deformity, numbness or "give-way" weakness, a loud painful pop, mechanical locking of the joint, or instability.

Overuse Injuries

Overuse injuries are caused by repetitive microtrauma that exceeds the body's rate of repair. This occurs in muscles, tendons, bone, bursae, cartilage, and nerves. Overuse injuries occur in all sports but more commonly in sports emphasizing repetitive motion (swimming, running, tennis, and gymnastics). Factors can be categorized into extrinsic (training errors, poor equipment or workout surface) and intrinsic (athlete's anatomy or medical conditions). Training error is the most commonly identified factor. At the beginning of the workout program, athletes might violate the 10% rule: Do not increase the duration or intensity of workouts more than 10% per week. Intrinsic factors include abnormal biomechanics (leg-length discrepancy, pes planus, pes cavus, tarsal coalition, valgus heel, external tibial torsion, and femoral anteversion), muscle imbalance, inflexibility, and medical conditions (deconditioning, nutritional deficits, amenorrhea, and obesity). The athlete should be asked about the specifics of training. Runners should be asked about their shoes, orthotics, running surface, weekly mileage or time spent running per week, speed or hill workouts, and previous injuries and rehabilitation. When causative factors are identified, they can be eliminated or modified so that after rehabilitation the athlete does not return to the same regimen and suffer reinjury.

For athletes engaged in excessive training that causes an overuse injury (e.g., multiple-sport school athletes), curtailing all exercise may not be necessary. Treatment is a reduction of training load (relative rest) combined with a rehabilitation program designed to return athletes to their sport as soon as possible while minimizing exposure to reinjury. Early identification of an overuse injury requires less alteration of the workout regimen.

The goals of treatment are to control pain and spasm to rehabilitate flexibility, strength, endurance, and proprioceptive deficits (Table 687-1). In many overuse injuries, the role of inflammation in the process is minimal. For most injuries to tendons, the term *tendinitis* is obsolete because there is little or no inflammation on histopathology of tendons. Instead, there is evidence of microscopic trauma to the tissue. Most of these entities are now more appropriately called **tendinosis** and, when the tendon tissue is scarred and very abnormal, **tendinopathy**. With tendinosis, there is less of a role for antiinflammatory medication in the treatment, except as an analgesic.

INITIAL EVALUATION OF THE INJURED EXTREMITY

Initially, the examiner should determine the quality of the peripheral pulses and capillary refill rate as well as the gross motor and sensory function to assess for neurovascular injury. The first priorities are to maintain vascular and skeletal stability.

Criteria for immediate attention and rapid orthopedic consultation include vascular compromise, nerve compromise, and open fracture. The exposed wound should be covered with sterile saline-soaked gauze, and the injured limb should be padded and splinted. Pressure should

Table 687-1 Staging of Overuse Injuries

GRADE	GRADING SYMPTOMS	TREATMENT
I	Pain only after activity Does not interfere with performance or intensity Generalized tenderness Disappears before next session	Modification of activity, consider cross-training, home rehabilitation program
II	Minimal pain with activity Does not interfere with performance More localized tenderness	Modification of activity, cross-training, home rehabilitation program
III	Pain interferes with activity and performance Definite area of tenderness Usually disappears between sessions	Significant modification of activity, strongly encourage cross-training, home rehabilitation program, and outpatient physical therapy
IV	Pain with activities of daily living Pain does not disappear between sessions Marked interference with performance and training intensity	Discontinue activity temporarily, cross-training only, oral analgesic, home rehabilitation program, and intensive outpatient physical therapy
V	Pain interferes with activities of daily living Signs of tissue injury (e.g., edema) Chronic or recurrent symptoms	Prolonged discontinuation of activity, cross-training only, oral analgesic, home rehabilitation program, and intensive outpatient physical therapy

be applied to any site of bleeding. Additional criteria include deep laceration over a joint, unreducible dislocation, grade III (complete) tear of a muscle–tendon unit, and displaced, significantly angulated fractures (depends on the bone involved, the degree of displacement and angulation, and neurovascular status of the extremity).

TRANSITION FROM IMMEDIATE MANAGEMENT TO RETURN TO PLAY

Rehabilitation of a musculoskeletal injury should begin on the day of the injury.

Phase 1

Limit further injury, control swelling and pain, and minimize strength and flexibility losses. **PRICE** principles (**P**rotection, **R**est, **I**ce, **C**ompression, and **E**levation) need to be applied. Crutches, air stirrups for ankle sprains, slings for arm injuries and elastic wraps (4-8 inches) for compression are a helpful inventory of office supplies. Ice can be placed directly over the injury as tolerated for 20 min continuously 3-4 times per day until the swelling resolves. Compression limits further bleeding and swelling but should not be so tight that it limits perfusion. Elevation of the extremity promotes venous return and limits swelling. A nonsteroidal antiinflammatory drug or acetaminophen is indicated for analgesia.

Pain-free isometric strengthening and range of motion should be initiated as soon as possible. Pain inhibits full muscle contraction; deconditioning results if the pain and resultant nonuse persist for days to weeks, thus delaying recovery. Education about the nature of the injury and the specifics of rehabilitation exercises, including handouts with written instructions and drawings demonstrating the exercises, are helpful.

Phase 2

Improve strength and range of motion (i.e., flexibility) while allowing the injured structures to heal. Protective devices are removed when the patient's strength and flexibility improve and activities of daily living are pain free. Flexibility can then be improved by a program of specific stretches, held for 15-30 sec for 3-5 repetitions, once or twice daily. A physical therapist or athletic trainer is invaluable in guiding the athlete through this process. Protective devices might need to be used for months during sports participation. Swimming, water jogging, and stationary cycling are good aerobic exercises that can allow the injured extremity to get relative rest or be used pain free while maintaining cardiovascular fitness.

Phase 3

Achieve near-normal strength and flexibility of the injured structures and further improve or maintain cardiovascular fitness. Strength and endurance are improved under controlled conditions using elastic bands and eventually exercise equipment followed by free weights. Sensory proprioceptive training allows the athlete to redevelop the kinesthetic sense critical to joint function and stability.

Phase 4

Return to exercise or competition without restriction. When the athlete has reached nearly normal flexibility, strength, proprioception, and endurance, the athlete can start sports-specific exercises. The athlete will make the transition from the rehabilitation program to functional rehabilitation appropriate for the sport. Substituting sports participation for rehabilitation is inappropriate; rather, there should be progressive stepwise functional return to a full activity or play program. For instance, a basketball player recovering from an ankle injury might begin a walk-run-sprint-cut program before returning to competition. At any point in this progression, if pain is experienced, the athlete needs to stop, apply ice, avoid running for 1-2 days, continue to do ankle exercises, and then resume running at a lower intensity and progress accordingly.

Relative Rest and Return-to-Play Guidelines

Relative rest means that the athlete can do whatever the athlete wants as long as the injured structures do not hurt during or within 24 hr of the activity. Exercising beyond the pain threshold delays recovery.

DIFFERENTIAL DIAGNOSES OF MUSCULOSKELETAL PAIN

Traumatic, rheumatologic, infectious, hematologic, psychologic, congenital, and oncologic processes can cause the presenting complaint of musculoskeletal pain. Symptoms such as fatigue, weight loss, rash, multiple joint complaints, fever, chronic or recent illness, and persistent pain despite conservative care suggests a diagnosis other than sports-related trauma. The possibility of child abuse as an etiology is not to be overlooked permeating all socioeconomic strata. Incongruity between the patient's history and physical examination findings should lead to further evaluation. A negative review of systems with an injury history consistent with the physical findings suggests a sports-related etiology.

687.1 Growth Plate Injuries

Kevin P. Murphy and Aaron M. Karlin

Approximately 20% of pediatric sports injuries seen in the emergency department are fractures, and 25% of those fractures involve an epiphyseal growth plate or physis (see Chapter 683). Growth in long bones occurs in 3 areas and is susceptible to injury. Immature bone can be acutely injured at the **physis** (Salter-Harris fractures, see Chapter 683.2), the **articular surface** (osteochondritis dissecans), or the **apophysis** (avulsion fractures). Boys suffer about twice as many physeal fractures as girls; the peak incidence of fracture is during peak height velocity (girls: age 12 ± 2.5 yr; boys: age 14 ± 2 yr). The physis is a pressure growth plate and is responsible for longitudinal growth in bone. The apophysis is a bony outgrowth at the attachment of a tendon and is a traction physis. The epiphysis is the end of a long bone, distal or proximal to the long bone, and contains articular cartilage at the joint.

Physeal injuries of the distal radius occur most often in the growing child or adolescent resulting from excessive force applied to the upper extremity. Injuries of this nature can be seen in athletes including those participating in gymnastics, cheerleading, ice skating, hockey and weight lifting. Mechanisms of injury include falls onto an outstretched hand or repetitive dorsiflexion and axial loading through the distal radius (see Chapter 693). Chronic wrist pain can be seen in up to 79% of young gymnasts, particularly female gymnasts between the ages of 12 and 14 yr. With repetitive axial loading temporary metaphyseal ischemia may be induced preventing cartilage calcification and causing the physis to widen. With widening of the distal radial physis, microfractures can develop. Clinical features involve radial wrist pain particularly dorsal with passive and active hyperextension activities relieved with suspension of the offending activity. Tenderness or focal pain around the circumference of the distal radius is often noted. Differential diagnosis includes metacarpal fractures, scaphoid fracture and in the older child, De Quervain tenosynovitis. Juvenile idiopathic arthritis always needs to be considered in a child with a painful swollen wrist not to exclude malignancy or an infectious process. X-rays of the wrist can be helpful particularly when compared to the contralateral extremity. Radiographs can show physeal widening with cystic changes involving the metaphyseal segment, beaking of the distal epiphysis and in later stages, positive ulnar variance. Bone scan may be helpful for stress fractures followed by MRI if subsequently needed. PRICE principles are followed with nonnarcotic pain management. Salter-Harris fractures types I and II can be treated with closed reduction and immobilization. Ulnar shortening osteotomy may be necessary in the athlete with significant ulnar positive variance. Physeal injuries at the knee (distal femur, proximal tibia) are rare. Growth disturbance following a growth plate injury is a function of location and the part of the physis fractured. These factors influence the probability a physeal bar will form, resulting in growth arrest. The areas making the largest contribution to longitudinal growth in the upper extremities are the proximal humerus and distal radius and ulna; in the lower extremities, they are the distal femur and the proximal tibia and fibula. Injuries to these areas are more likely to cause growth disturbance compared with physeal injuries at the other end of these long bones. The type of the physis fracture relative to risk of growth disturbance is described by the Salter-Harris classification system (see Table 683-1). A grade I injury is least likely to result in growth disturbance, and grade V is the most likely fracture to result in growth disturbance.

Osteochondritis dissecans (OCD) affects the subchondral bone and overlying articular surface (see Chapter 683). With avascular necrosis of subchondral bone, the articular surface can flatten, soften, or break off in fragments. The etiology is unknown but may be related to repetitive stress injury in some patients. The condition most commonly affects the knee (lateral aspect of the medial femoral condyle in 70% of patients and lateral femoral condyle in 20%) with the patella in 10%. Other joints where OCD lesions are also seen are the ankle (talus), elbow (usually involving the capitellum), and radial head. OCD classically affects athletes in their 2nd decade. The most common presentation is poorly localized vague knee pain. There is rarely a history of recent acute trauma. Some OCD lesions are asymptomatic (diagnosed on "routine" radiographs), whereas others are manifested as joint effusion, pain, decreased range of motion, and mechanical symptoms (locking, popping, catching). Activity usually worsens the pain.

Figure 687-1 Osteochondritis dissecans in the elbow. *(From Anderson SJ: Sports injuries.* Curr Probl Pediatr Adolesc Health *35:105–176, 2005.)*

Physical examination might show no specific findings. Sometimes tenderness over the involved condyle can be elicited by deep palpation with the knee flexed. Diagnosis is usually made with plain radiographs (Fig. 687-1). A tunnel view radiograph can be obtained to better view the posterior two-thirds of the femoral condyle. Treatment of OCD remains controversial. Intact lesions can often be treated symptomatically with or without activity modification or immobilization. Free fragments often require surgical removal. Drilling techniques can be utilized and are helpful in stimulating new bone formation, healing, and return of mobile bodies to their original donor sites. Long-term sequelae can be seen in up to 25% with atypical lesions, older age, effusion, and lesions of large size.

Avulsion fractures occur when a forceful muscle contraction dislodges the apophysis from the bone. They occur most commonly around the hip (Fig. 687-2) and are treated nonsurgically. Acute fractures to other apophyses (knee and elbow) require urgent orthopedic consultation. Chronically increased traction at the muscle–apophysis attachment can lead to repetitive microtrauma and pain at the apophysis. The most common areas affected are the knee (Osgood-Schlatter and Sinding-Larsen-Johansson disease), the ankle (Sever disease) (Fig. 687-3), and the medial epicondyle (Little League elbow). Traction apophysitis of the knee and ankle can potentially be treated in a primary care setting. The main goal of treatment is to minimize the intensity and incidence of pain and disability. Exercises that increase the strength, flexibility, and endurance of the muscles attached at the

apophysis, using the relative rest principle, are appropriate. Symptoms can last for 12-24 mo if untreated. As growth slows, symptoms abate.

Bibliography is available at Expert Consult.

687.2 Shoulder Injuries

Kevin P. Murphy and Aaron M. Karlin

Shoulder pain associated with radiating symptoms down the arm should raise the possibility of a neck injury. *Neck pain and tenderness or limitation of cervical range of motion requires that the cervical spine be immobilized and that the athlete be transferred for further evaluation.* If there is no neck pain or tenderness or limitation of motion of the cervical spine, then the shoulder is likely the site of the primary injury.

CLAVICLE FRACTURES

Clavicle fracture is one of the most common shoulder injuries. Injury is usually sustained by a fall on the lateral shoulder, on an outstretched hand, or by direct blow. Approximately 80% of fractures occur in the middle third of the clavicle. With younger children, plastic bowing of the clavicle may be present instead of an overt fracture and should be treated in the same fashion. Treatment is conservative and includes the use of an arm sling for comfort and protection. Healing time is shorter in comparison to adults, generally 4-6 wk. And additional 2-3 wk period of protection from contact/collision activities is recommended after clinical and radiographic healing is achieved to prevent reinjury. If nondisplaced, most medial and lateral clavicular fractures can be managed similar to middle 3rd clavicular fractures. Displaced lateral and medial third fractures require orthopedic consultation because of a higher incidence of acromioclavicular osteoarthritis (lateral) and physeal involvement (medial). Distal clavicular osteolysis is likely an overuse injury associated with slow dissolution and resorption of bone. The cause of injury is unclear, appearing most consistent with a stress reaction or fracture at the site of considerable force. This lesion is commonly seen in weightlifting athletes and can be seen in the older children. Nonoperative treatment including activity limitations, ice, nonsteroidal antiinflammatory agents and cortisone injections can be helpful. Gripping the bar at a greater distance for the weightlifter may be helpful. For those not willing to modify weightlifting activity or with persistent symptoms despite conservative care, surgery can be very successful and involves removal of the distal clavicle (approximately 1 cm) with no loss of strength and full return to activity anticipated.

ACROMIOCLAVICULAR SEPARATION

An acromioclavicular (AC) separation most commonly occurs when an athlete sustains a direct blow to the acromion with the humerus in an adducted position, forcing the acromion inferiorly and medially. Force is directed toward the AC and coracoclavicular ligaments because of the inherent stability of the sternoclavicular joint. Patients have point tenderness at the AC joint, pain with lifting their arms above the level of their shoulder, and may have an apparent step-off between the distal clavicle and the acromion (Fig. 687-4).

Type I AC injuries involve isolated sprain of the AC ligament with the periosteal sleeve intact. There is no visible deformity and radiographs are normal. Pain is elicited with adduction of the humerus across the chest. **Type II** injuries involve the AC ligament and coracoclavicular ligament, as well as partial disruption of the periosteal sleeve. Radiographs may show slight widening of the AC joint though the distance between the clavicle and the coracoid process is unchanged in comparison to the uninjured shoulder. Treatment of type I and type II AC injuries is conservative and nonoperative and consists of ice, nonsteroidal antiinflammatories and a sling for immobilization and pain control acutely. Shoulder range of motion exercises and strengthening of the rotator cuff, deltoid and trapezius musculature are incorporated early in the course once pain free range improves to prevent residual joint stiffness. A short course of physical therapy may be helpful if range of motion limitations are present 2-4 wk out from

injury. Consideration for return to play is made when the patient no longer has focal AC joint tenderness, exhibits full painless range of motion, has strength sufficient to be functionally protected from a collision or fall, and can perform maneuvers required within their sport. Typically, return to play from a type I AC injury is 1-2 wk, and 2-4 wk for type II.

Type III injury is more severe involving further tearing of the AC and coracoclavicular ligaments and disruption of the periosteal tube with instability of the distal clavicle because of deltotrapezial fascial detachment. Radiographs will commonly show superior displacement of the distal clavicle from the coracoid of 25-100%. Treatment of type III AC injuries is controversial, although many can be treated nonoperatively similar to that described for types I and II AC injuries if there is no damage to the overlying skin or neurovascular compromise to the injured limb. The patient should be counseled regarding this injury, likely resulting in a noticeable defect, to ascertain whether this is acceptable. Surgery for type III AC injuries are uncommon and primarily for cosmetic reasons. **Types IV, V, and VI** AC injuries have progressive worsening of ligamentous and fascial disruption with varied locations of the clavicular displacement. These injuries should be referred to an orthopedist for consultation and operative repair.

ANTERIOR DISLOCATION

The most common mechanism of injury is making contact with another player with the shoulder abducted to 90 degrees and forcefully rotated externally. A common example of the latter is a football player tackling another player only with the arm. Patients complain of severe pain and that their shoulder "popped out of place" or "shifted." Patients with an unreduced anterior dislocation have a hollow region inferior to the acromion and a bulge in the anterior portion of the shoulder caused by anterior displacement of the humeral head. Abnormal sensation of the lateral deltoid region (axillary nerve) and the extensor surface of the proximal forearm (musculocutaneous nerve) should be noted.

Reduction of a dislocated shoulder should be made expediently assuming no presence of crepitans (concerning for fracture). Numerous safe methods for closed reduction have been described, including the traction–counter traction technique, the Stimson maneuver, and the abduction maneuver. Postreduction radiographs are helpful and may show evidence of a posterior lateral humeral head impaction fracture (Hill-Sachs lesion). Injuries to the surrounding soft tissues, including the anterior capsule and labrum, are best evaluated by MRI, often with an accompanying arthrogram of the glenohumeral joint. Once reduced, initial treatment of a dislocation includes placing the patient into an arm sling for comfort and protection. The duration of immobilization is controversial and may last anywhere from a few days to 4-6 wk. The most significant risk after an acute traumatic dislocation is recurrence. Most sports medicine practitioners encourage early range of motion and strengthening exercises as tolerated. Rehabilitation focuses upon progressive strengthening of the rotator cuff, deltoid, and periscapular muscles at increasing degrees of abduction and external rotation. Strengthening of the rotator cuff muscles is extremely important as they are the dynamic stabilizers of the glenohumeral joint, integral in preventing future dislocation. Plyometric exercises may also be incorporated near the end of rehabilitation to improve proprioceptive function in preparation for return to athletics. Patients can return to play when strength, flexibility, and proprioception are equal to the uninjured shoulder to the extent that they are able to protect the shoulder and perform sports specific activities without pain. Surgery is to be considered in cases of multiple recurrent dislocations or in those individuals that fail to heal adequately after prolonged rehabilitation. Additionally, early operative repair should be considered for athletes participating in contact or collision spots that inherently have higher recurrence rates.

ROTATOR CUFF INJURY

The rotator cuff muscles comprise the supraspinatus, infraspinatus, teres minor, and subscapularis. The function of these muscles is to rotate the humerus and stabilize the humeral head against the glenoid. The supraspinatus is most commonly injured, an acute strain caused by trauma or chronic tendinosis from overuse. Specifically, rotator cuff tendinosis commonly presents with complaint of pain with overhead arc of motion, such as with throwing, lifting, or reaching for objects above one's head. Pain is often poorly localized about the shoulder, although may be referred to the deltoid. Onset of pain is often insidious and commonly associated with increased frequency or duration of overhead throwing or lifting activities. Pain is exacerbated with these or other activities but is often present at rest; nighttime pain in more severe cases. On exam, manual muscle testing of the cuff muscles often produces pain and in some cases weakness in comparison to the uninjured shoulder. Supraspinatus tendinosis produces pain with active abduction against resistance in which the patient abducts the arm to 90 degrees, forward flexes to 30 degrees anterior to the parasagittal plane, and internally rotates the humerus.

Treatment of rotator cuff tendinosis includes relative rest from athletics or activities causing pain, ice, analgesia or nonsteroidal antiinflammatory use. Strengthening of the rotator cuff and scapular stabilizer musculature, modifications of technique, and core strengthening are important components of rehabilitation often supervised by a physical therapist. In the young athlete, rotator cuff pain is most commonly a result of glenohumeral instability and not rotator cuff impingement syndrome, more commonly seen in adults and caused by impingement of the rotator cuff by the bony structures superior to it. As a result, treatment focusing on stretching alone can make symptoms worse. Return to play often includes gradual increases in load placed upon the rotator cuff as the patient resumes their prior activities such as an interval throwing program in baseball.

Glenoid labrum tears may present in similar insidious fashion to rotator cuff tendinosis or be associated with an acute traumatic dislocation. This is frequently manifested with pain in the glenohumeral joint

and may be associated with a sensation of clicking or catching in the shoulder. This can frequently be reproduced on exam. One of the most common lesions is a superior labrum anterior and posterior lesion. Throwing athletes are at particular risk. Mechanism of injury is thought to be related to a traction injury along the long head of the biceps at its attachment at the superior glenoid labrum occurring during a throwing cycle. Radiographs are usually normal. MRI with arthrogram is the best study to identify glenoid labrum pathology.

Proximal humeral stress fracture (epiphysiolysis) is an uncommon cause of proximal shoulder pain and is suspected when shoulder pain does not respond to routine measures. Gradual onset of deep shoulder pain occurs in a young (open epiphyseal plates) athlete involved in repetitive overhead motion, such as in baseball, tennis, or swimming, but with no history of trauma. Tenderness is noted over the proximal humerus; the diagnosis is confirmed by detecting a widened epiphyseal plate on plain radiographs, increased uptake on nuclear scan, or edema of the physis on MRI. Treatment is total rest from throwing for 6-8 wk.

Non–sports-related conditions that need to be considered in the child with a painful shoulder include the Sprengel deformity. This deformity involves the scapula, which fails to descend from its cervical region overlying the 1st through 5th ribs. Children often present with a shortened neckline and lack of normal scapular thoracic motion. Malpositioning of a glenoid can cause limited forward flexion and abduction of the shoulder. An omovertebral bar is present in up to 50% of cases. This bar connects the superior medial angle of the scapula and the cervical spine and consists of fibrous cartilaginous tissue or bone. Other regional abnormalities can include scoliosis with a prominent scapula on the convex side, rib anomalies, and Klippel-Feil syndrome. Winging of the scapula always raises the question of muscular dystrophy, particularly scapular thoracic. Family histories can be most helpful. Primary bone tumors (see Chapter 501) common to the upper extremities include Ewing sarcoma of the scapula and osteogenic sarcoma of the proximal humerus, in addition to osteoblastomas and chondroblastomas common to the diaphysis and epiphysis of long bones. The most common presenting manifestations of osteosarcoma are pain, upper limb dysfunction, and swelling. Similar presentations can be seen in Ewing sarcoma, along with weight loss and fever. Symptoms not responding to conservative treatment require further investigation and specialty consultation.

Bibliography is available at Expert Consult.

687.3 Elbow Injuries

Kevin P. Murphy and Aaron M. Karlin

ACUTE INJURIES

The most commonly dislocated joint in childhood is the elbow. Radial head subluxation, or "nurse maid's elbow," comprises the majority of these and is discussed in more depth in Chapter 681. Posterior dislocation is the next most common type of elbow dislocation, with its mechanism being that of falling backward onto an outstretched arm with the elbow in extension. The dislocation may be complete or incomplete, termed "perched," with the trochlea subluxed upon the top of the coronoid process. The ulnar collateral ligament is commonly disrupted along with other components of the soft-tissue capsule about the elbow. Fractures of the olecranon (greater than 80%) or medial epicondyle may be present as well. An obvious deformity is visualized with the olecranon process displaced prominently behind the distal humerus. Careful examination of the distal radius and ulnar pulses to assess vascular integrity of the distal upper arm is important because of the potential for injury to the brachial artery. Sensation to the distal extremity should also be assessed because of possible injury to the radial, median, and ulnar nerves. Reduction should be performed as soon as possible before significant swelling and muscle spasm potentially complicate the procedure. Longitudinal traction is applied to the forearm with gentle upward pressure on the distal humerus so that the coronoid process clears the trochlea. If reduction is unable to be performed, the arm should be placed in a padded splint and sling and the patient transported to an emergency facility.

Figure 687-5 Deflection of the coronoid fat pad with a joint effusion (fat pad sign) showing evidence of a fracture. *(From Gomez JE: Upper extremity injuries in youth sports.* Pediatr Clin North Am *49:593–626, 2002.)*

Supracondylar humeral fractures can result from the same mechanism of injury as elbow dislocations and can be difficult to distinguish from a posterior dislocation because of significant swelling about the elbow joint. These, too, can be complicated by concomitant injury to the brachial artery and to a lesser extent the median, radial, and ulnar nerves. The injury typically occurs in the 1st decade of life, which is associated with peak hyperlaxity of the elbow joint in children between the ages of 5 and 8 yr. An acute compartment syndrome can develop after these fractures, which is associated with a fat pad sign (Fig. 687-5). These fractures should be referred for orthopedic consultation and are discussed in more depth in Chapter 683.

Direct trauma to the elbow can cause bleeding and inflammation in the olecranon bursa resulting in *olecranon bursitis*. Aspiration is rarely required and this injury can be managed with ice, compressive dressing and analgesia (RICE principles). An overlying elbow pad provides comfort during activity and prevention of reinjury.

Chronic Injuries

Overuse injuries occur primarily in throwing sports and sports that require repetitive wrist flexion or extension or demand weightbearing on hands (gymnastics). "Little League elbow" is a broad term for several different elbow problems.

Throwing overhand creates valgus stress to the elbow with medial opening of the joint and lateral compressive forces.

Medial elbow pain is a common complaint of young throwers, resulting from repetitive valgus overload of the wrist flexor-pronator muscle groups and their attachment on the medial apophysis. In preadolescents who still have maturing secondary ossification centers,

traction apophysitis of the medial epicondyle is likely. Patients have tenderness along the medial epicondyle; pain is exacerbated by valgus stress or resisted wrist flexion and pronation. Wrist pain may be present in more severe cases. Radiographs may show widening of the growth plate at the medial apophysis in comparison to the uninjured elbow. Treatment includes no throwing for 4-6 wk, pain-free strengthening, and stretching of the flexor–pronator group followed by a 1-2 wk progressive functional throwing program with careful rehabilitation. Incorporation of core strengthening and scapular stabilizing exercise, as well as addressing proper throwing mechanics (to reduce the load upon the medial elbow), are important components of rehabilitation. This problem has to be treated with rest because of the risk of nonunion of the apophysis and chronic pain. If pain occurs acutely, *avulsion fracture of the medial epicondyle* must be considered. Radiographs should be taken in any thrower with acute elbow pain (Fig. 687-6). If the medial epicondyle is avulsed, orthopedic consultation is indicated.

In older adolescents and young adults with a fused apophysis, the vulnerable structure is the *ulnar collateral ligament* (UCL). UCL sprains/tears are common in sports requiring high-velocity throwing or overhead activities. Medial elbow pain primarily worse during the acceleration phase of throwing is common. A sensation of elbow "opening" during throwing is also frequently described. On exam focal tenderness to palpation over the UCL is present. Additionally laxity may be appreciated with valgus stress of the elbow when flexed to 30 and/or 90 degrees. Radiographs are generally unremarkable. MRI with arthrography or ultrasonography is often necessary to assess the integrity of the UCL. Partial tears can be treated with a period of time off from throwing (2-4 wk) followed by careful progressive rehabilitation as discussed above for medial elbow pain. If there is a complete tear, surgical repair is indicated if the athlete desires to continue a pitching career.

Medial epicondylitis (golfer's elbow) is another common cause of medial elbow pain in the individual with fused apophysis. It is commonly caused by overuse of the flexor pronator muscle groups at their origin at the medial humeral epicondyle. This occurs frequently in athletics or activities with repetitive wrist flexion. Tenderness is noted over the medical epicondyle and exacerbated by passive wrist extension or resisted wrist flexion. Treatment includes rest from the inciting activity, ice, stretching and strengthening of the wrist flexors, forearm straps, counterforce bracing, and analgesia. Ulnar nerve dysfunction can be a complication of valgus overload and can occur with any of the diagnoses previously discussed. Persisting paresthesia or motor weakness in the ulnar nerve distribution should be evaluated with electromyography and nerve conduction studies.

Lateral elbow pain can be caused by compression during the throwing motion at the radiocapitellar joint. *Panner disease* is osteochondrosis of the capitellum that occurs between ages 7 and 12 yr (Fig. 687-7). *OCD* of the capitellum occurs at age 13-16 yr (see Fig. 687-1). These 2 entities might represent a continuum of the same disease. Although patients with both conditions present with insidious onset of lateral elbow pain exacerbated by throwing, patients with OCD have mechanical symptoms (popping, locking) and, more commonly, decreased range of motion. Patients with Panner disease have no mechanical symptoms and often have normal range of motion. The prognosis of Panner disease is excellent, and treatments consist of relative rest (no throwing), brief immobilization, and repeat radiographs in 6-12 wk to assess bone remodeling. In OCD, radiographs show a more focal lesion in the capitellum with eventual flattening and potentially fragmentation. MRI scan can be very helpful in the diagnosis early on and with subsequent staging. A diagnosis of OCD requires orthopedic consultation with treatment dependent upon the severity of the lesion and fragmentation.

Lateral epicondylitis (tennis elbow), the most common overuse elbow injury in adults, is relatively uncommon in children and

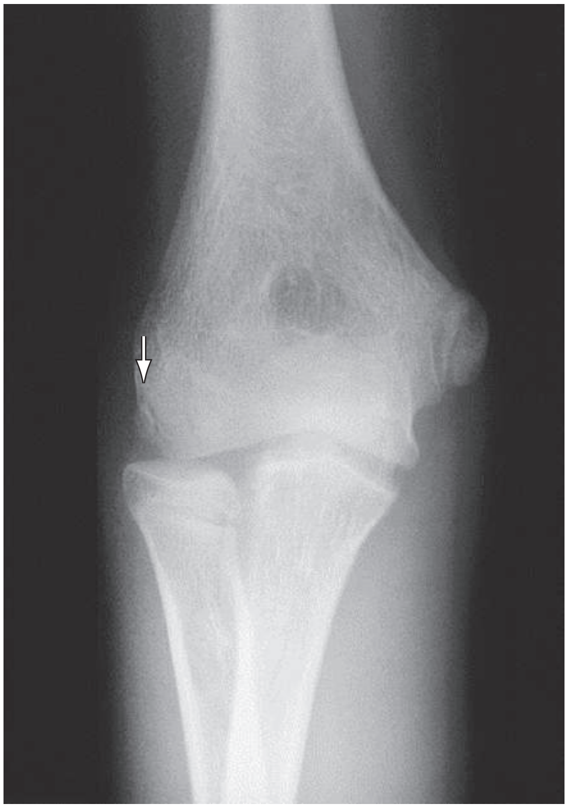

Figure 687-7 Panner disease. Note fragmentation of the humeral capitellum and flattening of the articular surface *(arrow). (Courtesy of Dr. Ralph J. Curtis. From Gomez JE: Upper extremity injuries in youth sports.* Pediatr Clin North Am *49:593–626, 2002.)*

adolescents. It is a tendinosis of the extensor muscle origin at the lateral humeral epicondyle commonly found in individuals performing activities requiring repetitive or prolonged grip. Tenderness is localized over the upper lateral epicondyle and is worsened with passive wrist flexion or resisted wrist extension. Treatment includes relative rest, analgesia, and specific stretching and strengthening exercises for the elbow and forearm. Improper equipment (i.e., wrong grip size or overstrung racket) and poor technique can contribute to onset of symptoms. Return to play should be gradual and progressive to prevent reinjury.

Elbow injuries can be minimized but not necessarily prevented by preseason stretching and strengthening exercises. The importance of core strengthening and scapular stabilization with respect to preventing elbow and shoulder injuries in the throwing athlete cannot be overstated. The most important consideration for preventing elbow injuries in throwers is limitation of the number of pitches and advising players, coaches, and athletes that they should stop immediately when they experience elbow pain. If it persists, they need medical evaluation. It has been recommended that a young pitcher have age specific limits on pitch counts including number of pitches thrown per game and per week, as well as maintaining appropriate days off between games pitched. A good rule of thumb is the maximal number of pitches per game should be approximately 6 times the pitcher's age in years.

Other less-common problems that cause elbow pain are ulnar neuropathy/subluxation, tricipital or bicipital tendonitis (distal), olecranon apophysitis, and loose bodies. Non–sports-related injuries that need to be considered in the child with a painful elbow include congenital conditions, such as radial dysplasia, including radial ulnar synostosis and mild persistent brachial plexus palsy. The elbow is not an uncommon site for inflammatory arthritides, including juvenile idiopathic arthritis, sepsis, hemophilia, and sickle cell disease. Neoplasia to consider includes osteoblastomas and chondroblastomas, common in the diaphysis and epiphysis of longer bones, in addition to osteosarcoma. As always, in the child with persistent symptoms who is not responding to conservative care, further diagnostic work up is always indicated.

687.4 Low Back Injuries

Kevin P. Murphy and Aaron M. Karlin

SPONDYLOLYSIS, SPONDYLOLISTHESIS, AND FACET SYNDROME

Spondylolysis

Spondylolysis, a common cause of back pain in athletes, is a stress fracture of the pars interarticularis (see Chapter 679.6). It can occur at any vertebral level but is most likely at L4 or L5. Complete spondylolysis has never been found in the newborn. Its occurrence increases between the ages of 5.5 and 6.5 yr to a rate of 5%, close to the frequency of 5.8% in the white population. Prevalence in adolescent athletes evaluated for low back pain is 13-47%. Besides acute hyperextension that causes an acute fracture, the mechanism of injury is either a congenital defect or hypoplastic pars, which is exacerbated by lumbar extension loading, or a stress fracture caused by repetitive extension loading. Ballet, weightlifting, gymnastics, and football are examples of sports in which repetitive extension loading of the lumbar spine occurs; it occurs in any activity in which there is repetitive extension loading, including swimming.

Patients often present with pain of insidious onset. However, there may be a precipitating injury such as a fall or single episode of hyperextension. The pain is worse with extension, can radiate to the buttocks, and can eventually affect activities of daily living. Rest or supine positioning usually alleviates the pain.

On examination, the pain is reproduced with lumbar extension while standing, especially when standing on 1 leg (single-leg hyperextension test). Limited forward spinal flexion and tight hamstrings may be seen. Neurologic examination should be normal. There is well-localized tenderness to deep palpation just lateral to the spinous process on the affected side and is usually at L4 or L5.

The diagnosis is confirmed by finding a pars defect on an oblique lumbar spine radiograph. The defect is rarely seen on anteroposterior (AP) and lateral views. Bone single-photon emission CT is needed to confirm diagnosis if radiographs are normal. A plain CT scan can help to identify the degree of bony involvement and is sometimes used to assess healing.

Treatment includes pain relief and activity restriction. Rehabilitation consisting of trunk strengthening, hip flexor stretching, and hamstring stretching is important in most cases. A thoracic lumbar sacral orthotic on a temporary basis may be helpful for the spondylolytic stress fracture resistant to healing by alternative conservative means.

Spondylolisthesis and Facet Syndrome

Spondylolysis, spondylolisthesis, and facet syndrome are injuries posterior to vertebral elements. *Spondylolisthesis* occurs when bilateral pars defects exist and forward displacement or slippage of a vertebra occurs on the vertebra inferior to it (see Chapter 679.6). *Facet syndrome* has a similar history and physical examination findings as spondylolysis. It is caused by instability or injury to the facet joint, posterior to the pars interarticularis and at the interface of the inferior and superior articulating processes. Facet syndrome can be established by identifying facet abnormalities on CT or by exclusion, requiring a nondiagnostic radiograph and nuclear scan to rule out spondylolysis.

Treatment of posterior element injuries is conservative, directed at reducing the extension-loading activity, often for 2-3 mo. Body mechanics, posture principals, core strengthening, and lumbar pelvic stabilization routines can be very helpful in the functional recovery of the motivated athlete. Walking, swimming and cycling can be appropriate exercises also during the rehabilitation phase. Rarely spinal segmental fusion can be indicated in the athlete with spondylolisthesis and persistent symptomatic segmental instability despite further conservative care.

LUMBAR DISK HERNIATION, STRAIN, AND CONTUSION

Intervertebral disc injury in children and the young athlete is uncommon. In contrast to the selective motor and sensory deficits often observed in adults with disc herniation, athletes younger than 20 yr of age have pain or tenderness less commonly identified over the course of the sciatic nerve. Physical examination findings may be minimal but usually include pain with forward flexion and lateral bending. It is unusual to have a positive straight leg test or any neurologic deficit in the young athlete with an injured disc. There may be tenderness of the vertebral spinous process at the level of the disc. A general aching sensation in the lower back or upper buttocks may be present. MRI usually confirms a clinical diagnosis. Assuming the herniation is not large and the pain is not intractable, the treatment of choice is conservative with analgesia and physical therapy. Surgery is rarely necessary.

Acute lumbar strain or contusion can be seen in the younger athlete and is usually associated with precipitating activity often outside of the normal routine. Physical examination reveals tenderness in the paraspinal and lateral soft tissues often associated with recreating the mechanisms of injury. Thoracic and lumbar strain in the school-age child is associated with obesity, deconditioning, positive family history, and poorly supervised and equipped recreational activity. Up to 20% of youth have experienced back pain at some point in their life (younger than age 15 yr). The school-age backpack is rapidly becoming the most common cause of back pain of a benign nature in children. Up to 74% of school backpackers experience pain. Back pain is more common with the heavy backpack (greater than 10-20% of body weight), female gender, large body mass index, and single shoulder strap.

Treatment is conservative including analgesia, myofascial release, massage, and physical therapy, as tolerated. The natural history of acute

back strain in adults is that 50% are better in 1 wk, 80% in 1 mo, and 90% in 2 mo, regardless of therapy. The course of back pain in young athletes is likely similar given the elimination of obvious precipitating influence and/or activities, as discussed above.

SACROILIITIS

Sacroiliitis manifests as pain over the sacroiliac joints; it is usually chronic but occasionally associated with a history of trauma. Patients have a positive result with the **Patrick test,** which includes resting the foot of the affected side on the opposite knee (hip flexed 90 degrees), stabilizing the opposite iliac crest, and externally rotating the hip on the affected side (pushing the knee down and lateral). Symptomatic improvement with knee-to-chest maneuvers and subsequent posterior pelvic tilt may be present. A radiograph of the sacroiliac joints is indicated, and if results are positive, exploration for a rheumatologic disease (ankylosing spondylitis [see Chapter 156], juvenile rheumatoid arthritis [see Chapter 155], ulcerative colitis [see Chapter 336]) is warranted.

Treatment is with relative rest, nonsteroidal antiinflammatory drugs, and physical therapy. Ankylosing spondylitis is more likely if the onset of lower back pain is before age 40 yr, if there is morning stiffness that is associated with improvement with activity, and if the pain has a gradual onset and has lasted longer than 3 mo.

OTHER CAUSES

Non–sports-related causes of low back pain are numerous and include infection (osteomyelitis, diskitis) and neoplasia. These should be considered in patients with fever, weight loss, other constitutional signs, or lack of response to initial therapy. Osteomyelitis of the lower back or pelvis is often, but not always, associated with fever. Scheuermann disease needs to be considered more common in males and younger adolescents, and needs to be distinguished from symptomatic postural roundback and congenital decompensating kyphosis. Atypical Scheuermann disease or thoracolumbar apophysitis can progress and become the pediatric equivalent of an adult compression fracture. Benign tumors of the spine include osteoid osteoma with intense focal nighttime pain, not activity related and almost always relieved by aspirin or nonsteroidal antiinflammatory agents. Osteoblastoma, eosinophilic granuloma, aneurismal bone cyst, and fibrous dysplasia are additional benign tumors not to be excluded. Malignant spinal tumors include the Ewing sarcoma (onion skin appearance) and osteogenic sarcoma (sunburst pattern) both associated with the Codman triangle. Metastatic tumors of the spine include neuroblastoma, spinal cord tumors, leukemia, and lymphoma. Wilms tumor can also metastasize to the spine and be associated with hemihypertrophy. Referred pain to the spine always needs to be considered. Conditions that can refer pain include pyelonephritis, renal osteodystrophy, pneumonia, endocarditis, cholecystitis, nephrolithiasis, pancreatitis, megacolon, constipation/ileus, hiatal hernia/reflux, pelvic inflammatory disease, and sickle cell crisis. Pregnancy is always a consideration in the age-appropriate female. Psychogenic pain and fibromyalgia can be seen in children. Child abuse can present in the spine with soft-tissue injuries more common than fractures. Posterior rib and spinous process fractures can be seen in up to 30% of abused children. Skeletal survey can be helpful with multiple injuries in multiple stages of healing.

Bibliography is available at Expert Consult.

687.5 Hip and Pelvis Injuries

Kevin P. Murphy and Aaron M. Karlin

Hip and pelvis injuries represent a small percentage of sports injuries, but they are potentially severe and require prompt diagnosis. Hip pathology can manifest as knee pain and normal findings on knee examination.

In children, *transient synovitis* is the most common cause. It usually manifests with acute onset of a limp, with the child refusing to use the affected leg and having painful range of motion on examination. There may be a history of minor trauma. This is a self-limiting condition that usually resolves in 48-72 hr.

Legg-Calvé-Perthes disease (avascular necrosis of the femoral head) also manifests in childhood with insidious onset of limp and hip pain (see Chapter 678.3).

Until the skeleton matures (Table 687-2), younger athletes are susceptible to apophyseal injuries (e.g., the anterior superior iliac spine). *Apophysitis* develops from overuse or from direct trauma. *Avulsion fractures* occur in adolescents playing sports requiring sudden, explosive bursts of speed (see Fig. 687-2). Large muscles contract and create force greater than the strength of the attachment of the muscle to the apophysis. Biomechanical susceptibility of the pelvis allows separation to occur in the cartilaginous region between the apophysis and the adjoining bone. The most common sites of avulsion fractures are the anterior superior iliac spine (sartorius and tensor fasciae lata), anterior inferior iliac spine (rectus femoris), lesser femoral trochanter (iliopsoas), ischial tuberosity (hamstrings), and the iliac crest (abdominal muscles). Symptoms include localized pain and swelling, with decreased strength and range of motion. Bilateral radiographs are important in order to allow for comparison to assess for displacement, if any, of the fracture fragment. Significant displacement or presence of a large fragment may require orthopedic consultation. Initial **treatment** includes ice, analgesics, rest, and pain-free range-of-motion exercises. Crutches are usually needed for ambulation. Surgery is usually not indicated because most of these fractures—even large or displaced ones—heal well. Direct contact to the bone around the hip and pelvis causes exquisitely tender subperiosteal hematomas called

hip pointers. These injuries are more commonly seen around the anterior superior iliac spine and the iliac crest. Limited active range of motion can be identified about the hip brought on by contracture of locally attached musculature such as hip flexors and hip abductors. Symptomatic care includes rest, ice, analgesia, and protection from reinjury.

Slipped capital femoral epiphysis usually occurs in the 11-15 yr age range during the time of rapid linear bone growth (see Chapter 678.4).

A *femoral neck stress fracture* can manifest as vague progressive hip pain in an endurance athlete. Girls with the female athlete triad are especially at risk. This diagnosis should always be kept in mind in the running athlete with vague anterior thigh pain. On examination, there may be pain with passive stretch of the hip flexors and pain with hip rotation. If radiographs do not demonstrate a periosteal reaction consistent with a stress fracture, a bone scan or MRI may be required. Orthopedic consultation is necessary in femoral neck stress fractures because of their predisposition to nonunion and displacement with minor trauma or continued weight bearing. These fractures carry increased risk of avascular necrosis of the femoral head.

Osteitis pubis is an inflammation at the pubic symphysis that may be caused by excessive side-to-side rocking of the pelvis. It can be seen in an athlete in any running sport and is more common in sports requiring more use of the adductor muscles such as ice hockey, soccer, and inline skating. Athletes typically present with vague groin pain that may be unilateral or bilateral. On physical examination, there is tenderness over the symphysis and sometimes over the proximal adductors. Adduction strength testing causes discomfort. Radiographic evidence (irregularity, sclerosis, widening of the pubic symphysis with osteolysis) might not be present until symptoms are present for 6-8 wk; a bone scan and MRI are more sensitive to early changes. Relative rest for 6-12 wk may be required. Some patients require corticosteroid injection as adjunctive therapy.

Acetabular labrum tears can occur in the hip, similar to glenoid labrum tears in the shoulder. Athletes might have a history of trauma and complain of sharp anterior hip pain associated with a clicking or catching sensation. Clinical diagnosis is difficult; magnetic resonance arthrography is useful for diagnosis.

Snapping hip syndrome is caused by the iliopsoas musculotendinous unit riding over the pectineal eminence of the pelvis, anterior hip capsule or the iliotibial band over the greater trochanter. Lack of flexibility in these muscles results in snapping, as the musculotendinous unit slides over the associated bony prominences. It is commonly seen in ballet dancers and runners; it can occur as an acute or overuse injury (more common). Athletes present with either a painful or painless click or snap in the hip, usually located lateral or anterior and deep in the joint. Examination often reproduces the symptoms. Radiographs are not usually needed in the work-up. Core weakness may be present leading to excessive movement about the hip girdle contributing to increased sliding of the tight muscle over the boney prominence. **Treatment** involves an analgesia, relative rest, biomechanical assessment, core flexibility, with stretching and strengthening of the involved soft tissue. The athlete may return to activity as tolerated. Common soft-tissue injuries around the hip and pelvis include strain and tendinosis of the hip flexors (groin) and hamstrings in addition to quadriceps contusions and greater trochanteric bursitis. Sportsman hernia also needs to be considered in the athlete with insidious onset exertional groin pain, worsening with Valsalva. Pain may radiate into the anterior thigh, inguinal region, rectum, perineum and/or scrotum. Tenderness to deep palpation may or may not be present. Resisted hip flexion and/or half sit ups may be provocative. MRI, CT scan, and bone scan can be helpful in ruling out other diagnoses, but usually are negative with respect to sports hernia pathology. Patients who continue with symptoms despite conservative care may be surgical candidates. Surgical repair can be 95% successful if anatomical lesions are identified. As with any child or adolescent presenting with a painful hip or pelvis, non–sports-related conditions need to be considered. Differential diagnoses may also include the epiphyseal dysplasias, recurrent or undiagnosed congenital or developmental hip dysplasia, additional causes of avascular necrosis including sickle cell anemia, Gaucher disease, rheumatoid arthritis, and other collagen disorders including steroid therapy. Traumatic hip dislocations are relatively rare in children but not to be overlooked. Leg-length discrepancies can be symptomatic at the hip in an otherwise able bodied child. Common tumors in lower extremities include osteosarcoma along with osteoblastoma, aneurismal bone cysts, and fibrous dysplasia (more common in the pelvis). Metastatic tumors to the lower extremities include neuroblastoma and lymphomas of various types, not to exclude leukemic infiltration with joint arthralgia. Child abuse always needs to be considered in a young patient with musculoskeletal pain no matter what the socioeconomic status.

687.6 Knee Injuries

Kevin P. Murphy and Aaron M. Karlin

Knee pain is common among adolescents. Acute knee injuries that cause immediate disability are likely to be due to fracture, patellar dislocation, anterior cruciate ligament (ACL) injury, or meniscal tear. The mechanism of injury is usually a weightbearing event. If the knee swells more immediately (within several hours of injury), the swelling is likely caused by a hemarthrosis and more severe injury. The injury most likely to occur with a hemarthrosis is an **ACL** injury. This injury (rare in children younger than 12 yr) is usually caused from being hit directly, landing off-balance from a jump, quickly changing direction while running, or hyperextension. Instability is often present but may be hard to detect in the presence of significant swelling. Girls are more than twice as likely as boys to disrupt their ACL, with a soccer injury a common scenario. Often, these injuries are associated with an avulsion injury of the anterior tibial spine. The majority of athletes with significant ACL injury need orthopedic consultation with consideration of ACL reconstruction. Chronic ACL insufficiency may increase the risk of meniscal injury and further joint dysfunction. Additional physeal-sparing reconstructions with minimal risk of growth arrest or angular deformity have been reported with success in children younger than 12 yr and adolescents.

Posterior cruciate ligament injury occurs from a direct blow to the region of the proximal tibia, such as might occur with a dashboard injury or a fall to the knees in volleyball. Posterior cruciate ligament injuries are rare and are usually treated nonsurgically.

Medial collateral ligament injuries result from a valgus blow to the outside of the knee. Isolated *lateral collateral ligament* injuries are uncommon and result from significant varus knee stress. Because they are extraarticular, lateral collateral ligament injuries should not produce much of a knee effusion and are generally less disabling. Isolated medial and lateral collateral injuries are generally managed nonsurgically with conservative care and appropriate rehabilitation.

Meniscal tears generally occur by the same mechanisms as ACL injuries. They are often associated with less hemarthrosis, significant joint line pain, and increased pain with full knee flexion. MRI scan will often yield the diagnosis; conservative care, including **PRICE** principles, is therapeutic for smaller injuries. Orthopedic consultation is indicated for larger tears not healing with conservative care and causing significant dysfunction inhibiting quality of life. An isolated meniscal tear in a child younger than age 10 yr is unusual, with surgery, again, only if conservative measures fail. The choice is often repair of the meniscus rather than surgical resection because of the increased potential in children for cartilaginous healing. Physeal injuries tend to predominate in younger patients, whereas the more skeletally mature adolescents tend to sustain medial collateral ligament injuries. Discoid meniscus (anatomical variant covering lateral tibial plateau) always needs to be considered, particularly in children younger than age 12 yr.

Patellar dislocation occurs most often as a noncontact injury when the quadriceps muscles forcefully contract to extend the knee while the lower leg is externally rotated. Patellar dislocation is the second most

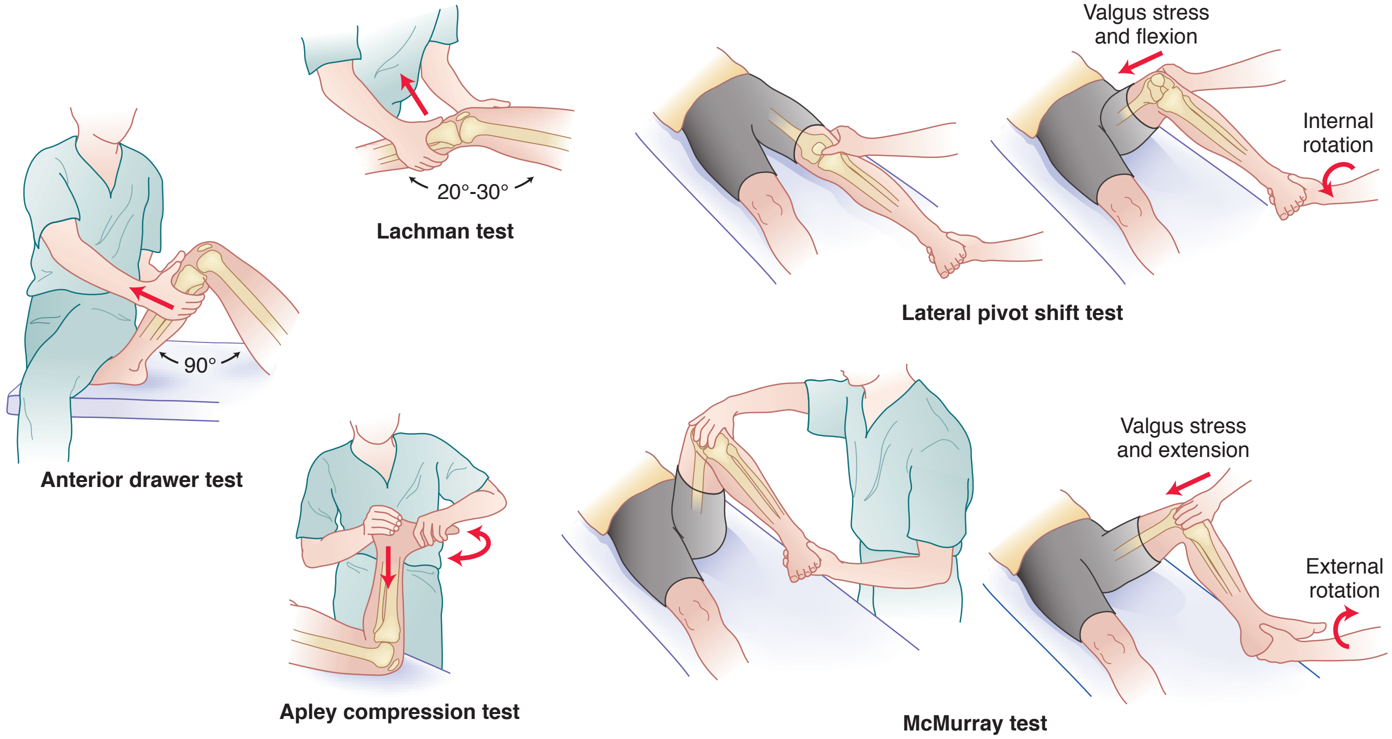

Figure 687-8 **Examination maneuvers include the Lachman, anterior drawer, lateral pivot shift, Apley compression, and McMurray tests (the right knee is shown).** The Lachman test, performed to detect anterior cruciate ligament (ACL) injuries, is conducted with the patient supine and the knee flexed 20-30 degrees. The anterior drawer test detects ACL injuries and is performed with the patient supine and the knee in 90 degrees of flexion. The lateral pivot shift test is performed with the patient supine, the hip flexed 45 degrees, and the knee in full extension. Internal rotation is applied to the tibia while the knee is flexed to 40 degrees under a valgus stress (pushing the outside of the knee medially). The Apley compression test, used to assess meniscal integrity, is performed with the patient prone and the examiner's knee over the patient's posterior thigh. The tibia is externally rotated while a downward compressive force is applied over the tibia. The McMurray test, used to assess meniscal integrity, is performed with the patient supine and the examiner standing on the side of the affected knee.

common cause of hemarthrosis. The patella is almost always dislocated laterally, and this motion tears the medial patellar retinaculum, causing bleeding in the joint. Recurrent episodes of patellar instability are associated with less swelling. Patellar dislocations are often associated with genu valgum, external tibial torsion, and general ligamentum hyperlaxity. Exercises to strengthen the quadriceps, particularly the vastus medialis, and the use of patella-tracking braces may be helpful. Recurrent instability can require surgical intervention. Surgical stabilization of the medial patellar tissues and lateral retinacular release can be helpful in more difficult cases.

INITIAL TREATMENT OF ACUTE KNEE INJURIES

The physician should inspect for an effusion and obvious deformities; if any deformity is present, the physician should assess neurovascular status and transfer the patient for emergency care as indicated. If no gross deformities are present and neurovascular integrity is intact, initial maneuvers include full passive extension and gentle valgus and varus stress to the knee while in extension. Comparison to the noninjured knee is always helpful for assessing degrees of laxity and range of motion. The patient's ability to contract the quadriceps should be noted. Pain occurring with quadriceps contraction or inability to contract the quadriceps muscle implies an injury to the extensor mechanism. Tenderness over the medial patella, medial retinaculum, or above the adductor tubercle is associated with a patellar dislocation (usually lateral). Point tenderness is consistent with fracture or injury to the underlying structure. Meniscal tears usually manifest as tenderness along the joint line, accentuated with flexion of the knee often beyond 90 degrees. Pain or limitation in either flexion or extension while rotating the tibia implies a meniscal injury. Ligament injury is manifested as pain or laxity with the appropriate maneuver (Fig. 687-8).

If a patient cannot weight-bear pain free or has clinical signs of instability, significant swelling or other major concern, the knee should be immobilized, crutches provided, and plain radiographs obtained. If the patella is dislocated, reduction may be achieved with gentle active assistive knee extension Straight-leg immobilizers offer no structural support and are only used for comfort and reminding the patient to be careful with any weight-bearing. A derotational hinge brace may be indicated for stabilization such as an injury when both ACL and medial collateral ligament have been traumatized. The leg should be elevated and an elastic wrap can be applied for compression (PRICE principles).

CHRONIC INJURIES

Patellofemoral Stress Syndrome

Patellofemoral stress syndrome (PFSS) is the most common cause of anterior knee pain. PFSS is also known as *patellofemoral pain syndrome* or *patellofemoral dysfunction* (see Chapter 677.5). It is a diagnosis of exclusion used to describe anterior knee pain that has no other identifiable pathology. Chondromalacia may be seen in association with softening of the articular cartilage underneath the patellar surface. Pain is usually difficult to localize. Patients indicate a diffuse area over the anterior knee as the source, or they might feel as if the pain is coming from behind the patella. Bilateral pain is common, and pain is often worse going up stairs, after sitting for prolonged periods, or after squatting or running. There should be a negative history for significant swelling, which would indicate a more serious injury. History of change

in activity is common, such as altered training surface or terrain, increased training regimen, or performance of new tasks.

Examination should include evaluation of stance and gait for lower limb alignment, musculature, and midfoot hyperpronation. Flexibility of the hamstrings, iliotibial band (ITB), and gastrocnemius should be assessed, because stress is increased across the patellofemoral joint when these structures are tight. Hip range of motion should be assessed to rule out hip pathology. Medial patellar tenderness or pain with compression of the patellofemoral joint confirms the diagnosis in the absence of a significant effusion and other positive findings. PFSS is a clinical diagnosis usually managed without imaging.

Treatment focuses on assessing and improving flexibility, strength, and gait abnormalities. In the presence of midfoot hyperpronation (ankle valgus), new shoes or use of arch supports can improve patellofemoral mechanics and improve pain. Ice and an analgesic can be used to help control pain. Reduced overall activity or training is important initially in rehabilitation along with limiting knee flexion no greater than 60 degrees as possible. Short arc quadriceps strengthening exercises can be helpful (active knee extension with or without resistance between 0 and 30 degrees of knee flexion). Therapeutic taping techniques to help improve patella tracking within the trochlear groove can be helpful with the assistance of a sports physical therapist.

Osgood-Schlatter Disease

Osgood-Schlatter disease is a traction apophysitis occurring at the insertion of the patellar tendon on the tibial tuberosity (see Chapter 677.4). Because it is also related to overuse of the extensor mechanism, Osgood-Schlatter disease is **treated** like PFSS. A protective pad to protect the tibial tubercle from direct trauma can be used. Therapeutic taping of the tibial tubercle may provide comfort, along with well-fitted knee sleeves and/or straps. Nonsteroidal antiinflammatory drugs are often prescribed as well. Pain-free strengthening of weightbearing soft tissues using more closed-kinetic chain techniques may be best. PRICE principles apply. Make certain that patients and parents are aware that resolution is usually slow, often requiring 12-18 mo. Complications are rare and can include growth arrest with recurvatum deformity and rupture or avulsion of the patellar tendon/tibial tubercle.

Other Chronic Injuries

Sinding-Larsen-Johansson disease is a traction apophysitis occurring at the inferior pole of the patella. It occurs most often in volleyball and basketball athletes. **Treatment** is similar to that of PFSS and Osgood-Schlatter disease.

Patellar tendinosis (jumper's knee) is caused by repetitive microtrauma of the patellar tendon, usually at the inferior pole of the patella. In approximately 10% of the cases, the quadriceps tendon above the patella is affected. It is associated with jumping sports but occurs in runners as well. **Treatment** is similar to that for PFSS. Relative rest is more important in patellar tendinosis because chronic pain can be associated with irreversible changes in the tendon.

ITB friction syndrome is the most common cause of chronic lateral knee pain. Generally it is not associated with swelling or instability. It is from friction of the ITB along the lateral knee, resulting in bursitis. Tenderness is elicited along the ITB as it courses over the lateral femoral condyle or at its insertion at the Gerdy tubercle, along the lateral tibial plateau. Tightness of the ITB is also noted using the Ober test. To perform an Ober test, the athlete lies on one side and the superior hip is extended with the knee flexed. The examiner holds the ankle in midair, and if the knee moves inferiorly, it implies a flexible ITB and a negative Ober test. If the knee and leg stay in midair, the ITB is tight and the Ober test is positive. **Treatment** principles follow those for PFSS, except emphasis is on improving flexibility of the ITB.

Other soft-tissue injuries not to be excluded include prepatellar and pes anserine bursitis, plical syndromes, and Hoffa syndrome. The pes anserine bursa lies just under the conjoined tendon of the sartorius, gracilis, and semitendinosus muscles as it attaches medially to the proximal tibia. In Hoffa syndrome, the fat pad beneath the patella and posterior to the patella ligament becomes pinched with anterior pain on knee extension. These conditions are generally more common in adolescents, those with genu recurvatum, and long distance runners. Non–sports-related conditions, again, always need to be considered in the context of any child with a painful knee, particularly in a child younger than age 12 yr. These include conditions such as OCD (see Chapter 677.3), which is most common on the lateral aspect of the medial femoral condyle. Inflammatory and infectious arthritis, Baker's cyst (see Chapter 677.2), and hip pain referred to the knee are additional considerations. Tumors more common to the knee joint include osteogenic sarcoma (distal femoral and proximal tibial), histiocytosis X in the diaphysis, and eosinophilic granuloma in the epiphysis of long bones. Metastatic tumors to the lower extremities include neuroblastoma and lymphomas of various types. As with any apparent musculoskeletal injury in a child not responding to conservative care, more in-depth diagnostic pursuit for alternative pathology is mandatory.

687.7 Lower Leg Pain: Shin Splints, Stress Fractures, and Chronic Compartment Syndrome

Kevin P. Murphy and Aaron M. Karlin

Stress injury to the bones of the lower leg occurs on a continuum from mild injury (shin splints) to stress fracture. All occur by an overuse mechanism.

Shin splints, also known as medial tibial stress syndrome, manifests with pain along the medial tibia or both tibiae and is the most common overuse injury of the lower leg. The pain initially appears toward the end of exercise, and if exercise continues without rehabilitation, the pain worsens and occurs earlier in the exercise period. There is diffuse tenderness over the lower third to half of the distal medial tibia. Any focal tenderness or tenderness of the proximal tibia is suspicious for a stress fracture. A stress fracture tends to be painful during the entire workout. Shin splints can usually be distinguished from a **tibial stress fracture** in which the tenderness is more focal (2-5 cm) and more severe. Shin splints and stress fracture represent a continuum of stress injury to the tibia and are thought to be related to traction of the soleus on the tibia. Eccentric contraction of the medial aspect of the soleus is required to control pronation from initial contact to mid-stance with running. This contraction increases the stress of the fascial origin of the soleus possibly through Sharpey's fibers causing disruption to the tibial periosteum and fibrocartilaginous attachments.

The diagnosis can be made by history and physical examination. Findings on plain radiographs of the tibia are normal with shin splints and in tibial stress fractures within the 1st 2 wk of the injury. Afterward, the radiographs can demonstrate periosteal reaction if a stress fracture is present. Sensitivity of plain radiographs may be increased by obtaining 4 views of the tibia: AP, lateral, and both oblique views. A bone scan is the most sensitive test to diagnose stress fractures; it demonstrates discrete tracer uptake at the site(s) of the stress fracture. Increased uptake may be noted in the presence of shin splints, but in a fusiform pattern along the periosteal surface. If results of the bone scan are normal, the diagnosis is likely to be shin splints or chronic compartment syndrome. MRI has replaced bone scan as the most sensitive tool for diagnosing stress fractures in long bones in many medical centers.

The treatment of shin splints and tibial stress fractures is similar, involving relative rest, correcting training errors and addressing quartile muscle imbalances and abnormal mechanical alignment. Orthotics and/or new shoes may be useful in patients who hyperpronate. Fitness can be maintained with non-weightbearing activities, such as swimming, cycling, and water jogging. With shin splints, after

7-10 days, patients can usually start on the walk–jog program. If pain worsens, 2-3 pain-free days are required before resuming the walk–jog program. Ice should be used daily and an analgesic should be used for pain control. Stretching the plantar flexors, hamstrings and strengthening the ankle dorsiflexors may be useful. Therapeutic taping and wrapping techniques to support the soft-tissue attachments have been useful in some when directed by a skilled sports therapist. Being pain free for 7-10 days is recommended before exercises are commenced. Individuals with pain at rest and not responsive to treatment require continued suspicion for stress fracture.

Chronic compartment syndrome occurs in an athlete in a running sport, usually during a period of heavy training. It is caused by muscle hypertrophy and increased intracompartmental pressure with exercise. There is typically a pain-free period of about 10 min at the beginning of a workout before onset of constant throbbing pain that is difficult to localize. It lasts for minutes to hours after exercise and is relieved by ice and elevation. In a classic case, there is numbness of the foot associated with high pressure within the corresponding muscle compartment. The most common compartment affected is the anterolateral compartment with compression of the fibular nerve followed by the deep posterior compartment. The physical examination in the office is often normal but weakness of the extensor hallucis longus (anterolateral compartment) and decreased sensation between the 1st and 2nd toe may be present. X-rays, bone scan, and MRI are negative and are used to rule out other conditions. Compartment pressure measurements are the test of choice. Treatment involves reduction of activity, antiinflammatory medication, orthotics (hyperpronation), heel cord stretching, light strengthening of distal musculature, optimal footwear, and crosstraining (swimming, cycling and water jogging). Cryotherapy and superficial heat can be of help in addition. Persistent systems, despite conservative care, require fasciotomy (successful in up to 90% of cases).

Bibliography is available at Expert Consult.

687.8 Ankle Injuries

Kevin P. Murphy and Aaron M. Karlin

Ankle injuries are the most common acute athletic injury. Approximately 85% of ankle injuries are sprains, and 85% of those are inversion injuries (foot planted with the lateral fibula moving toward the ground), 5% are eversion injuries (foot planted with the medial malleolus moving toward the ground), and 10% are combined.

EXAMINATION AND INJURY GRADING SCALE

In obvious cases of fracture or dislocation, evaluating neurovascular status with as little movement as possible is the priority. If no deformity is obvious, the next step is inspection for edema, ecchymosis, and anatomic variants. Key sites to palpate for tenderness are the entire length of the fibula; the medial and lateral malleoli; the base of the 5th metatarsal; the anterior, medial, and lateral joint lines; and the navicular and the Achilles tendon complex. Assessment of active range of motion (patient alone) in dorsiflexion, plantar flexion, inversion, and eversion along with gentle resisted range of motion can be helpful.

Provocative testing attempts to evaluate the integrity of the ligaments. In a patient with a markedly swollen, painful ankle, provocative testing is difficult because of muscle spasm and involuntary guarding. It is more useful on the field before much bleeding and edema have occurred. The anterior drawer test assesses for anterior translation of the talus and competence of the anterior talofibular ligament. The inversion stress test examines the competence of the anterior talofibular and calcaneofibular ligaments (Fig. 687-9). In the acute setting, the integrity of the tibiofibular ligaments and syndesmosis is examined by the syndesmosis squeeze test. Pain with squeezing the lower leg implies injury to the interosseous membrane and syndesmosis between the tibia and fibula, making a high ankle sprain or more severe injury suspicious. Athletes with this injury cannot bear any weight and also have severe pain with external rotation of the foot. Occasionally, the peroneal tendon dislocates from the fibular groove simultaneously with an ankle sprain. To assess for peroneal tendon instability, the examiner applies pressure from behind the peroneal tendon with resisting eversion and plantar flexion, and the tendon pops anteriorly. If either a significant syndesmotic injury or an acute peroneal dislocation is suspected, orthopedic consultation should be sought.

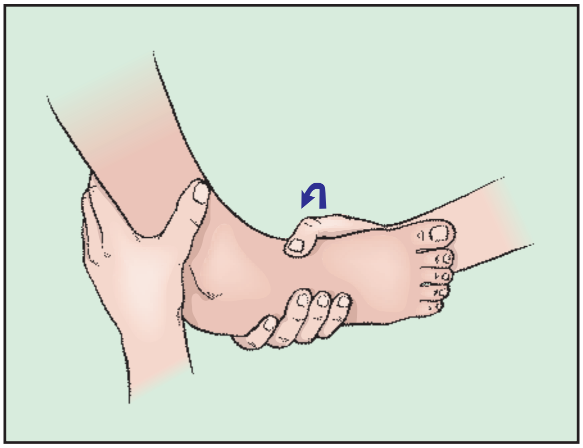

Figure 687-9 Inversion stress tilt test for ankle instability. *(From Hergenroeder AC: Diagnosis and treatment of ankle sprains. A review, Am J Dis Child 144:809–814, 1990.)*

RADIOGRAPHS

AP, lateral, and mortise views of the ankle are obtained when patients have pain in the area of the malleoli, are unable to bear weight, or have focal bone tenderness over the distal tibia or fibula. The Ottawa ankle rules help define who requires radiographs (Fig. 687-10). A foot series (AP, lateral, and oblique views) should be obtained when patients have pain in the area of the midfoot or bone tenderness over the navicular or 5th metatarsal. It is important to differentiate an avulsion fracture of the proximal 5th metatarsal (Dancer's fracture) from the Jones fracture of the proximal 5th metatarsal (a lucency about 2 cm from the proximal end). The former is treated more like an ankle sprain; the latter fracture has an increased risk of nonunion and requires orthopedic consultation. Injury to the deltoid ligament in the medial ankle (more rare) should raise the question of proximal fibular fracture. In this circumstance more proximal tibial imaging may be necessary. The *talar dome fracture* is manifested as an ankle sprain that does not improve. Radiographs on initial presentation can have subtle abnormalities. Any suspicion on the initial radiographs of a talar dome fracture warrants orthopedic consultation and further imaging. In the early adolescent, always look carefully at the tibial epiphysis. Nondisplaced Salter III fractures can be subtle and need to be recognized early and referred to an orthopedic surgeon promptly.

INITIAL TREATMENT OF ANKLE SPRAINS

Ankle sprains need to be **treated** with **PRICE**. This should be followed for the 1st 48-72 hr after the injury to minimize bleeding and edema. For an ankle injury, this might consist of crutches and an elastic wrap, although other compression devices such as an air stirrup splint work quite well. This allows early weightbearing with protection and can be removed for rehabilitation. It is important to start a rehabilitation program as soon as possible.

Rehabilitation

Rehabilitation should begin the day of injury; for patients who have pain with movement, isometric strengthening can be started. Early phase intervention includes restoration of functional range of motion, strengthening with emphasis on peroneal musculature and early sensory proprioceptive training. Later intervention includes

higher-level balance activities, advanced proprioception exercises, and endurance training. When determining when an athlete is ready for running, there must be full range of motion and nearly full strength compared to the uninjured side. While standing on the uninjured side only, the athlete is instructed to hop 8-10 times, if possible. When this can be achieved without pain on the injured side, the athlete can begin to run, starting out with jogging and gradually progressing in speed, and finally to sprints. The athlete must stop if there is significant pain or limp. Finally, before returning to sport, the athlete must be able to sprint and change directions off the injured ankle comfortably. Performing some sport-related tasks is also helpful in determining readiness for return to play.

Recurrent ankle injuries are more likely in patients who have not undergone complete rehabilitation. Ankle sprains are less likely in players wearing high-top shoes. Proper taping of the ankle with adhesive tape can provide functional support but loosens with use and is often unavailable. Lace-up ankle supports are felt to be more useful for preventing recurrences by many. They are more supportive than tape and can be tightened repeatedly during the course of a practice or a game. Most sports physicians recommend their use indefinitely to help prevent further sprains. Surgery is a consideration for chronic mechanical instability with lateral complex ligamentous laxity in the failure of more conservative care. Salter-Harris grade I distal fibular fractures need careful consideration, particularly in the child younger than 12 yr old. The physeal plates are generally the weakest link in the musculoskeletal chain and tend to slide or pull apart before the surrounding soft tissue and/or ligaments tear in this younger population. Toddler's fracture also needs to be considered especially in those younger than age 8 yr. The proposed mechanism involves sheer stress with lack of displacement because of the periosteum that is relatively strong compared to the elastic bone in younger children. Additional radiographs may be inconspicuous (a faint spiral oblique line) or even normal. After 1 or 2 wk callous develops. The condition can be mistaken for osteomyelitis, transient synovitis, and/or even child abuse. Toddler's fracture usually occurs in the lower third of the tibia, whereas nonaccidental injury typically affects the upper two-thirds or midshaft of the tibia. Other, more rare conditions that cannot be excluded include os fibulare, a congenital unfused secondary ossification center of the distal fibula. This can be seen in younger patients with recurrent ankle sprains, particularly as their body weight and activity increase during the early academic years. Tarsal coalitions can be seen also in the presence of ankle sprains in younger children the most common being talocalcaneal and calcaneal navicular. More common muscular strains and/or tendinosis remains more prevalent in the older child and adolescent including peroneal, posterior tibialis, and gastrocnemius/Achilles types. Tarsal tunnel syndrome is also more prevalent in the adolescent/younger adult and can be associated with medial ankle pain with burning or tingling into the sole of the foot.

Bibliography is available at Expert Consult.

687.9 Foot Injuries

Kevin P. Murphy and Aaron M. Karlin

Metatarsal stress fractures can occur in any running athlete. The history is insidious pain with activity that is getting worse. Examination reveals point tenderness over the midshaft of the metatarsal, most commonly the 2nd or 3rd metatarsal. Radiographs might not show the periosteal reaction before pain has been present for 2 wk or more. **Treatment** is relative rest for 6-8 wk. Shoes with good arch supports reduce stress to the metatarsals.

Vague dorsal foot pain in an athlete in a running sport can represent a **navicular stress fracture.** Unlike other stress fractures, it might not localize well on examination. If there is any tenderness around the navicular, a stress fracture should be suspected. This stress fracture can take many weeks to show up on plain radiographs, so a bone scan or MRI should be obtained to make the diagnosis. Because this fracture is at high risk of nonunion, immobilization and non-weightbearing for 8 wk is the usual **treatment.** A CT scan should be obtained to document full healing after the period of immobilization.

Sever disease (calcaneal apophysitis) occurs at the insertion of the Achilles tendon on the calcaneus and manifests as activity-related pain (see Fig. 687-3). It is more common in boys (2:1), is often bilateral, and usually occurs between ages 8 and 13 yr. Tenderness is elicited at the insertion of the Achilles tendon into the calcaneus, especially with squeezing the heel (positive squeeze test). Sever disease is associated with tight Achilles tendons and midfoot hyperpronation that puts more stress on the plantar flexors of the foot. **Treatment** includes relative rest, ice, massage, stretching, and strengthening the Achilles tendon. Correcting the midfoot hyperpronation with orthotics, arch supports, or better shoes is important in most athletes with Sever disease. If the foot is neutral or there is mild hyperpronation, in-heel

lifts can be helpful to unload the Achilles tendon and its insertion. With optimal management, symptoms improve in 4-8 wk. Generally, if there is no limp during the athletic activity, young athletes with Sever disease should be allowed to play.

Plantar fasciitis is an overuse injury resulting in degeneration of the plantar aponeurosis. Rare in prepubertal children, this diagnosis is more likely in an adolescent or young adult. Athletes report heel pain with activity that is worse with first steps of the day or after several hours of non-weightbearing. Tenderness is elicited on the medial calcaneal tuberosity. Relative rest from weightbearing activity is helpful. Athletes get plantar fasciitis when shoes are worn with inadequate arch supports. New shoes or use of semirigid arch supports often lessen the pain. Stretching the calves and plantar fascia helps, assisted at times with therapeutic ultrasound treatment. Some patients benefit from night splints even though they can make sleep difficult. As long as there is no limping with athletic activity, the athlete may continue participation. Complete recovery is usually seen at 6 mo. Corticosteroid and extracorporeal shock-wave therapy are reserved for severe, chronic cases.

Calcaneal stress fracture is seen in the older adolescent or young adult involved in a running sport. There is heel pain with any weightbearing activity. The physical examination reveals pain with squeezing the calcaneus. Sclerosis can show up on the AP and lateral radiographs after 2-3 wk of pain. A bone scan or MRI needs to be performed to clinch the diagnosis in some cases. The calcaneus is an uncommon location for a stress fracture; it is associated with osteopenia (amenorrheic girls). **Treatment** is rest from running and other weight-bearing activity for at least 8 wk. Immobilization is rarely necessary.

Flatfeet or pes planus may be flexible or rigid. Flexible pes planus is usually asymptomatic, at least in the early years and is the most common type found in children. Scaphoid pads or medial inserts may be helpful to create plantigrade weightbearing posture. Untreated sports progression may occur with compensatory hallux valgus, planovalgus, and secondary bunion and toe deformities. With progression pain may develop, along with shortening in the peroneal musculature. Rigid pes planus is a congenital deformity associated with other anomalies in 50% of cases. It is caused by failure of the tarsal bones to separate leaving a bony cartilaginous or fibrous bridge or coalition between 2 or more tarsal bones. Talocalcaneal coalitions are more symptomatic between 8 and 12 yr of age, whereas calcaneal navicular coalitions are more symptomatic between 12 and 16 yr of age. Symptoms are insidious with occasional acute arch, ankle, and midfoot pain, at times brought on with sports-related activities. The hindfoot often does not align in its normal varus position on tiptoe maneuvers. Patients are predisposed to ankle sprains secondary to limited subtalar motion and stress to the subtalar and transverse tarsal joints frequently causes pain. CT scans are diagnostic and initial treatment is conservative with short leg casting and/or molded orthoses and rest. In the case of failure of conservative care, surgical intervention is usually necessary. Rigid cavus feet can also be associated with metatarsalgia, clawing, and intrinsic muscle atrophy, all possible in the young athlete. With a cavus foot, underlying neurologic conditions, such a Charcot-Marie-Tooth disease, spinal dysraphism, Friedrich ataxia, or other spinal tumor, need be considered. Custom-molded orthotics may be helpful. Family history can be critical. Coleman block test can help determine hindfoot flexibility and more rigid vs flexible pes planus. Plantar fascial surgical release is standard for all cavus foot procedures. Accessory navicular bones and sesamoiditis need to be considered in all symptomatic feet, especially those with rigid components. These conditions are more common in the adolescent or younger adult and can be exacerbated with sporting activities.

Other conditions not to be excluded include Lisfranc sprain and/or dislocation, more common in football linemen or other athletes requiring heavy loading on the mid and forefoot joints and gymnasts using the balance beam. Lisfranc joint is the tarsal metatarsal articulation of the 3 cuneiform bones and the cuboid with the 5 proximal metatarsals. Turf toe can be seen, particularly in the older child and/or adolescent running on artificial or synthetic surfaces. It usually involves hyperextension through the 1st metatarsal phalangeal joint, spraining the ligaments surrounding the joint often in a football and/or soccer activity.

Iselin apophysitis is an apophysitis that occurs at the tuberosity of the fifth metatarsal. The apophysis at this site appears between the ages of 9 and 14 yr and is located within the insertion of the peroneus brevis tendon. This condition can be a predisposing factor to the Dancer's fracture (see Chapter 687.8). Osteochondroses (see Chapter 674.08) of the foot to always consider include Freiberg disease, which involves collapse of the articular service and subchondral bone, usually of the 2nd metatarsal. Kohler disease involves irregular ossification of the tarsal navicular joint with localized pain and increased density. Freiberg disease is more common in girls between the ages of 12 and 15 yr, whereas Kohler disease occurs in younger individuals, age 2-9 yr, and is frequently reversible with conservative care including orthoses and casting.

Chapter 688

Sports-Related Traumatic Brain Injury (Concussion)

Christopher W. Liebig and Joseph A. Congeni

Concussion is defined as a traumatically induced transient disturbance of brain function that involves a complex pathophysiologic process. Concussion may be caused either by a direct blow to the head, face, neck, or elsewhere on the body with an "impulsive" force transmitted to the head, whether these are linear or rotational forces. Concussion is a subset of mild traumatic brain injury; it is important to communicate this fact to families and patients as the word "concussion" unintentionally and incorrectly has been found to communicate to some families that a brain injury has not occurred, resulting in less-than-adequate follow-up.

EPIDEMIOLOGY

At least 1.6-3.8 million concussions occur in the United States each year during competitive sports and other recreational activities. This number is likely to represent only a fraction of the true incidence as there is underreporting of symptoms by athletes from direct withholding of information to continue participation and poor understanding of their symptoms. From 1997 to 2007, visits to emergency departments for sports concussion doubled in the 8-13 yr old group; in 14-19 yr olds, the incidence has increased by more than 200%. Activities include football, bicycling, hockey, lacrosse, soccer, field hockey, basketball, and playground injuries.

PATHOPHYSIOLOGY

The pathophysiologic process following a concussion is best described as an "energy crisis" following a neurometabolic cascade. In animal models, these ionic and metabolic events, along with microscopic axonal injury, results in a desperation use of glucose to begin the healing process. The increased energy demand is met with a decreased cerebral blood flow, resulting in less available energy for other brain processes and a true mismatch of energy supply and demand.

ASSESSMENT OF THE INJURED PLAYER

The most current assessment tools are the Sport Concussion Assessment Tool (SCAT3) and the Child-SCAT3 for children ages 5-12, available at: http://bjsm.bmj.com/content/47/5/259.citation; http://bjsm.bmj.com/content/47/5/263.citation

These tests include the Glasgow coma scale, presence and duration of loss of consciousness, memory of the activity ("Who scored last?" "What team did you play last week?"), general memory/orientation (date, day of week, season), short-term memory (list 3 words and have patient repeat), concentration (give digits: 5-8-3, and have patient repeat backwards or do serial 7s), balance testing (double, single, tandem leg stances), finger to nose coordination, and cognitive testing (repeat list of words).

The signs and symptoms of concussion fall into 4 categories: physical, cognitive, emotional, and sleep (Table 688-1), with the most common symptom reported being headache. Transient loss of consciousness occurs in less than 10% of concussions and does not correlated with severity of injury. Assessment can be challenging as several or only 1 of the symptoms listed are identified. Furthermore, patients with preexisting mental health disorders such as depression or attention-deficit/hyperactivity disorder may experience exacerbations in their symptoms, making them more difficult to control.

Table 688-1 Postconcussion Symptom Scale

Symptom							
Headache	0	1	2	3	4	5	6
Nausea	0	1	2	3	4	5	6
Vomiting	0	1	2	3	4	5	6
Balance problems	0	1	2	3	4	5	6
Dizziness	0	1	2	3	4	5	6
Fatigue	0	1	2	3	4	5	6
Trouble falling to sleep	0	1	2	3	4	5	6
Excessive sleep	0	1	2	3	4	5	6
Loss of sleep	0	1	2	3	4	5	6
Drowsiness	0	1	2	3	4	5	6
Light sensitivity	0	1	2	3	4	5	6
Noise sensitivity	0	1	2	3	4	5	6
Irritability	0	1	2	3	4	5	6
Sadness	0	1	2	3	4	5	6
Nervousness	0	1	2	3	4	5	6
More emotional	0	1	2	3	4	5	6
Numbness	0	1	2	3	4	5	6
Feeling "slow"	0	1	2	3	4	5	6
Feeling "foggy"	0	1	2	3	4	5	6
Difficulty concentrating	0	1	2	3	4	5	6
Difficulty remembering	0	1	2	3	4	5	6
Visual problems	0	1	2	3	4	5	6

Scale: 0, no symptoms; 3, moderate; 6, severe.

Use of the postconcussion symptom scale: The athlete should complete the form, on the athlete's own, by circling a subjective value for each symptom. This form can be used with each encounter to track progress toward symptom resolution. Many athletes may have some of these reported symptoms at a baseline, such as concentration difficulties in the patient with attention-deficit disorder or sadness in an athlete with underlying depression. This must be taken into consideration when interpreting the score. Athletes do not need a total score of 0 to return to play if they had symptoms before their concussion. This scale has not been validated to determine concussion severity.

From Halstead ME, Walter KD, Council on Sports Medicine and Fitness. Sport-related concussion in children and adolescents. Pediatrics *126(3):597–615, 2010.*

A gold-standard assessment of suspected concussion has been difficult to ascertain throughout the years. Particularly difficult is the sideline evaluation where simply recognizing the injury can be most challenging for medical personnel. Initial sideline evaluation should include cervical spine stabilization, 4-limb neurologic testing, and evaluation of ABCs (airway, breathing, circulation). Secondly, discussion of the athlete's symptoms with an accepted sideline assessment tool (SCAT3 or Child-SCAT3) with balance testing should be completed because sensory coordination and vestibular systems are also affected by concussion. When available, preinjury baseline performance can be compared to the individual's postinjury test. Given the variability in concussion presentation, medical personnel are encouraged to err on the side of safety by adapting the phrase *when in doubt, sit them out*. If concussion is suspected, an athlete must be removed from participation and forbidden to return on the day of injury.

Evaluation with neuropsychologic testing provides another objective measurement of brain function. Computerized neurocognitive tests can be most useful to those familiar with the test and when athletes were able to perform baseline testing.

Concussion lacks structural changes with conventional imaging studies (MRI and CT) limiting their usefulness in evaluation. Neuroimaging should be used if suspicion of intracerebral lesion exists. Advances in functional neuroimaging have shown positive findings but require further research before clinical utilization and recommendation. Imaging may be indicated for possible related neck injury (see Chapter 689). CT imaging may be indicated for prolonged loss of consciousness, persistent altered mental status, focal neurologic deficits, suspicion of a skull fracture, or signs of clinical deterioration.

MANAGEMENT AND TREATMENT

Initial Phase

Management of a concussion also continues to evolve and is primarily based on symptom control while protecting the athlete from activities that may slow recovery. Initiating a management plan consisting of complete physical and cognitive rest is paramount. Symptoms may be followed with a postconcussion symptom scale (see Table 688-1), where symptoms are more likely to be reported. Concussed patients will often complain of increased symptoms with cognitive activities such as reading, video games, music, and even texting. They often have difficulty attending school, focusing on schoolwork, and trying to keep up with assignments. Taking standardized tests while recovering from a concussion is discouraged as lower-than-expected scores may occur. Cognitive rest may include shortened school days, reduced workload, or even temporary leave of absence with gradual return to school. Controlling symptoms can be difficult as there is no evidence-based pharmacologic treatment to offer a concussed athlete. However, medication is considered in those with prolonged recovery and specific symptoms. Vestibular therapy consisting of balance and oculomotor exercises has shown results in combating dizziness and vertigo. The duration of rest has been controversial, but one randomized controlled trial suggested that rest for 1-2 days when compared to 5 days resulted in **fewer** daily postconcussive symptoms and **faster** recovery.

Returning to Sport

No athlete should return to sport until clinically and completely asymptomatic at rest and without medication use. Each athlete's return should be individually based as recovery occurs at different rates with the majority of youth fully recovered by 1-3 wk; some may require 1-2 mo, particularly those who have had repeated concussions. Younger athletes may take longer to recover to neurocognitive and symptom baseline than older athletes. A return to play protocol provides a structured guideline that athletes progress through gradually, provided that the athlete remains asymptomatic for 24 hr at each step (Table 688-2). If no symptoms return, the athlete should wait 5 full days to complete and return to play. If symptoms have occurred, the athlete is required to rest until asymptomatic for 24 hr and resume at the previous asymptomatic step. It is important to consider individual factors at this juncture that are suspected to prolong recovery or increase patient

Table 688-2 Graduated Return to Play Protocol

REHABILITATION STAGE	FUNCTIONAL EXERCISE AT EACH STAGE OF REHABILITATION	OBJECTIVE OF EACH STAGE
1. No activity	Symptom limited physical and cognitive rest	Recovery
2. Light aerobic exercise	Walking, swimming or stationary cycling keeping intensity <70% maximum permitted heart rate No resistance training	Increase heart rate
3. Sport-specific exercise	Skating drills in ice hockey, running drills in soccer. No head impact activities	Add movement
4. Noncontact training drills	Progression to more complex training drills, e.g., passing drills in football and ice hockey May start progressive resistance training	Exercise, coordination and cognitive load
5. Full-contact practice	Following medical clearance participate in normal training activities	Restore confidence and assess functional skills by coaching staff
6. Return to play	Normal game play	

From McCrory P, Meeuwise WH, Aubry M, et al. Consensus statement on concussion in sport: the 4th International Conference on Concussion in Sport held in Zurich, November 2012. Br J Sports Med *47:250–258, 2013.*

susceptibility. Females may be at greater risk for concussion, increased severity, and longer duration of recovery.

After sustaining a concussion, a child is 2-6–fold more likely to sustain another concussion. This risk is heightened while recovering from an initial injury with a rare, yet catastrophic injury known as **second-impact syndrome**. In this injury, seen more frequently in child athletes, a mild impact may result in brain swelling and death. Previous and repeat concussions may be associated with slower recovery with more cognitive, emotional, physical, and sleep symptoms than those who have experienced 1 or no concussions.

Those with multiple concussions may experience a cumulative effect resulting in difficulty in attention and concentration. Prolonged concussive symptoms or postconcussion syndrome is another complication that is most simply noted as symptoms of concussion that persist beyond an expected time frame. Causes and correlations have yet to be determined, making this diagnosis difficult to establish.

PREVENTION

Despite ongoing research and technologic advances, personal protective equipment has not decreased the severity or reduced the incidence of concussion in team sports. Therefore, educating athletes, coaches, officials, and parents to adhere to rule changes should be emphasized. Concussion-related legislations may prove to be the most effective methods in managing and preventing concussion.

when a force is applied to the top of the head in this flexed position transmitting force through the spine.

SOFT-TISSUE INJURY

The most frequent injury resulting from trauma to the head and neck involves the muscles, tendons, and ligamentous structures. Even though strains, sprains, and contusions are common, proper examination and evaluation is required to rule out more serious injuries. Even without bony abnormalities, the cervical spine may become unstable secondary to soft-tissue injury.

Spinal laxity results when most restraining ligaments are injured. When compared to adjacent vertebra, laxity should horizontally be less than 3.5 mm, and angular displacement less than 11 degrees on plain flexion/extension films. However, younger athletes have more baseline laxity making the criteria less applicable and muscle spasm can acutely mask instability. If subluxation is remotely suspected, a hard cervical collar should be placed and imaging obtained again at 2-4 wk when inflammation and spasm have subsided.

Disk injuries are rare in pediatric patients. Rupture or herniation must be considered in any cervical pain differential (see Chapter 679.8).

SPEAR TACKLER'S SPINE

This clinical entity is characterized by progressive spinal changes secondary to incorrect tackling form. Findings on plain x-ray consist of (1) narrowing of cervical spinal canal, (2) loss or reversal of normal cervical lordosis, and (3) preexisting minor posttraumatic x-ray evidence of bony or ligamentous injury. Although rule changes in collision and contact sports have limited the practice of making contact with a "head-down" neck position, this condition still persists.

Many experts argue that this condition disqualifies athletes from return to play. Others argue that if physical therapy and rehabilitation are able to correct the curvature and improper technique is corrected, then athletes are not at a high risk of reinjury and could return. Data are lacking and more research required for a definitive answer.

CERVICAL FRACTURES

All significant neck injuries should be treated seriously until cleared with appropriate examination and imaging. Although many cervical fractures are stable, improper management or inadequate evaluation could end with catastrophic results. **Until properly evaluated, the patient should be immobilized and treated as if the patient has an unstable cervical fracture.**

STINGERS (BURNERS)

Stingers are unilateral peripheral nerve injuries occurring somewhere between the cervical nerve root and the brachial plexus. Three

Chapter 689

Cervical Spinal Injuries

Joseph A. Congeni and John H. Lockhart

Sports participation has surpassed motor vehicle crashes as the number 1 cause of cervical spine injuries in youth older than 9 yr of age. American football, hockey, and wrestling have the highest incidence in the United States; internationally, rugby is nearly as high.

The normal cervical spine has a lordotic curve, allowing it to absorb shock and dissipate force. When the neck is flexed forward, the spine straightens, losing this shock-absorbing property. Axial loading is

proposed mechanisms are traction or tensile stretch injury, compressive injury, and direct trauma. Typical presentation is a transient episode of unilateral pain, with or without paresthesia, in an upper extremity. Symptoms of C5 and C6 roots and upper trunk are most common. Careful examination for weakness should be performed, especially shoulder abduction, external rotation, and elbow flexion. Cervical spine should have pain-free full range of motion and have no tenderness to palpation. Spurling's Compression test, a head-tilting maneuver that when positive differentiates cervical radiculopathy from other causes of upper-extremity pain, may or may not be positive. The test is only 30% sensitive, but specificity is 93%.

Return to play may be considered the same day if the exam is reassuring. This requires complete resolution of symptoms, full range of motion, and normal strength. Multiple stingers, bilateral symptoms, or symptoms persisting for longer than 1 hr should prompt further evaluation before resumption of any physical activities.

TRANSIENT QUADRIPARESIS

Transient quadriparesis (TQ) is a temporary neurologic episode encompassing sensory symptoms with or without motor changes. TQ is also known as *cervical cord neurapraxia*, *burning hands syndrome*, *commotio spinalis*, and *spinal cord concussion*. TQ can be divided into 3 types: plegia (complete loss of motor function), paresis (motor weakness), and paresthesia (sensory symptoms only). There is also a 3-part grading system: grade 1 symptoms last <15 min, grade 2 symptoms last 15 min to 24 hr, and grade 3 symptoms persist beyond 24 hr. TQ must be differentiated from just a stinger and the player should be removed from activity and spinal cord injury considered.

Mechanisms of injury include hyperextension, hyperflexion, and axial loading. Anatomically, when the neck is hyperflexed or hyperextended, the spinal canal is narrowed by up to 30%, increasing the likelihood of cord injury.

Burning hands syndrome is the most common presentation. The athlete has intense paresthesias in both upper extremities. This is suggestive of a central cord syndrome and includes burning, tingling, and loss of sensation. Treat athletes with full cervical precautions to prevent injury progression.

Evaluation should start with plain flexion and extension films if stable. CT can be utilized if cervical fracture is suspected. MRI should then be used to evaluate for intrinsic spinal cord abnormalities or ongoing cord or root compression. Spinal stenosis is discussed below.

Return to play for TQ is heavily debated and lacks data to support it. Conservatively, some argue that 1 episode is a contraindication to return to contact sports, whereas others agree with utilizing the Return to Play Table (Table 689-1) for absolute and relative contraindications for return. If allowed to return to play and second episode of TQ occurs, the complete work-up needs repeating.

CONGENITAL SPINAL STENOSIS

Developmental narrowing of the cervical spinal canal predisposes an athlete to higher risk of spinal cord injury. This condition can be found incidentally while working up other conditions. The Torg Ratio, the ratio of vertebral body width to canal width on plain lateral film (cutoff for normal is 0.7 or 0.8, depending on clinical setting), is being evaluated for utility as a diagnostic test. Alternatively, a canal width measuring <13 mm between C3 and C7 can be used to define stenosis, with "normal" being >15 mm.

Functional stenosis can be seen with dynamic MRI in flexion and extension to see if the canal space decreases with movement. The positioning of the canal in flexion or extension causes narrowing from positioning of the vertebra and ligament, respectively. The measured diameter may be irrelevant if disc protrusion or ligament hypertrophy causes compression. This narrow "reserve space" around the spinal cord puts the athlete at greater risk for injury as compared to the same force on a normal spine.

SPINAL CORD INJURY

Spinal cord injury is the most dreaded complication of cervical trauma and is categorized into 4 entities. Hemorrhage and transection are

Table 689-1 Return to Play (RTP) Table

NO CONTRAINDICATION TO RTP	
Healed fractures including:	Healed C1 or C2 fracture with normal cervical spine range of motion (ROM) Healed subaxial fracture without sagittal plane deformity Asymptomatic clay-shoveler's (C7) spinous process avulsion fracture
Congenital conditions	Klippel-Feil (single-level anomaly not C0/C1 articulation) Spina bifida occulta
Degenerative/ postsurgical conditions	Cervical disc disease (no change in baseline neurologic status) Single-level anterior cervical fusion (ACF) with/without instrumentation Single- or multiple-level posterior cervical laminotomy
Recurrent stingers	Less than 3 episodes lasting <24 hr Must have full cervical range of motion No persisting neurologic deficit
Transient quadriparesis	Single episode Full cervical range of motion Normal neurologic exam No radiologic instability Normal spinal reserve (as evidenced on MRI)
RELATIVE CONTRAINDICATION TO RTP	
Stingers/Burners	Prolonged symptomatic burner/stinger Three or more stingers
Transient quadriparesis	Transient quadriparesis lasting >24 hr More than 1 episode with symptoms of any duration
Postsurgical	Healed 2-level ACF Posterior cervical fusion (PCF) with/ without instrumentation
ABSOLUTE CONTRAINDICATION TO RTP	
Transient quadriparesis and any 1 or more of:	Cervical myelopathy Continued neck discomfort Reduced ROM Neurologic deficit from baseline after injury
Surgical procedures	C1 + C2 fusion Cervical laminectomy Three-level ACF or PCF
Soft-tissue injuries	Asymptomatic ligamentous laxity (>11 degrees of kyphotic deformity) C1 + C2 hypermobility with anterior dens >3.5 mm (adult), >4 mm (child), i.e., Down syndrome (see Chapter 680) Symptomatic cervical disc herniation
Other conditions including:	Spear tackler's spine Multilevel Klippel-Feil anomaly (see Chapter 680) Healed subaxial fracture with sagittal kyphosis coronal plane abnormality, or cord encroachment Ankylosing spondylitis Rheumatoid arthritis with spinal abnormalities Spinal cord abnormality (cord edema, compression, etc.) Arnold-Chiari syndrome Basilar invagination Occipital-C1 assimilation (occipitalization or connection) Spinal stenosis (canal width <13 mm between C3 and C7)

Figure 689-1 A magnetic resonance image (sagittal) demonstrating spinal cord contusion (edema in central portion of spinal cord). *(From Krabak BJ, Kanarek SL: Cervical spine pain in the competitive athlete.* Phys Med Rehabil Clin N Am *22:459–471, 2011, Fig. 2.)*

considered irreversible and associated with complete cord injury, whereas contusion and edema (Fig. 689-1) are considered to have more potential for recovery. Steroids and hypothermia are 2 proposed treatments to prevent secondary injury. These severe injuries should be managed by providers with expertise in this area.

Chapter 690

Heat Injuries

Gregory L. Landry

Heat illness is the third leading cause of death in U.S. high school athletes. It is a continuum of clinical signs and symptoms that can be mild (heat stress) to fatal (heatstroke) (see Chapter 70). Children are more vulnerable to heat illness than adults because they have greater ratio of surface area to body mass and produce greater heat per kilogram of body weight during activity. The sweat rate is lower in children and the temperature at which sweating occurs is higher. Children can take longer to acclimatize to warmer, more humid environments (typically 8-12 near-consecutive days of 30-45 min exposures). Children also have a blunted thirst response compared to adults and might not consume enough fluid during exercise to prevent dehydration.

Three categories for heat illness are generally used: **heat cramps, heat exhaustion,** and **heat stroke** (Table 690-1). However, symptoms of heat illness overlap and advance as the core temperature rises. **Heat cramps** are the most common heat injury and usually occur in mild dehydration and/or salt depletion, usually affecting the calf and hamstring muscles. They tend to occur later in activity, as muscle fatigue is reached and water loss and sodium loss worsen. They respond to oral rehydration with electrolyte solution and with gentle stretching. The athlete can return to play when ability to perform is not impaired. **Heat syncope** is fainting after prolonged exercise attributed to poor vasomotor tone and depleted intravascular volume, and it responds to fluids, cooling, and supine positioning. **Heat edema** is mild edema of the hands and feet during initial exposure to heat; it resolves with acclimatization. **Heat tetany** is carpopedal tingling or spasms caused by heat-related hyperventilation. It responds to moving to a cooler environment and decreasing respiratory rate (or rebreathing by breathing into a bag).

Table 690-1	Spectrum of Heat Illness
Heat cramps and dehydration: Cautious return to play Muscle cramps Thirst Fatigue Light-headedness Sweating Flushed face **Heat Exhaustion:** Remove from play Dizziness Rapid pulse Headaches Nausea Vomiting Loss of coordination Profuse sweating Core temperature less than 40°C (104°F) **Heat Stroke:** Medical emergency, call 911 Core temperature of 40°C (104°F) or higher Hot dry skin Multiple system failure Delirium Convulsions Abnormal vital signs	

(From Merkel DL, Molony JT Jr. Medical sports injuries in the youth athlete: emergency management. Int J Sports Phys Ther *7:242–251, 2012, Table 4.)*

Heat exhaustion is a moderate illness with core temperature 37.7-39.4°C (100-103°F). Performance is obviously affected, but central nervous system dysfunction is mild, if present. It is manifested as headache, nausea, vomiting, dizziness, orthostasis, weakness, piloerection, and possibly syncope. **Treatment** includes moving to a cool environment, cooling the body with fans, removing excess clothing, and placing ice over the groin and axillae. If a patient is not able to tolerate oral rehydration, IV fluids are indicated. Patients should be monitored, including rectal temperature, for signs of heat stroke. If rapid improvement is not achieved, transport to an emergency facility is recommended.

Heat stroke is a severe illness manifested by central nervous system disturbances and potential tissue damage. It is a medical emergency; *the mortality rate is 50%*. Sports-related heat stroke is characterized by profuse sweating and is related to intense exertion, whereas "classic" heatstroke with dry, hot skin is of slower onset (days) in elderly or chronically ill persons. Rectal temperature is usually >40°C (104°F). Significant damage to the heart, brain, liver, kidneys, and muscle occurs, with possible fatal consequences if untreated. **Treatment** is immediate whole-body cooling via cold water immersion. Airway, breathing, circulation, core temperature, and central nervous system status should be monitored constantly. Rapid cooling should be ceased when core temperature is approximately 38.3-38.9°C (101-102°F). IV fluid at a rate of 800 mL/m^2 in the 1st hr with normal saline or lactated Ringer solution improves intravascular volume and the body's ability to dissipate heat. Immediate transport to an emergency facility is necessary. Physician clearance is required before return to exercise.

Dehydration is common to all heat illness; consequently, measures to prevent dehydration can also prevent heat illness. Thirst is not an adequate indicator of hydration status because it is initiated at 2-3% dehydration. Athletes are advised to be well hydrated before exercise and should drink every 20 min during exercise (5 oz for those

Category	Heat index	Possible heat disorders for people in high risk groups
Extreme danger	130°F or higher (54°C or higher)	Heat stroke or sunstroke likely.
Danger	105 - 129°F (41 - 54°C)	Sunstroke, muscle cramps, and/or heat exhaustion likely. Heatstroke possible with prolonged exposure and/ or physical activity.
Extreme caution	90 - 105°F (32 - 41°C)	Sunstroke, muscle cramps, and/or heat exhaustion possible with prolonged exposure and/ or physical activity.
Caution	80 - 90°F (27 - 32°C)	Fatigue possible with prolonged exposure and/or physical activity.

Heat index reference chart provided by the National Weather Service, Tulsa, Oklahoma.
Note: Exposure to full sunshine can increase Heat Index values by up to 15°F

Figure 690-1 Heat stroke index. *(From Jardine DS: Heat illness and heat stroke,* Pediatr Rev *28:249–258, 2007.)*

weighing 40 kg, 9 oz for 60 kg, and 10-12 oz for those >60 kg). Free access to cold water should be advocated to coaches. During a football practice, scheduled breaks every 20-30 min with helmets off to get out of the heat can decrease the cumulative amount of heat exposure. Practices and competition should be scheduled in the early morning or late afternoon to avoid the hottest part of the day. Guidelines have been published about modifying activity related to temperature and humidity (Fig. 690-1). Proper clothing such as shorts and T-shirts without helmets can improve heat dissipation. Prepractice and post-practice weight can be helpful in determining the amount of fluid necessary to replace (8 oz for each pound of weight loss).

Water is adequate for most persons who exercise <1 hr, although there is evidence that children drink more water when it is flavored. Fluids with electrolyte and carbohydrate are more important for persons who exercise for longer than 1 hr. Salt pills should not be used by most people because of the risk of their causing hypernatremia and delayed gastric emptying. They may be useful in a person with a high sweat rate or recurrent heat cramps. Prolonged exercise (marathon running) with only water replacement places the athlete at risk of hyponatremia.

Chapter **691**

Female Athletes: Menstrual Problems and the Risk of Osteopenia

Gregory L. Landry

Physical training in young women can adversely affect reproductive function and bone mineral status especially when combined with calorie restriction (see Chapters 28 and 116).

The majority of bone mass is acquired by the end of the 2nd decade (see Chapter 707). Approximately 60-70% of adult bone mass is genetically determined, and the remaining is influenced by 3 controllable factors: exercise, calcium intake, and sex steroids, primarily estrogen. Exercise promotes bone mineralization in the majority of young women and is to be encouraged. In girls with eating disorders and those who exercise to the point of excessive weight loss with amenorrhea or oligomenorrhea, exercise can be detrimental to bone mineral acquisition, resulting in reduced bone mineral content, or **osteopenia**.

Specifically, bone mineralization is negatively affected by amenorrhea (absence of menstruation for ≥3 consecutive months). This may be influenced by abnormal eating patterns, or "disordered eating." When occurring together, disordered eating, amenorrhea, and osteoporosis form the **female athlete triad**. At health supervision visits and the preparticipation physical examination, special attention should be given to screening for any features of the triad.

Menstrual abnormalities (including **amenorrhea**) results from suppression of the spontaneous hypothalamic pulsatile secretion of gonadotropin-releasing hormone (see Chapter 116.1). It is believed that the amenorrhea results from reduced energy availability, defined as energy intake minus expenditure. Energy availability below a threshold of 30 kcal/kg/day lean body mass is thought to result in menstrual disturbances. Negative energy balance also appears to lower levels of leptin, which affects both nutritional state and the reproductive system. Other causes to be ruled out are pregnancy (see Chapter 118), pituitary tumors, thyroid abnormalities, polycystic ovary syndrome (see Chapter 552), anabolic–androgenic steroid use (see Chapters 114 and 692), and other medication side effects.

The low estrogen state of amenorrhea predisposes the female athlete to osteopenia and puts her at risk for stress fractures, especially of the spine and lower extremity. If left unchecked, bone loss is partially irreversible despite resumed menses, estrogen replacement, or calcium supplements. Routine bone mineral density screening is not recommended but can help guide treatment and return to activity in severe cases.

Normal ovulation and menses can be recovered in athletes with amenorrhea. This usually involves decreasing exercise amount and/or increasing caloric intake. However, many athletes are resistant to a decrease their training, and other methods, such as hormone supplementation, should be discussed. Nutritional counseling is important to help the athlete develop a plan for increasing calories. Calcium intake should be addressed, with the goal being at least 1,500 mg daily. If amenorrhea is present for ≥6 mo, hormone supplementation is recommended.

Three eating disorders can occur in the context of amenorrhea. Anorexia nervosa manifests as weight <85% of estimated ideal body weight with evidence of starvation manifesting as bradycardia, hypothermia, and orthostatic hypotension or orthostatic tachycardia. Bulimia nervosa manifests as recurrent episodes (at least once weekly) of binge eating with a sense of lack of control over eating during an episode with recurrent episodes of compensatory behaviors. A third category, "Unspecified Feeding and Eating Disorder," is a general description for disorders failing to meet the criteria for the 2 previous disorders. With the revised diagnostic criteria for bulimia and anorexia nervosa in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition,* it is anticipated that many young women who previously were diagnosed as "Unspecified Feeding and Eating Disorder" will receive a specific diagnosis of anorexia or bulimia. Signs of an eating disorder are weight loss, food restriction, depression, fatigue, and worsened athletic performance, and preoccupation with calories and weight. The athlete might avoid events surrounding food consumption or might hide and discard food. Signs and symptoms include fat depletion, muscle wasting, bradycardia worsened from baseline, orthostatic hypotension, constipation, cold intolerance, hypothermia, gastric motility problems, and, in some cases, lanugo (see Chapter 28). Electrolyte abnormalities can lead to cardiac dysrhythmias. Psychiatric problems (depression [see Chapter 26], anxiety [see Chapter 25], suicide risk [see Chapter 27]) are of higher incidence in this population.

For **treatment** of eating disorders, control of the symptoms is a central theme. The first step is confronting the athlete about the abnormal behavior and unhealthy weight. Generally, exercise is not recommended if the body weight is <85% of estimated ideal body weight, although there are exceptions, especially if the athlete is eumenorrheic. If the athlete is unable to gain weight with nutrition and medical counseling alone, then psychologic consultation is sought.

Most athletes will not initially admit a problem, and many are unaware of the serious physical consequences. A helpful technique in talking to these athletes is to sensitively point out performance issues. Education about decreased strength, endurance, and concentration can be a motivating factor for treatment. Often, the athlete's family needs to be involved, and the athlete should be encouraged to reveal necessary information to them. Psychology or psychiatry referral is important in the multidisciplinary approach to treatment of disordered eating. It is important for the physician to monitor the athlete's physical health while the mental health professional is caring for the mental aspects of the eating disorder.

Chapter 692

Performance-Enhancing Aids

Gregory L. Landry

See also Chapter 114.

Ergogenic aids are substances used for performance enhancement, most of which are unregulated supplements (Table 692-1). The 1994 Dietary Supplement and Health Education Act limited the ability of the U.S. Food and Drug Administration to regulate any product labeled as a supplement. Many agents have significant side effects without proven ergogenic properties. In 2005, the American Academy of Pediatrics published a policy statement strongly condemning their use in children and adolescents. The 2004 Controlled Substance Act outlawed the purchase of steroidal supplements such as androstenediol, and androstenedione, with the exception of dehydroepiandrosterone (DHEA).

The prevalence of lifetime steroid use is highest among boys in the United States; among a large representative sample in 2010, 5.5% of

Table 692-1 Ergogenic Drugs				
ERGOGENIC DRUG	**CATEGORY**	**GOALS OF USE**	**ATHLETIC EFFECT**	**ADVERSE EFFECTS**
Anabolic–androgenic steroids	Controlled substance	Gain muscle mass, strength	Increase muscle mass, strength	Multiple organ systems: infertility, gynecomastia, female virilization, hypertension, atherosclerosis, physeal closure, aggression, depression
Androstenedione	Controlled substance	Increase testosterone to gain muscle mass, strength	No measurable effect	Increase estrogens in men; overlaps systemic risks with steroids
Dehydroepiandrosterone (DHEA)	Nutritional supplement	Increase testosterone to gain muscle mass, strength	No measurable effect	Increase estrogens in men; impurities in preparation
Growth hormone	Controlled substance	Increase muscle mass, strength, and definition	Decreases subcutaneous fat; no performance effect	Acromegaly effects: increased lipids, myopathy, glucose intolerance, physeal closure
Creatine	Nutritional supplement	Gain muscle mass, strength	Increase muscle strength gains; performance benefit in short, anaerobic tasks	Dehydration, muscle cramps, gastrointestinal distress, compromised renal function
Ephedra alkaloids	Possibly returning as nutritional supplement	Increase weight loss, delay fatigue	Increases metabolism; no clear performance benefit	Cerebral vascular accident, arrhythmia, myocardial infarction, seizure, psychosis, hypertension, death

From Calfee R, Fadale P: Popular ergogenic drugs and supplements in young athletes, Pediatrics *117:e577–e589, 2006.*

boys in middle school and 6.6% of those in high school report having used steroids for muscle-enhancement. The European School Survey Project on Alcohol and Other Drugs found that 1% of European youth reported any use of steroids. Steroids in oral, injectable, and skin cream form are taken in various patterns. *Cycling* is a term used to describe taking multiple doses of steroids for a period, ceasing, and then starting again. *Stacking* refers to the use of different types of steroids in both oral and injectable forms. *Pyramiding* involves slowly increasing the steroid dose to a peak amount and then gradually tapering down.

Anabolic–androgenic steroids have been used in supraphysiologic doses for their ability to increase muscle size and strength and decrease body fat. An evidence-base does support the increase in muscle mass and strength; the effects appear to be related to the myotrophic action at androgen receptors as well as competitive antagonism at catabolism-mediating corticosteroid receptors. However, they have significant endocrinologic side effects, such as decreased sperm count and testicular atrophy in men and menstrual irregularities and virilization in women. Hepatic problems include elevated aminotransaminases and γ-glutamyl transferase, cholestatic jaundice, peliosis hepatitis, and a variety of tumors, including hepatocellular carcinoma. There is evidence that anabolic–androgenic steroids might cause cardiovascular problems as well, including higher blood pressure, lower high-density lipoprotein, higher low-density lipoprotein, higher homocysteine, and decreased glucose tolerance. The psychologic effects include aggression, several personality disorders, and a variety of other psychologic problems (anxiety, paranoia, mania, depression, psychosis). Physical findings in males include gynecomastia, testicular shrinkage, jaundice, male pattern baldness, acne, and marked striae. Women can develop hirsutism, voice deepening, cliterol hypertrophy, male-pattern baldness, acne, and marked striae.

Testosterone precursors (also known as *prohormones*) include androstenedione and DHEA. Their use in the adolescent population has increased markedly in conjunction with reports of high-profile athletes' use. They are androgenic but have not been proved to be anabolic. If they are anabolic at all, they work by increasing the production of testosterone. They also increase production of estrogenic metabolites. The side effects are similar to those of anabolic–androgenic steroids and far outweigh any ergogenic benefit. Since January 2005, these substances cannot be sold without prescription.

Creatine is an amino acid mostly stored in skeletal muscle. Its key feature is ability to rephosphorylate adenosine diphosphate to adenosine triphosphate, therefore increasing muscle performance. Its use has increased, especially since other supplements have been withdrawn from the market. Thirty percent of high school football players have used creatine. There is evidence that creatine, as a source of increased energy, enhances strength and maximal exercise performance when used during training. There is no evidence that creatine affects hydration or temperature regulation. Concerns about nephritis in case reports have not been supported by controlled studies. However, there are few long-term studies evaluating creatine use.

Caffeine is an active ingredient in energy drinks and some endurance sport supplements. More of a problem as an energy drink when combined with alcohol, excessive caffeine ingestion may result in tachycardia, gastritis, nausea, vomiting, and central nervous system excitation. Overdoses may result in seizures, arrhythmias, and hypotension.

Chapter 693

Specific Sports and Associated Injuries

Kevin P. Murphy and Aaron M. Karlin

GYMNASTICS

Typically, males and females begin gymnastics participation at 4-5 yr of age. The highest level of competition is in the mid-teens followed by retirement, often by 20 yr for females and mid-twenties for males. Lower-extremity injuries are more common in female gymnasts,

whereas upper body injuries occur with higher frequency in male gymnasts. Apparatus competed upon accounts for this discrepancy, such as the horizontal bar and ring exercises for male gymnasts, which place a great deal of stress upon the shoulders. In addition to mechanical or traumatic injuries, female gymnastics commonly have delayed menarche and are at risk for hypothalamic amenorrhea or oligomenorrhea, as well as low body weight for height related to disordered eating. Despite the presence of these 2 components of the *female athlete triad* (see Chapter 691), the third component, reduced bone density or osteoporosis, is not commonly seen. In fact, bone density tends to be high in most gymnasts, which is thought to be secondary to their performance involving repetitive high-impact activities. Nevertheless, stress fractures, in both the upper and lower extremities, are a significant problem. The short stature associated with male and female gymnasts is probably caused by selection bias and not the result of gymnastics training.

Both acute and chronic injuries are seen in gymnasts and commonly involve the ankles, wrists, and spine. The incidence of injury increases with the skill level and is greatest with the floor exercise. The amount of weightbearing through the upper extremities in gymnastics lends itself to the development of both traumatic and overuse injuries. At the wrist, this can manifest as Salter I stress fractures of the distal radial physis *(gymnast's wrist*), triangular fibrocartilage tears, scaphoid fractures, dorsal ganglions, and, most commonly, wrist sprains (see Chapter 683.2). Spine injuries are notable for a high incidence of spondylolysis (stress fracture of the pars interarticularis) and, in less frequent cases, spondylolisthesis, both related to repetitive extension loading of spine (see Chapter 679.6). Ligamentous laxity can predispose to elbow or shoulder dislocation and ankle sprains.

Treatment of many of these injuries includes relative rest from the inciting activity, immobilization, ice, and nonsteroidal antiinflammatory drugs. Imaging begins with radiographs but may include bone scan with single-photon emission computed tomography to evaluate spondylolysis, or MRI to rule out intraarticular tears, loose bodies, ligamentous instability, or physeal injury. A pediatrician should have a low threshold for referral to a sports medicine or orthopedic specialist in a child with a wrist injury not improving with rest.

SWIMMING

Injuries of the shoulder in competitive swimming are most common and generally a result of chronic, overuse. *Swimmer's shoulder* is a combination of subacromial bursitis and tendinosis of the rotator cuff and long-head of the biceps. Commonly, increased laxity of the shoulder capsule and weakness of the scapular stabilizers contribute over time leading to the insidious onset of shoulder pain (see Chapter 687.2). Freestyle, back, and butterfly strokes tend to exacerbate the pain. Pain may be provoked on exam by passively abducting the arm to 90 degrees, forward flexing to 30 degrees, and internally rotating the humerus with the elbow extended while having the patient actively abduct against resistance (*Empty Can* Test). The Hawkins impingement test involves the same position of the shoulder with the elbow flexed to 90 degrees and the examiner internally rotating the humerus. Pain and/or weakness indicates supraspinatus injury. Treatment includes relative rest, ice, and modification of stroke technique. The multi-axial instability of the glenohumeral joint common to swimmers is addressed with rehabilitation focusing upon strengthening of the rotator cuff and scapular stabilizer musculature. Prevention includes monitoring training load, proper technique and strengthening exercises.

Swimmer's ear, or otitis externa, presents with pain and often drainage from the external auditory canal. It is caused by bacterial, or less commonly, fungal infection of the external auditory canal due to chronic, excessive wetness (see Chapter 639).

BASEBALL

Throwing injuries of the elbow and shoulder (particularly among pitchers) are the most common baseball injuries (see Chapters 687.2 and 687.3). Monitoring the number of pitches thrown per game, no more than 6 times the young athlete's age in years and per week based upon the athlete's age, is important. Counseling athletes (and coaches) to stop all throwing activities if the player experiences elbow pain, with medical evaluation to be sought if there is no resolution with rest, is essential. Death or serious injury in baseball is rare and generally from direct contact by the ball, causing serious head injury or, in the case of chest wall impact, *commotio cordis*. Batting helmets need to be worn properly to try to prevent face and head injuries; modifications to the hardness of baseballs used with younger athletes is also helpful. Injures to catchers can involve traumatic brain injury with various levels of concussion from contact of the ball to the face mask. Catchers are more vulnerable to traumatic sprains of the interphalangeal and metacarpal phalangeal joints along with internal derangement and ligamentous sprain of the knees associated with the deep squatting posture.

DANCE

Dance is a highly demanding activity that may be associated with delayed menarche and disordered eating in females (see Chapter 691). Acute injuries commonly involve the lower extremities. Overuse injuries are likely, due to the repetitive nature of maneuvers incorporated into training and performance. Frequently, kinetic chain dysfunction contributes to injury and this should be considered when evaluating the dancer. Common mistakes in technique can cause injury, such as forcing excessive "turnout" (external rotation at the hip) in ballet can result in undue stress being placed upon the knees (see Chapter 687.6). An unrehabilitated ankle sprain may cause favoring of the affected leg leading to development of a stress fracture of the contralateral tibia. In contrast to injuries in most types of dance, injuries associated with breakdancing more frequently involve the spine and upper extremities than lower extremities. This likely relates to the significant amount of twisting of the torso and weight bearing through the hands inherent in this genre of dance.

Foot problems are not uncommon and include metatarsal stress fractures, subungual hematomas, sesamoiditis, plantar fasciitis, calluses, and bunions (see Chapter 687.9). A *Dancer's fracture* is an avulsion fracture of the distal shaft of the 5th metatarsal. This is treated with immobilization for 4-6 wk, although poor healing, a result of the tenuous blood supply in the area, may necessitate surgical fixation. Common ankle injuries include acute sprains, anterior and posterior impingement syndromes, and osteochondritis dissecans of the talus. Medial tibial stress syndrome ("shin splints") and tibial stress fractures are noted in the lower leg. Patellar malalignment/hypermobility can result in patellofemoral pain syndrome or, less frequently, patellar subluxation/dislocation. Medial snapping hip syndrome, caused by the iliopsoas tendon riding over the anterior hip capsule, and hip flexor (rectus femoris, iliopsoas) tendinosis are commonly noted in addition. Gluteal region pain with sciatica may be a result of *piriformis syndrome,* which occurs because of the repetitive external hip rotation required in ballet (see Chapter 687.5).

The proper timing of allowing a ballet dancer to go *en pointe* is a common question asked by dancers and parent alike. An average age to go en pointe is 12 yr. A functional test should be part of that decision: If the young dancer is able to perform a passé steadily away from the barre as well as being able to maintain an en pointe position without pain or instability the dancer is likely ready to begin dancing en pointe.

WRESTLING

Wrestlers have great fluctuations in weight to meet weight-matched competition standards. Such fluctuations are associated with fasting, dehydration, and then binging. Counseling to wrestlers and their parents regarding impaired performance resulting from these components of disordered eating, especially with respect to decreased speed and strength, is important in order to deter athletes from incorporating them into routine practice.

Wrestling holds apply a variety of torques or forces to the extremities and spine producing a number of common injuries. Takedown maneuvers and subsequent impact with the mat can produce concussions, neck strain/sprain, or spinal cord injury (see Chapter 689). *Stingers* and *burners*, also seen among football players, are caused by stretching or pinching of the brachial plexus (see Chapter 689). Pain at the shoulder

often radiates down the arm and is frequently associated with paresthesias and weakness; the latter most commonly involving the deltoid and other C5/C6 innervated muscles. Overall, the 2 most common sites of injury in wrestling are the shoulder and knee.

At the shoulder, subluxation is common. This generally occurs anteriorly with the shoulder forcibly abducted and extended. Patients are commonly aware of their shoulder slipping in and out (see Chapter 687.2).

Injuries to the hand are less common and typically include metacarpophalangeal and proximal interphalangeal joint sprains. Treatment consists of buddy taping and/or splinting.

Knee injuries (see Chapter 687.6) are also common and include prepatellar bursitis, medial and lateral collateral ligament sprains, and medial and lateral meniscus tears. Acute or recurrent traumatic impact to the mat can result in prepatellar bursitis. Swelling is noted over the patella with the patient experiencing limitations to range of motion primarily with knee flexion as a result. If the overlying skin is broken, septic bursitis must be considered. Distinguishing between a traumatic and infected bursitis may require aspiration of the bursa. Treatment of traumatic bursitis includes protective padding upon return to wrestling, ice, nonsteroidal antiinflammatory drugs (NSAIDs), and, on occasion, aspiration if flexion is markedly impaired. Recurrence after aspiration is not uncommon. Rarely, bursectomy is needed if there are several reoccurrences.

Dermatologic problems associated with wrestling include herpes simplex (see Chapter 252: *herpes gladiatorum*), impetigo (see Chapter 665.1), staphylococcal furunculosis or folliculitis, superficial fungal infections, and contact dermatitis. Herpes gladiatorum and impetigo are contraindications to wrestling until the lesions have resolved. Treatment of herpes gladiatorum with oral antiviral medications, such as Acyclovir, for both acute outbreaks and long-term suppression is recommended. Washing of the wrestling mats with appropriate antibacterial and antifungal solution is required after daily wrestling sessions to keep the mats disinfected and protect the spread of dermatologic contagion.

Auricular hematoma is caused by friction or direct trauma to the auricle (see Chapter 642). If allowed to remain without evacuation, irreversible deformity of the auricle often results, termed *cauliflower ear*. Properly fitted headgear is the best means of prevention.

FOOTBALL

Football is the sport with the highest number of injuries, with the greatest number of participants (especially at the high school level) and with a higher rate of injury. The majority of these injuries is relatively minor and compared to many other sports, the injuries are less severe, as evidenced by less number of days lost from injury. The most common football injuries include joint sprains, muscle strains, and contusions, with the lower extremities injured most frequently. Treated appropriately, these injuries generally result in minimal time away from football. An important exception to this, contusions to the arm or thigh muscles can result in the development of a large hematoma if not treated aggressively in the acute stage, resulting in prolonged time away from football. Without the presence of fracture, treatment includes ice and compression for the 1st few days to reduce the expansion of the hematoma. Pain-free stretching and strengthening exercises are then incorporated. Therapeutic ultrasound per physical therapy staff can be helpful in stretching deeper tissue and resolving persistent hematoma limiting further flexibility. Return to contact play is initiated when baseline range of motion and strength are achieved. Large hematomas and those allowed to persist are at risk for development of myositis ossificans.

Although the majority of catastrophic sports injuries in the United States have occurred in football, these injuries are rare. Catastrophic injury is defined as a fatal injury or a severe injury with or without permanent severe functional disability. Disabling injuries include cervical spine and cerebral injuries.

Head and neck injuries in football include concussion, neck sprain, and brachial plexopathy. The latter, also seen among wrestlers, is referred to as a *stinger* or *burner* and represents a brachial plexus neurapraxia (see Chapter 689). This is the most common nerve injury in football and is often the result of a traction or compression injury to the upper nerve roots of the brachial plexus caused by forceful lateral neck bending. This results in painful arm dysesthesias and deltoid muscle weakness. This is usually transient, resolving in minutes to days, with return to play upon return of full range of motion, comfort and strength.

Compared to other sports, brain injury (**concussions)** occurs with the highest rate in football, a result of the frequent exposure to contact during practices and games. The prevention, diagnosis, and management of this significant injury with potentially lifelong implications are discussed in full in Chapter 688**.**

Lumbar spine injury manifested as low back pain can indicate spondylolysis (see Chapter 679.6). Shoulder trauma can cause glenohumeral dislocation, the majority of which are anterior dislocations, acromioclavicular joint sprain, and fractures to the clavicle or humerus (see Chapter 687.8). Knee injuries (see Chapter 687.6) are common and include anterior cruciate ligament and, less frequently, posterior cruciate ligament tears along with medial collateral ligament sprains.

Ankle sprains occur frequently, and the risk of reinjury may be reduced by rehabilitation and the use of a lace-up ankle brace (see Chapter 687.6). Turf toe, a sprain to the 1st metatarsophalangeal joint, is caused by forceful dorsiflexion of the toe while wearing soft, lightweight, flexible shoes. Treatment of turf toe includes ice, NSAIDs, and orthotic to limit extension of the great toe, along with rest.

ICE HOCKEY

Ice hockey is classified as a collision sport and is associated with injuries caused by contact from the puck or stick as well as from other players, the ice, or the boards. These injuries commonly include contusions, lacerations, fractures, sprains, or concussions. The risk of injury is reduced by the use of proper equipment (helmets with facemasks) and enforcement of the rules regarding dangerous body contact (checking from behind, high sticking, and fighting).

Specific hockey injuries include ankle sprains (dorsiflexion, eversion, and external rotation in contrast to the usual inversion sprain in other sports), hip adductor strain, osteitis pubis, and various shoulder injuries from body contact. The latter include acromioclavicular joint sprain, glenohumeral dislocation, and clavicle fractures (see Chapter 687.2). The most serious injuries are to the head and neck (see Chapters 688 and 689).

BASKETBALL AND VOLLEYBALL

Common maneuvers of these 2 sports include jumping, pivoting, running and sudden stopping which increase the risk for knee and ankle injuries. Similarly, injury to the fingers may result from the passing, catching, and striking of the ball inherent in these sports.

Knee injuries include those caused by overuse, such as **traction apophysitis** (Osgood-Schlatter disease) and **patellar tendinosis** (*jumper's knee*) (see Chapter 687.6). As with other jumping sports, acute ligament sprains (medial collateral with or without anterior cruciate ligaments) can occur. Shoulder injuries in volleyball players are similar to other overhead athletes and include rotator cuff tendinosis and glenohumeral instability.

Ankle sprain is the most common injury and is usually caused by inversion with plantar flexion, placing the lateral ligaments at high tension. An avulsion fracture of the base of the 5th metatarsal at the insertion of the peroneus brevis tendon is another sequelae of inversion ankle injuries. In terms of overuse injuries at the ankle, Achilles tendinosis is common. Foot pain may be from calcaneal apophysitis (Sever disease), retrocalcaneal bursitis, posterior tibialis tendinosis, accessory tarsal navicular, plantar fasciitis, stress fracture of the tarsal navicular, Jones's stress fracture of the 5th metatarsal, sesamoiditis, blisters, subungual hematoma, and paronychia (see Chapters 687.8 and 687.9).

RUNNING

Running problems are typically caused by an overuse injury related to muscle imbalance; a minor skeletal deformity; repetitive overload

trauma; or poor flexibility, strength, endurance, or proprioception. With each step while running, the foot impact ranges from 3-8 times the athlete's body weight. Errors in training, including increasing the distance or intensity of workouts too rapidly, often result in injury to the runner. Minor variations (e.g., malalignment) in anatomy that do not cause problems at rest can predispose to injury at specific sites, such as overpronation, contributing to increased patellofemoral stress. Muscle fatigue, environmental temperature (see Chapter 690), and running surface (grass vs unyielding concrete) also contribute to injury. Prevention of injuries is possible by muscle-strengthening exercises, incorporating periods of rest into training plans, and the use of good-quality running shoes that match an athlete's foot type. Those who overpronate may benefit from a motion control shoe for maximal rearfoot and arch support. Those who mildly overpronate should utilize a stability shoe that combines extra support in the medial midsole with midsole cushion. Those who supinate should wear a neutral, cushioned shoe with increased shock absorption in the midsole and less arch support.

Stress fractures of all bones of the lower extremities can occur in runners (see Chapter 683.4). They have been documented at the femoral neck, inferior pubic rami, subtrochanteric area, proximal femoral shaft, proximal tibia, fibula, navicular, metatarsals, desmoids, and calcaneal apophysis. The most common are in the metatarsals, tibia, and fibula. The anterior proximal tibia, femoral neck, and tarsal navicular are most at risk for nonunion. Muscle strains most frequently affect the hamstrings, followed by the quadriceps, hip adductors, soleus, and gastronomies muscles. Tendinosis is most common in the Achilles tendon, followed by the posterior tibial, peroneal, iliopsoas, and proximal hamstrings. Achilles tendinosis characterized by tenderness and crepitance if acute and nodularity if chronic, initially might get better when running, and must be distinguished from retrocalcaneal bursitis. Treatment includes a period of rest from running (substitute cross-training), a heel lift, Achilles tendon stretching, and NSAIDs.

Knee pain in the runner is frequently anterior in location and commonly caused by patellofemoral stress syndrome (**runner's knee**), which results from excessive dynamic, usually lateral, motion of the patella in relationship to the femoral intracondylar groove (see Chapter 687.6). The athlete's body habitus (i.e., increased Q-angle, overpronation) and presence of core weakness may contribute to this overuse injury. Posterior knee pain can be caused by gastrocnemius strain, while posteromedial pain may be caused by proximal tibial stress fracture or semimembranosus/semitendinosus tendinosis. Lateral knee pain is commonly caused by **iliotibial band syndrome** and less so by popliteal tendinosis. Iliotibial band syndrome may combine both a component of bursitis and tendinosis owing to mechanical friction of the iliotibial band (an extension of the tensor fasciae latae) over the lateral femoral epicondyle. Treatment for knee pain in the runner includes relative rest from running, ice, and stretching of the quadriceps, hamstrings, and, in some cases, the iliotibial band. Strengthening exercises should include the quadriceps, hips, and core muscles. Foot orthotics may be indicated if there is no improvement with this treatment plan.

Shin splints, or medial tibial stress syndrome, is a descriptive term for pain located diffusely over the distal medial tibia and should be distinguished from tibia stress fracture and chronic compartment syndrome. Medial tibial stress syndrome often occurs in new runners with overpronation, or runners that have markedly increased their training duration in a short period of time. See Chapter 687.7 for prevention, diagnosis, and treatment.

Chronic compartment syndromes involve any of the muscle compartments with the most common being anterior. There is typically poorly localized throbbing pain that onsets 10-15 min into a run. Pain typically prevents further training limiting the risk of nerve injury. Physical exam is usually normal. Diagnosis is made by measurement of intracompartmental pressures at rest or during exercise.

Plantar fasciitis is an inflammation of the supporting structures of the longitudinal arch, due to repetitive cyclic loading with foot strike. Pain is typically worst with the first step out of bed in the morning and with running and is located on the medial aspect of the heel. Pes planus and overpronation are common in these patients. Treatment includes relative rest, ice, heel cord stretching, transverse friction massage, proper shoes, use of a posterior night splint, and corticosteroid injection. Therapeutic ultrasound by a trained physical therapist can be helpful in stretching the deep plantar fascia pre-friction massage in certain individuals. Calcaneal stress fracture should be considered, especially in the amenorrheic distance runner (see Chapter 691).

SOCCER

Injuries in soccer include any of the running injuries previously noted as well as abrasions, contusions, muscle strains, and ligament sprains (ankle, knee predominantly), partly from body-to-body contact, falls, running, and kicking. Hip problems include the *hip pointer* (iliac crest contusion), iliac crest apophysitis, and chronic groin pain (muscle strain, hernia, osteitis pubis). Femoral neck stress fractures, slipped femoral capital epiphysis, and avulsion fractures of the pelvis or femur should also be considered in the differential despite being uncommon (see Chapter 687.5). In general, most other upper- and lower-extremity injuries can occur in soccer.

Traumatic brain injury (see the discussion of concussions in Chapter 688) is common in soccer because of contact between players, player and goal post, and player and ground. The American Academy of Pediatrics recommends that youth soccer participants minimize heading the ball until more is known about the risks in young children. Proper heading technique is vital and should be taught in youth soccer. Additional points of play to consider include: On long kicks, the receiving player should trap the ball with the chest or leg, not strike it with the head; players should kick the ball about 5 ft in front of their teammates so that the latter have to come to the ball and trap with their legs; players avoid heading the ball backward toward the goal (with cervical extension); referees, as with all sports, have to keep the game under control and penalize dangerous play; and guidelines for returning to play after a concussion should be followed.

TENNIS

Tennis injuries occur twice as often in the lower extremity compared to the upper extremity with overall injury rates similar for boys and girls. Common areas of injury include the muscles, tendons, and ligaments of the ankle, thigh, elbow, shoulder, back, wrist, and abdomen. The risk of injury is increased by increased training duration and intensity; anatomic considerations (muscle imbalance, malalignment); poorly rehabilitated injuries with resultant deficits in flexibility and strength; and poor technique. Injuries can also be related to improper equipment, such as a racquet that is too big, or trying to learn techniques, such as hitting with top spin or with power before proper coordination and technique have been established.

Acute injuries include ankle sprains, abdominal or extremity muscle strains, and knee sprains. Overuse injuries involve both the upper and lower extremities as well as the back. Lower-extremity injuries are related to the frequent directional changes inherent in the sport, creating significant concentric and eccentric loads on the lower extremities. These include patellofemoral stress syndrome, proximal tibial stress fractures, traction apophysitis of the calcaneus (Sever disease), and tibial tubercle (Osgood-Schlatter disease) (see Chapters 687.6 and 687.7)

In the upper extremities, overuse injuries include stress fractures of the humerus, ulna, and metacarpals, as well as traction apophysitis at the medial humeral epicondyle. The marked and rapid load and directional change associated with serving in tennis contributes to injuries of the back.

Tennis elbow, or lateral epicondylitis, is from repetitive overload of the wrist extensor-supinator mechanism, especially the extensor carpi radialis brevis (see Chapter 687.3). Medial epicondylitis is caused by repetitive overload of the wrist flexor–pronator muscle groups. This can secondarily involve the ulnar collateral ligament at the elbow. In young athletes, medial epicondylar apophysitis may also be associated with ulnar nerve dysfunction in the presence of an avulsion injury.

Olecranon apophysitis is similar to Osgood-Schlatter disease and is marked by pain at the olecranon with elbow extension.

At the shoulder (see Chapter 687.2), rotator cuff tendinosis is caused by repetitive overuse and may be related to anteroposterior glenohumeral instability. Subluxation of the glenohumeral joint may also be present. Biceps tendinosis can present as anterior shoulder pain. Wrist problems include an enlarged dorsal ganglion cyst, radiocarpal joint capsular (impingement) synovitis, chronic degenerative tears of the triangular fibrocartilage complex, and acute fracture of the hook of the hamate.

Basic treatment includes relative rest, ice, NSAIDs, rehabilitation, learning proper mechanics, use of properly sized racquets, counterforce bracing (elbow, wrist), forearm straps, strengthening exercises, and gradual return to tennis. Corticosteroid injections in the wrist extensor–supinator muscle group for tennis elbow are not recommended as outcomes at 1 yr are poorer than those treated with rehabilitation.

SKIING AND SNOWBOARDING

Injuries are related to falls (concussions, contusions, lacerations), and ski-specific mechanisms. Overall injuries have declined, partly because of better equipment (boots, bindings, poles) and slope conditions. It is strongly advised that children, adolescents, and adults wear helmets for skiing and snowboarding. Wrist protectors are also recommended for snowboarders. Injury patterns differ between these two sports with lower extremity injuries more commonly associated with skiing. Upper-extremity injuries (often from falls onto an outstretched arm) are more common in snowboarding related to the fact that both of the snowboarder's feet are strapped onto the same board reducing torque at the knees. The upper extremities, not poles, are used for balance in snowboarding putting them at increased risk.

Skier's thumb, a sprain of the ulnar collateral ligament of the thumb, often results from a fall with the thumb in abduction and hyperextension. Complete tears with a 45 degree joint opening require surgical intervention. Smaller degrees of joint opening can be treated with immobilization in a thumb spica cast × 4 wk. Care should be taken to rule out a concomitant Salter-Harris III fracture, which would require open reduction and internal fixation if the epiphyseal fracture is displaced. In snowboarding, shoulder dislocation, acromioclavicular joint sprain, and fractures of the wrist or collarbone are common injuries.

Lower-extremity injuries include fractures (often spiral) of the tibia ("boot top") and sprains of the high ankle and anterior cruciate ligament, the latter may include tibial eminence fracture. Hemarthrosis is present in fractures and anterior cruciate ligament injuries. Treatment is described in Chapter 683.4.

CHEERLEADING

Cheerleading injuries are mostly related to the gymnastic component of the sport, primarily stunting, tumbling, and pyramids. Sprains and strains comprise the majority of these injuries followed by fractures and contusions. These injuries involve the upper and lower extremities nearly equally, with the ankle being the most commonly injured joint followed by the head, neck, knee, and lower back. The use of impact-absorbing surfaces for practices reduces the risk of serious injury from falls. Ankle sprains in cheerleading predominantly involve the lateral ligaments with the ankle injured when forced into excessive plantarflexion and inversion during landings.

Similar to gymnasts, the excessive amount of repetitive hyperextension, flexion, rotation, and axial loading of the spine associated with stunting and tumbling maneuvers results in significant stress being placed upon the lower back. Another common mechanism of injury involves the act of spotting or basing another cheerleader during partner or group stunts. This involves the lifting or throwing of a teammate above the level of one's head, followed by catching them upon their descent. Injuries with this activity include sprains and strains to the upper and lower back, contributed to by poor technique, requiring coaching to avoid excessive lordosis and encourage lifting with one's legs. Concussions (brain injury) are not uncommon in cheerleading, primarily due to falls while stunting or from a pyramid. This sometimes places the cheerleaders on the bottom of these formations at greater risk of injury than those held aloft or thrown. Prevention, diagnosis, and treatment of concussion are described in Chapter 688.

SKATEBOARDING

Injuries associated with skateboarding are predominantly acute including contusions, lacerations, sprains, and fractures, affecting the wrists, forearms, and to a lesser extent, ankles and head. Fractures involving the upper extremities are more common in younger skateboarders, often from a fall onto an outstretched arm (see Chapter 683.3). Lower-extremity fractures and head injuries predominate in the adolescent population, likely because of higher complexity of the often airborne maneuvers attempted. Loss of balance leading to a fall when failing to perform a particular maneuver is generally the primary cause of injury. These falls can occur at high velocities, with speeds up to 40 mph documented in the literature, placing the skateboarder at risk for serious injuries.

Traumatic brain injuries are not uncommon within this sport, the incidence increasing with age as well as more common in males than females. In older children and adolescents, the neglected use of helmets and increased speed of their skating contribute to this fact. The prevention, diagnosis, and treatment of traumatic brain injuries are discussed in Chapter 688.

In addition to helmet use, other safety measures recommended include wrist guards with elbow and knee pads. The building of skateboard parks has been a recent strategy to remove skateboarders from pedestrians, bicyclists, and traffic while also encouraging adult supervision.

Section 3

The Skeletal Dysplasias

Chapter 694

General Considerations

William A. Horton and Jacqueline T. Hecht

The **skeletal dysplasias**, **bone dysplasias**, and **osteochondrodysplasias** are a genetically and clinically heterogeneous group of disorders of skeletal development and growth with an estimated prevalence of 1 in 4,000 births. They can be divided into the osteodysplasias typified by osteogenesis imperfecta (see Chapter 701) and the chondrodysplasias. The latter result from mutations of genes that are essential for skeletal development and growth. The clinical picture is dominated by skeletal abnormalities. The manifestations may be restricted to the skeleton, but in most cases nonskeletal tissues are also involved. The disorders range in severity from lethal in utero to such mild features as to go undetected.

The chondrodysplasias are distinguished from other forms of short stature by a disproportionality of skeletal manifestations. Figure 694-1 notes the importance of cartilage in bone formation. There are 2 basic categories: predominantly with short limbs and predominantly with short trunks. Efforts to define the extent of clinical heterogeneity resulted in the delineation of well over 100 distinct entities. Many of these disorders result from mutations of a relatively small group of genes, the *chondrodysplasia genes*. An International Working Group on

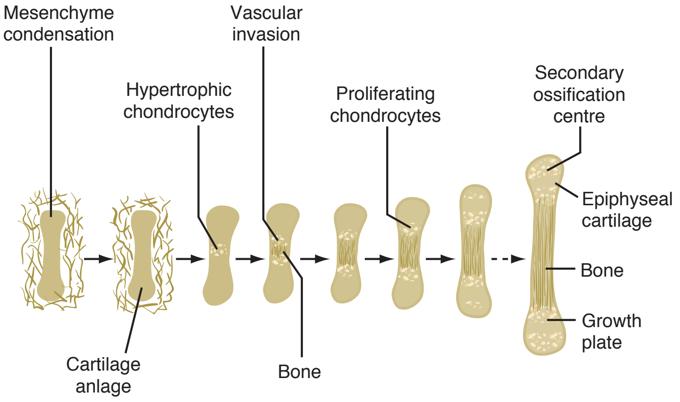

Figure 694-1 The importance of cartilage in bone formation. *(From Horton WA: Skeletal development: Insights from targeting the mouse genome,* Lancet *362:560, 2005.)*

Bone Dysplasias has named and classified these disorders into groups based on genetic cause if known or on similarities of clinical and radiographic manifestations, which often imply a common pathogenesis and a common genetic basis, if the cause is unknown (Table 694-1). The better-defined chondrodysplasia groups, such as the achondroplasia and type II collagenopathy groups, contain graded series of disorders that range from very severe to very mild. This may be true for other groups as more mutations are found and the full spectrum of clinical phenotypes associated with mutations of a given gene is defined. These disorders are clinical phenotypes distributed along spectra of phenotypic abnormality associated with mutations of particular genes. For mutations of some genes, such as *COL2A1,* the distribution is fairly continuous, with clinical phenotypes merging into one another across a broad range. There is much less clinical overlap for mutations of some other genes, such as *FGFR3,* in which the distribution is discontinuous. Because most clinicians and most reference materials refer to the disorders as distinct entities, this vernacular continues to be used.

Most chondrodysplasias require the analysis of information from the history, physical examination, skeletal radiographs, family history, and laboratory testing to make a diagnosis. The process involves recognizing complex patterns that are characteristic of the different disorders (Tables 694-2, 694-3, 694-4, and 694-5). Comprehensive descriptions of disorders and references are at the Online Mendelian Inheritance in Man (OMIM) Internet site (http://omim.org/about).

CLINICAL MANIFESTATIONS

Growth

The hallmark of the chondrodysplasias is disproportionate short stature. Although this refers to a disproportion between the limbs and the trunk, most disorders exhibit some shortening of both, and subtle degrees of disproportion may be difficult to appreciate, especially in premature, obese, or edematous infants. Disproportionate shortening of the limbs should be suspected if the upper limbs do not reach the mid pelvis in infancy or the upper thigh after infancy. Disproportionate shortening of the trunk is indicated by a short neck, small chest, and protuberant abdomen. Skeletal disproportion is usually accompanied by short stature (length and height below the 3rd percentile); these measurements are occasionally within the low-normal range early in the course of certain conditions.

There may also be disproportionate shortening of different segments of the limbs; the particular pattern can provide clues for specific diagnoses. Shortening is greatest in the proximal segments (upper arms and legs) in achondroplasia; this is termed **rhizomelic shortening.** Disproportionate shortening of the middle segments (forearms and lower legs) is called **mesomelic shortening; acromelic** shortening involves the hands and feet.

With some exceptions, there is a strong correlation between the age at onset and the clinical severity. Many of the lethal neonatal chondrodysplasias are evident during routine fetal ultrasound examinations performed at the end of the 1st trimester of gestation (see Table 694-4). Gestational standards exist for long-bone lengths; discrepancies are often detected between biparietal diameter of the skull and long-bone lengths. Many disorders become apparent around the time of birth; others manifest during the 1st yr of life. A number of disorders manifest in early childhood and a few in late childhood or later.

Non–Growth-Related Manifestations

Most patients also have problems unrelated to growth. Skeletal deformities, such as abnormal joint mobility, protuberances at and around joints, and angular deformities, are common and usually symmetric. Skeletal abnormalities can adversely affect nonskeletal tissues. Impaired growth at the base of the skull and of vertebral pedicles reduces the size of the spinal canal in achondroplasia and can contribute to spinal cord compression. Short ribs reduce thoracic volume, which can compromise breathing in patients with short trunk chondrodysplasias. Cleft palate (see Chapter 310) is common to many disorders, presumably reflecting defective palatal growth.

Manifestations may be unrelated to the skeleton; they reflect expression of mutant genes in nonskeletal tissues. Examples include retinal detachment in spondyloepiphyseal dysplasia congenita, sex reversal in camptomelic dysplasia, congenital heart malformations in Ellis-van Creveld syndrome, immunodeficiency in cartilage-hair hypoplasia, and renal dysfunction in asphyxiating thoracic dystrophy. These nonskeletal problems provide valuable clues to specific diagnoses and must be managed clinically (see Table 694-3).

Family and Reproductive History

A family history might identify relatives with the condition; a mendelian inheritance pattern may be elicited. Because the presentation can vary in some disorders, features that might be related to the disorder should be identified. Special attention should be given to mild degrees of short stature, disproportion, deformities, and other manifestations such as precocious osteoarthritis because they may be overlooked. Physical examination of relatives may be useful, as may the review of their photographs, radiographs, and medical and laboratory records.

A reproductive history might reveal previous stillbirths, fetal losses, and other abnormal pregnancy outcomes resulting from a skeletal dysplasia. Pregnancy complications, such as polyhydramnios or reduced fetal movement, are common in bone dysplasias, especially neonatal lethal variants.

Even though most of the skeletal dysplasias are genetic, it is common to have no family history of the disorder. New mutations are common for autosomal dominant disorders, especially lethal disorders in the perinatal period (thanatophoric dysplasia, osteogenesis imperfecta). Most cases of achondroplasia result from new mutations. Germ cell mosaicism, in which a parent has clones of mutant germ cells, has been observed in osteogenesis imperfecta and in other dominant disorders. A negative family history is usually seen in recessive disorders. Few of these conditions are caused by X-linked mutations. Prenatal diagnosis is available for disorders that have a genetic locus identified. Appropriateness of the testing depends on many factors, and genetic counseling is warranted for these families.

Radiographic Features

Radiographic evaluation for a chondrodysplasia should include plain films of the entire skeleton. Efforts should be made to identify which bones and which parts of bones (epiphyses, metaphyses, diaphyses) are most affected. If possible, films taken at different ages should be examined because the radiographic changes evolve with time. Films taken before puberty are generally more informative because pubertal closure of the epiphyses obliterates many of the signs needed for a radiographic diagnosis. Prenatal diagnosis may also be possible with fetal ultrasound.

DIAGNOSIS

If an infant or child is short with disproportionate features, a diagnosis is established by matching the observed clinical picture (defined

Table 694-2 Major Problems Associated with Skeletal Dysplasias

PROBLEM	EXAMPLE
Lethality*	Thanatophoric dysplasia
Associated anomalies†	Ellis-van Creveld syndrome
Short stature	Common to almost all
Cervical spine dislocations	Larsen syndrome
Severe limb bowing	Metaphyseal dysplasia, Schmid type
Spine curvatures	Metatropic dysplasia
Clubfeet	Diastrophic dysplasia
Fractures	Osteogenesis imperfecta
Pneumonias, aspirations	Camptomelic dysplasia
Spinal cord compression	Achondroplasia
Joint problems (hips, knees)	Most skeletal dysplasias
Hearing loss	Common (greatest with cleft palate)
Myopia/cataracts	Stickler syndrome
Immunodeficiency‡	Cartilage-hair hypoplasia, Schimke immunoosseous dysplasia
Poor body image	Variable, but common to all
Sex reversal	Camptomelic dysplasia

*Mostly a result of severely reduced size of thorax.
†See Table 694-3.
‡At least 4 additional disorders, all involving the metaphyses, can have immunodeficiency.

primarily from clinical, family, and gestational histories; physical examination; and radiographic evaluation) with clinical phenotypes of well-documented disorders. Pediatricians should be able to gather most of this information and, in consultation with a radiologist, diagnose the common chondrodysplasias. A number of reference texts and online databases provide information about the disorders and comprehensive lists of current references (http://www.ncbi.nlm.nih.gov/books/NBK1116/). For less-common disorders and for infants and children whose phenotypes do not closely match well-established clinical phenotypes, consultation with experts in the bone dysplasia field is warranted.

Molecular genetic testing for chondrodysplasias is very useful, especially for disorders in which recurrent mutations occur (typical achondroplasia has the same *FGFR3* mutation). Mutation testing for achondroplasia is available, although the diagnosis is usually made clinically. The greatest utility for testing may be for prenatal diagnosis for couples where both parents have typical (heterozygous) achondroplasia. Their children are at a 25% risk of the much more severe homozygous achondroplasia, which can be detected by mutation analysis. Preimplantation genetic testing can be used to identify double dominant mutations. Another example of testing is in disorders resulting from mutations of *DTDST*. These disorders are inherited in an autosomal recessive manner, and a limited number of mutant alleles have been found. If the mutations are identified in the patient, they should be detectable in the parents and potentially used for prenatal diagnosis. Mutational analysis is now commercially available for many of the skeletal dysplasias and is increasingly used to confirm clinical diagnosis and for future pregnancy planning.

Many of the chondrodysplasias have distinct histologic changes of the skeletal growth plate. Sometimes such tissues obtained at biopsy or discarded from a surgical procedure are helpful diagnostically. It is uncommon to make a diagnosis histologically if it was not already suspected on clinical or radiographic grounds.

Table 694-3 Associated Anomalies in Skeletal Dysplasias

ANOMALY	EXAMPLE
Heart defects	Ellis-van Creveld syndrome, Jeune syndrome
Polydactyly	Short rib polydactyly, Majewski type
Cleft palate	Diastrophic dysplasia
Ear cysts	Diastrophic dysplasia
Spinal cord compression	Achondroplasia
Encephalocele	Dyssegmental dysplasia
Hemivertebrae	Dyssegmental dysplasia
Micrognathia	Camptomelic dysplasia
Nail dysplasia	Ellis-van Creveld syndrome
Conical teeth, oligodontia	Ellis-van Creveld syndrome
Multiple oral frenula	Ellis-van Creveld syndrome
Dentinogenesis imperfecta	Osteogenesis imperfecta
Pretibial skin dimples	Camptomelic dysplasia
Cataracts, retinal detachment	Stickler syndrome
Intestinal atresia	Saldino-Noonan
Renal cysts	Saldino-Noonan
Camptodactyly	Diastrophic dysplasia
Craniosynostosis	Thanatophoric dysplasia
Ichthyosis	Chondrodystrophia punctata
Hitchhiker thumb	Diastrophic dysplasia
Sparse scalp hair	Cartilage-hair hypoplasia
Hypertelorism	Robinow syndrome
Hypoplastic nasal bridge	Acrodysostosis
Clavicular agenesis	Cleidocranial dysplasia
Genital hypoplasia	Robinow syndrome
Tail	Metatropic dysplasia
Omphalocele	Beemer-Langer syndrome
Blue sclera	Osteogenesis imperfecta

Table 694-4 Lethal Neonatal Dwarfism

USUALLY FATAL*
Achondrogenesis (different types)
Thanatophoric dysplasia
Short rib polydactyly (different types)
Homozygous achondroplasia
Camptomelic dysplasia
Dyssegmental dysplasia, Silverman-Handmaker type
Osteogenesis imperfecta, type II
Hypophosphatasia (congenital form)
Chondrodysplasia punctata (rhizomelic form)

OFTEN FATAL
Asphyxiating thoracic dystrophy (Jeune syndrome)

OCCASIONALLY FATAL
Ellis-van Creveld syndrome
Diastrophic dysplasia
Metatropic dwarfism
Kniest dysplasia

*A few prolonged survivors have been reported in most of these disorders.

Table 694-5	Usually Nonlethal Dwarfing Conditions Recognizable at Birth or Within 1st Few Mo of Life
MOST COMMON	
Achondroplasia	
Osteogenesis imperfecta (types I, III, IV)	
Spondyloepiphyseal dysplasia congenita	
Diastrophic dysplasia	
Ellis-van Creveld syndrome	
LESS COMMON	
Chondrodysplasia punctata (some forms)	
Kniest dysplasia	
Metatropic dysplasia	
Langer mesomelic dysplasia	

MOLECULAR GENETICS

A number of chondrodysplasia genes have been identified (see Table 694-1). They encode several categories of proteins, including cartilage matrix proteins, transmembrane receptors, ion transporters, and transcription factors. The number of identified gene loci is smaller than anticipated from the number of recognized clinical phenotypes. The majority of patients have disorders that map to fewer than 10 loci; mutations at 2 loci (*COL2A1* and *FGFR3*) account for more than half of all cases. There may be a limited number of genes whose function is critical to skeletal development, especially linear bone growth; mutations in these genes give rise to a wide range of chondrodysplasia clinical phenotypes. New genes harboring mutations that cause chondrodysplasias continue to be identified with advances in detection technology.

Mutations at the *COL2A1* and *FGFR3* loci illustrate different genetic characteristics. *COL2A1* mutations are distributed throughout the gene, with few instances of recurrence in unrelated persons. In contrast, *FGFR3* mutations are restricted to a few locations within the gene, and occurrence of new mutations at these sites in unrelated persons is the rule. There is a strong correlation between clinical phenotype and mutation site for *FGFR3,* but not *COL2A1,* mutations.

PATHOPHYSIOLOGY

Chondrodysplasia mutations act through different mechanisms. Most mutations involving cartilage matrix proteins cause disease when only 1 of the 2 copies (alleles) of the relevant gene is mutated. These mutations usually act through a dominant negative mechanism in which the protein products of the mutant allele interfere with the assembly and function of multimeric molecules that contain the protein products of both the normal and mutant alleles. The type II collagen molecule is a triple helix composed of 3 collagen chains, which are the products of the type II collagen gene *COL2A1.* When chains from both normal and mutant alleles are combined to form triple helices, most molecules contain at least 1 mutant chain. It is not known how many mutant chains are required to produce a dysfunctional molecule but, depending on the mutation, it theoretically could be as few as 1.

Mutations involving type X collagen differ from the model just described. They map to the region of the chain that is responsible for chain recognition; the chains must recognize each other before they can assemble into collagen molecules. Mutations are thought to disrupt this process. As a result, none of the mutant chains are incorporated into molecules. This mechanism is haploinsufficiency because the products of the mutant allele are functionally absent and the normal allele is insufficient for normal function. Mutations involving ion transport genes also act through a loss of function of the transporters. Mutations of transmembrane receptors studied to date appear to act through a gain of function; the mutant receptors initiate signals in a constitutive manner independent of their normal ligands.

Regardless of genetic mechanism, the mutations ultimately disrupt endochondral ossification, the biologic process responsible for the development and linear growth of the skeleton (see Fig. 694-1). Indeed, a wide range of morphologic abnormalities of the skeletal growth plate, the anatomic structure in which endochondral ossification occurs, have been described in the chondrodysplasias.

TREATMENT

The first step is to establish the correct diagnosis. This allows one to predict a prognosis and to anticipate the medical and surgical problems associated with a particular disorder. Establishing a diagnosis helps to distinguish between lethal disorders and nonlethal disorders in a premature or newborn infant (see Tables 694-4 and 694-5). A poor prognosis for long-term survival might argue against initiating extreme lifesaving measures for thanatophoric dysplasia or achondrogenesis types Ib or II, whereas such measures may be indicated for infants with spondyloepiphyseal dysplasia congenita or diastrophic dysplasia, which have a good prognosis if the infant survives the newborn period.

Because there is no definitive therapy to normalize bone growth in any of the disorders, management is directed at preventing and correcting skeletal deformities, treating nonskeletal complications, providing genetic counseling, and helping patients and families learn to cope. Each disorder has its own unique set of problems, and consequently management must be tailored to each disorder.

There are a number of problems common to many chondrodysplasias for which general recommendations can be made. Children with most chondrodysplasias should avoid contact sports and other activities that cause injury or stress to joints. Good dietary habits should be established in childhood to prevent or minimize obesity in adulthood. Dental care should be started early to minimize crowding and malalignment of teeth. Children and relatives should be given the opportunity to participate in support groups, such as the Little People of America (http://www.lpoaonline.org) and Human Growth Foundation (http://www.hgfound.org).

Two controversial approaches have been used to increase bone length. Surgical limb lengthening has been employed for a few disorders. Its greatest success has been in achondroplasia in which nonskeletal tissues tend to be redundant and easily stretched. The procedure is usually performed during adolescence. Pharmacologic doses of human growth hormone comparable to those used to treat Turner syndrome have also been tried in several disorders; the results have been equivocal. Animal studies suggest that C-type natriuretic peptide may promote linear bone growth in achondroplasia. Clinical trials are beginning to test the efficacy of this approach.

Chapter 695

Disorders Involving Cartilage Matrix Proteins

William A. Horton and Jacqueline T. Hecht

Disorders of cartilage matrix proteins resulting in bone and joint disorders can be classified in 5 categories corresponding to the defective proteins: 3 collagens and the noncollagenous proteins COMP (cartilage oligomeric matrix protein), matrilin 3, and aggrecan. The clinical phenotypes and clinical severity differ between and within the groups, especially the **spondyloepiphyseal dysplasia (SED)** group.

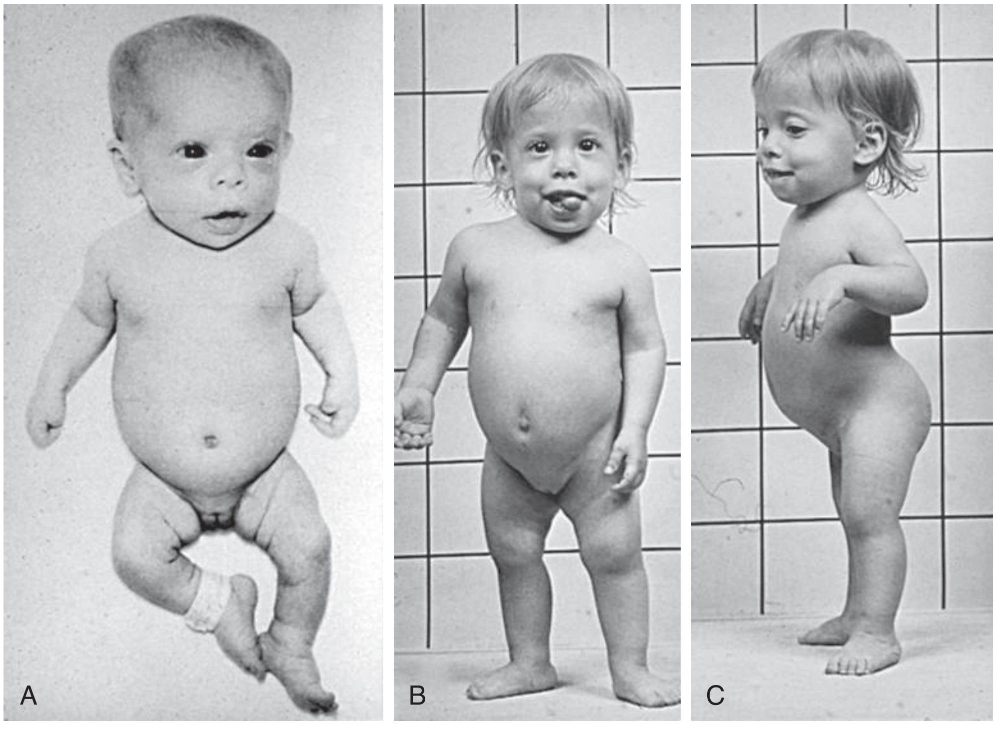

Figure 695-1 Spondyloepiphyseal dysplasia congenita is shown in infancy **(A)** and early childhood **(B, C).** Note the short extremities, relatively normal hands, flat facies, and exaggerated lordosis.

SPONDYLOEPIPHYSEAL DYSPLASIAS

The term *spondyloepiphyseal dysplasia* refers to a heterogeneous group of disorders characterized by shortening of the trunk and, to a lesser extent, the limbs. Severity ranges from achondrogenesis type II to the slightly less-severe hypochondrogenesis (although both types are lethal in the perinatal period) to SED congenita and its variants, including Kniest dysplasia (which is apparent at birth and is usually nonlethal), to late-onset SED (which might not be detected until adolescence or later). The radiographic hallmarks are abnormal development of the vertebral bodies and of epiphyses, the extent of which corresponds to the clinical severity. Most of the SEDs result from heterozygous mutations of *COL2A1;* they are autosomal dominant disorders. The mutations are dispersed throughout the gene; there is a poor correlation between the mutation's location and the resultant clinical phenotype. For familial cases, prenatal diagnosis is possible if the mutation is identified. Schimke immuno-osseous dysplasia may be an exception because it is an autosomal recessive disorder characterized by short stature, hyperpigmented macules, unusual facies, proteinuria and progressive renal failure, cerebral ischemia, and a T-cell defect with lymphopenia and recurrent infections.

Lethal Spondyloepiphyseal Dysplasias

Achondrogenesis type II (MIM 200610) is characterized by severe shortening of the neck and trunk and especially the limbs and by a large, soft head. Fetal hydrops and prematurity are common; infants are stillborn or die shortly after birth. Hypochondrogenesis (MIM 200610) refers to a clinical phenotype intermediate between achondrogenesis type II and SED congenita. It is typically lethal in the newborn period.

The severity of radiographic changes correlates with the clinical severity. Both conditions produce short, broad tubular bones with cupped metaphyses. The pelvic bones are hypoplastic, and the cranial bones are not well mineralized. The vertebral bodies are poorly ossified in the entire spine in achondrogenesis type II and in the cervical and sacral spine in hypochondrogenesis. The pedicles are ossified in both.

Spondyloepiphyseal Dysplasia Congenita

The phenotype of this group, SED congenita (MIM 183900), is apparent at birth. The head and face are usually normal, but a cleft palate is common. The neck is short and the chest is barrel shaped (Fig. 695-1). Kyphosis and exaggeration of the normal lumbar lordosis are common. The proximal segments of the limbs are shorter than the hands and feet, which often appear normal. Some infants have clubfoot or exhibit hypotonia.

Skeletal radiographs of the newborn reveal short tubular bones, delayed ossification of vertebral bodies, and proximal limb bone epiphyses (Fig. 695-2). Hypoplasia of the odontoid process, a short, square pelvis with a poorly ossified symphysis pubis, and mild irregularity of metaphyses are apparent.

Infants usually have normal developmental milestones; a waddling gait typically appears in early childhood. Childhood complications include respiratory compromise from spinal deformities and spinal cord compression because of cervicomedullary instability. The disproportion and shortening become progressively worse with age, and adult heights range from 95-128 cm. Myopia is typical; adults are predisposed to retinal detachment. Precocious osteoarthritis occurs in adulthood and requires surgical joint replacement.

KNIEST DYSPLASIA

The Kniest dysplasia variant of SED (MIM 156550) manifests at birth with a short trunk and limbs associated with a flat face, prominent eyes, enlarged joints, cleft palate, and clubfoot (Fig. 695-3). Radiographs show vertebral defects and short tubular bones with epiphyseal irregularities and metaphyseal enlargement that gives rise to a dumbbell appearance.

Motor development is often delayed because of the joint deformities, although intelligence is normal. Hearing loss and myopia commonly develop during childhood, and retinal detachment can occur as a late complication. Joint enlargement progresses during childhood and becomes painful; it is accompanied by flexion contractures and muscle atrophy, which may be incapacitating by adolescence.

Figure 695-2 Radiograph of spondyloepiphyseal dysplasia congenita pelvis demonstrating squared pelvis, hypoplastic capital femoral epiphyses, and femoral necks that are wide and short.

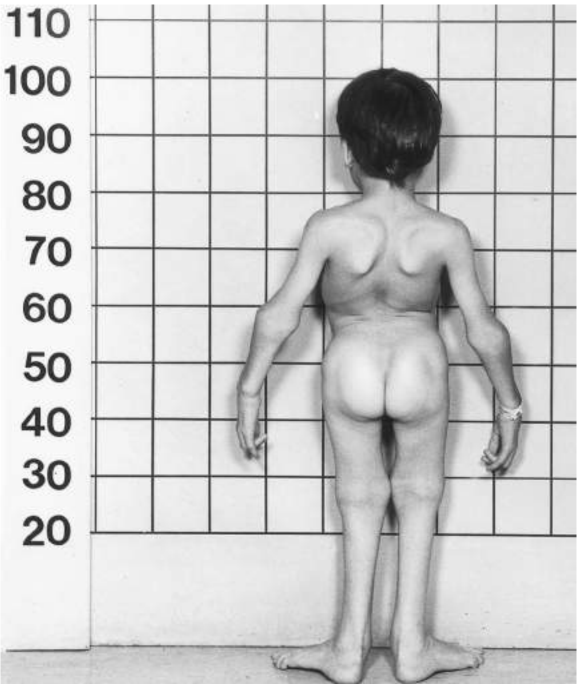

Figure 695-3 **Patient with Kniest dysplasia.** The trunk is short, and the epiphyses are broad. There is contracture of the fingers. *(From Traboulsi EI: Skeletal and connective tissue disorders with anterior segment manifestations. In Krachmer JH, Mannis MJ, Holland EJ, editors:* Cornea, *ed 3, Philadelphia, 2011, Elsevier, Fig. 60-9.)*

LATE-ONSET SPONDYLOEPIPHYSEAL DYSPLASIA

Late-onset SED is a mild to very mild clinical phenotype characterized by slightly short stature associated with mild epiphyseal and vertebral abnormalities on radiographs. It is typically detected during childhood or adolescence but can go unrecognized until adulthood when precocious osteoarthritis appears. This designation is nosologically distinct from SED tarda, which is clinically similar but results from mutation of the X-linked gene *SEDL.*

AGGRECAN-RELATED SPONDYLOEPIPHYSEAL DYSPLASIAS

Mutations of aggrecan have been detected in 2 SED-like conditions. SED-Kimberley (*MIM 608361*) is relatively mild, with short stature, stocky build, and early onset osteoarthritis of weightbearing joints. A more severe and generalized clinical phenotype with characteristic radiographic changes including widened metaphyses is observed in spondyloepimetaphyseal dysplasia–Aggrecan type (*MIM 612813*).

STICKLER SYNDROME/DYSPLASIA (HEREDITARY OSTEOARTHROOPHTHALMOPATHY)

Short stature is not a feature of Stickler dysplasia (MIM 184840). It resembles SED because of its joint and eye manifestations. Mutations of genes encoding type II (*COL2A1*), type XI (*COL11A1*, *COL11A2*), and type IX (*COL9A1*) collagens have been identified in Stickler-like disorders (MIM 184840, MIM 215150). Stickler dysplasia is often identified in the newborn because of cleft palate and micrognathia (Pierre Robin anomaly; see Chapter 311). Twenty-five percent of patients with Stickler syndrome have Pierre Robin anomaly; 30% of patients with Pierre Robin anomaly have Stickler syndrome. Infants typically have severe myopia and additional ophthalmologic complications, including choroidoretinal and vitreous degeneration; retinal detachment is common during childhood (Fig. 695-4). Sensorineural hearing loss can arise during adolescence, which is when symptoms of significant osteoarthritis can also begin. Special attention must be given to the eye complications even in childhood. Osteoarticular manifestations include joint hypermobility (especially hip), muscle hypotonia, metaphyseal–epiphyseal dysplasia; progressive osteoarthritis of spine and peripheral joints, which may require hip replacement surgery before age 30 yr and decreased bone density. Similar manifestations may be seen in other diseases with mutations in type II and XI collagen genes (Table 695-1).

SCHMID METAPHYSEAL DYSPLASIA

Schmid metaphyseal dysplasia (MIM 156500) is one of several chondrodysplasias in which metaphyseal abnormalities dominate the radiographic features. It typically manifests in early childhood with mild short stature, bowing of the legs, and a waddling gait (Fig. 695-5). Joints, such as the wrist, may be enlarged. Radiographs show flaring and irregular mineralization of the metaphyses of tubular bones of the proximal limbs (Fig. 695-6). Coxa vara is usually present and can require surgical correction. Short stature becomes more evident with age and affects the lower extremities more than the upper extremities; the manifestations are limited to the skeleton.

Schmid metaphyseal chondrodysplasia is caused by heterozygous mutations of the gene encoding type X collagen; it is an autosomal dominant trait. The distribution of type X collagen is restricted to the region of growing bone in which cartilage is converted into bone. This might explain why radiographic changes are confined to the metaphyses.

PSEUDOACHONDROPLASIA AND MULTIPLE EPIPHYSEAL DYSPLASIA

Pseudoachondroplasia (MIM 177170) and multiple epiphyseal dysplasia (MED) (MIM 600969) are 2 distinct phenotypes that are grouped together because they result from mutations of the gene encoding COMP. The mutations are heterozygous in both; they are autosomal dominant traits. The clinical phenotypes are restricted to skeletal tissues.

Newborns with pseudoachondroplasia are average in size and appearance. Gait abnormalities and short stature mainly affect the limbs and become apparent in late infancy. The short stature becomes marked as the child grows and is associated with generalized joint laxity (Fig. 695-7). The hands are short, broad, and deviated in an ulnar direction; the forearms are bowed. Developmental milestones and intelligence are usually normal. Lumbar lordosis and deformities of the knee develop during childhood; the latter often requires surgical correction. Pain is common in weightbearing joints during childhood and adolescence, and osteoarthritis develops late in the 2nd decade of life. Adults range in height from 105-128 cm.

Skeletal radiographs show distinctive abnormalities of vertebral bodies and of both epiphyses and metaphyses of tubular bones (Fig. 695-8).

The MED phenotype has skeletal abnormalities that predominantly affect the epiphyses as noted on radiographs. Two classic forms are a severe Fairbank type and a mild Ribbing type. Because of overlap in clinical features and because COMP mutations are found in both types,

they may be considered clinical variants. This nomenclature is not generally used now.

The more severe clinical phenotype has its onset during childhood, with mild short-limbed short stature, pain in weightbearing joints, and a waddling gait. Radiographs show delayed and irregular ossification of epiphyses. In more mildly affected patients the disorder might not be recognized until adolescence or adulthood. Radiographic changes may be limited to the capital femoral epiphyses. In the latter case, mild MED must be distinguished from bilateral Legg-Calvé-Perthes disease (see Chapter 678.3). Precocious osteoarthritis of hips and knees is the major complication in adults with MED. Adult heights range from 136-151 cm.

There are families with clinical and radiographic manifestations of MED that are not caused by mutations of COMP. Some are linked to the gene encoding 1 of the type IX collagen chains. It has been suggested that COMP and type IX collagen interact functionally in cartilage matrix, thus explaining why mutations of different genes produce similar pictures. Mutations of the genes coding for another cartilage

Figure 695-5 **Female patient with metaphyseal dysplasia, type Schmid.** The facies are normal and stature is mildly reduced. Mild tibia vara is present.

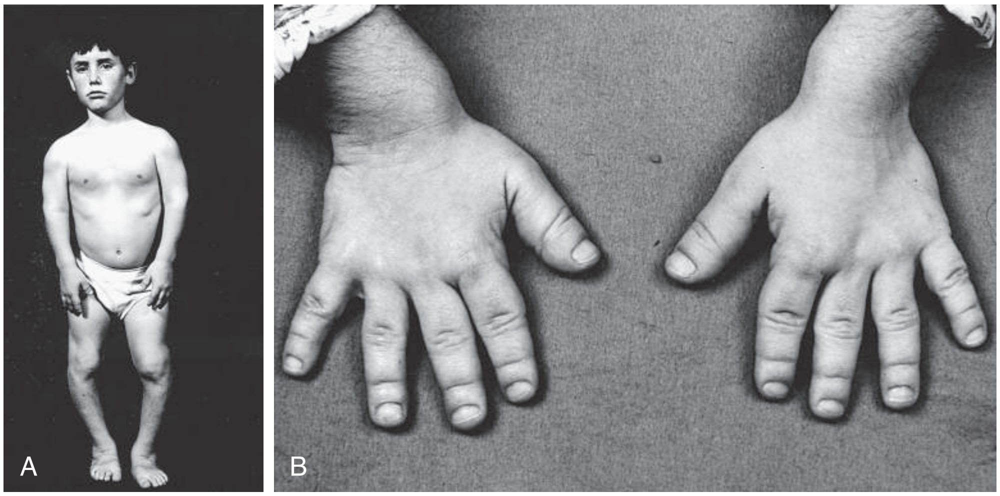

Figure 695-7 **A,** Pseudoachondroplasia in an adolescent boy. The facies and head circumference are normal. There is shortening of all extremities and bowing of the lower extremities. **B,** Photograph of hands, demonstrating short stubby fingers.

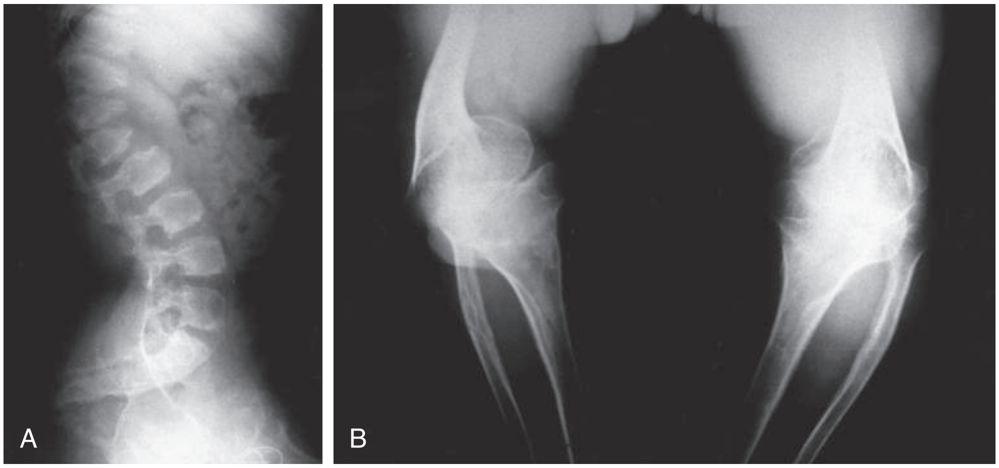

Figure 695-8 **A,** Lateral thoracolumbar spine radiograph of a patient with pseudoachondroplasia showing central protrusion (tonguing) of the anterior aspect of upper lumbar and lower thoracic vertebrae. Note reduced vertebral body heights (platyspondyly) and secondary lordosis. **B,** Lower-extremity radiograph of patient with pseudoachondroplasia showing large metaphyses, poorly formed epiphyses, and marked bowing of the long bones.

matrix protein, matrilin 3, and the diastrophic dysplasia sulfate transporter have also been found in patients with MED. For familial cases of pseudoachondroplasia and MED resulting from mutation in COMP, prenatal diagnosis is available.

Chapter 696

Disorders Involving Transmembrane Receptors

William A. Horton and Jacqueline T. Hecht

Heterozygous mutations of genes encoding *FGFR3* (fibroblast growth factor receptor 3) and *PTHR* (parathyroid hormone receptor) result in disorders involving transmembrane receptors. The mutations cause the receptors to become activated in the absence of physiologic ligands, which accentuates normal receptor function of negatively regulating bone growth. The mutations act by gain of negative function. In the *FGFR3* mutation group, in which the clinical phenotypes range from severe to mild, the severity appears to correlate with the extent to which the receptor is activated. *PTHR* and especially *FGFR3* mutations tend to recur in unrelated individuals.

ACHONDROPLASIA GROUP

The achondroplasia group represents a substantial percentage of patients with chondrodysplasias and contains thanatophoric dysplasia (TD), the most common lethal chondrodysplasia, with a birth prevalence of 1 in 35,000 births; achondroplasia, the most common nonlethal chondrodysplasia, with a birth prevalence of 1 in 15,000 to 1 in 40,000 births; and hypochondroplasia. All 3 have mutations in a small number of locations in the *FGFR3* gene. There is a strong correlation between the mutation site and the clinical phenotype.

Thanatophoric Dysplasia

TD (MIM 187600, 187610) manifests before or at birth. In the former situation, ultrasonographic examination in midgestation or later reveals a large head and very short limbs; the pregnancy is often accompanied by polyhydramnios and premature delivery. Very short limbs, short neck, long narrow thorax, and large head with midfacial hypoplasia dominate the clinical phenotype at birth (Fig. 696-1). The cloverleaf skull deformity known as **kleeblattschädel** is sometimes found. Newborns have severe respiratory distress because of their small thorax. Although this distress can be treated by intense respiratory care, the long-term prognosis is poor.

Skeletal radiographs distinguish 2 slightly different forms called TD I and TD II. In the more common TD I, radiographs show large calvariae with a small cranial base, marked thinning and flattening of vertebral bodies visualized best on lateral view, very short ribs, severe hypoplasia of pelvic bones, and very short and bowed tubular bones

Figure 696-1 Identical twins with type I thanatophoric dysplasia. Disproportionately large head, bell-shaped chest, and micromelia. *(From Gilbert-Barness E, Kapur RP, Oligny LL, Siebert JR, editors:* Potter's pathology of the fetus, infant and child, *ed 2, Philadelphia, 2007, Elsevier,* Fig. 20-47.*)*

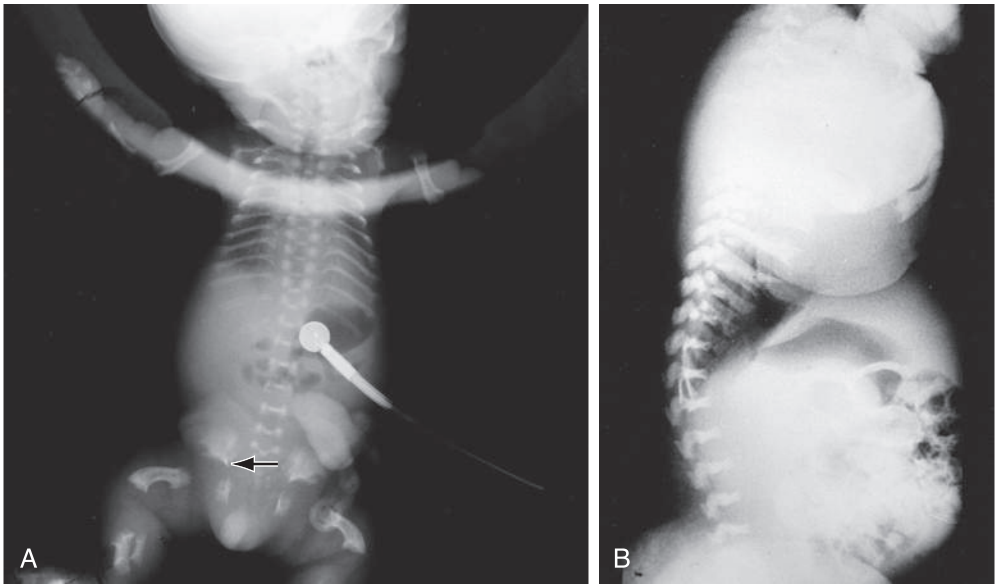

Figure 696-2 **A**, Neonatal radiograph of a child with thanatophoric dysplasia. Note medial acetabular spurs *(arrow)*, hypoplastic iliac bones, bowed femora with rounded protrusion of proximal femurs, hypoplastic thorax, and wafer-thin vertebral bodies. **B**, Lateral radiograph of the thoracolumbar spine in thanatophoric dysplasia, showing marked vertebral flattening and short ribs. Ossification defect of the central portion of the vertebral bodies is present.

with flared metaphyses (Fig. 696-2). The femurs are curved and shaped like a telephone receiver. TD II differs mainly in that there are longer and straighter femurs.

The TD II clinical phenotype is associated with mutations that map to codon 650 of *FGFR3*, causing the substitution of a glutamic acid for the lysine. This activates the tyrosine kinase activity of a receptor that transmits signals to intracellular pathways. Mutation of lysine 650 to methionine is associated with a clinical phenotype intermediate between TD and achondroplasia, referred to as **severe achondroplasia with developmental delay and acanthosis nigricans**. Mutations of the TD I phenotype mainly map to 2 regions in the extracellular domain of the receptor, where they substitute cysteine residues for other amino acids. Free cysteine residues are thought to form disulfide bonds promoting dimerization of receptor molecules, leading to activation and signal transmission.

TD I and TD II represent new mutations to normal parents. The recurrence risk is low. Because the mutated codons in TD are mutable for unknown reasons and because of the theoretical risk of germ cell mosaicism, parents are offered prenatal diagnosis for subsequent pregnancies.

Achondroplasia

Achondroplasia (MIM 100800) is the prototype chondrodysplasia. It typically manifests at birth with short limbs, a long narrow trunk, and a large head with midfacial hypoplasia and prominent forehead (Fig. 696-3). The limb shortening is greatest in the proximal segments, and the fingers often display a trident configuration. Most joints are hyperextensible, but extension is restricted at the elbow. A thoracolumbar gibbus is often found. Usually, birth length is slightly less than normal but occasionally plots within the low-normal range.

Diagnosis

Skeletal radiographs confirm the diagnosis (see Figs. 696-3 and 696-4). The calvarial bones are large, whereas the cranial base and facial bones are small. The vertebral pedicles are short throughout the spine as noted on a lateral radiograph. The interpedicular distance, which normally increases from the 1st to the 5th lumbar vertebra, decreases in achondroplasia. The iliac bones are short and round, and the acetabular roofs are flat. The tubular bones are short with mildly irregular and flared metaphyses. The fibula is disproportionately long compared with the tibia.

Clinical Manifestations

Infants usually exhibit delayed motor milestones, often not walking alone until 18-24 mo. This is because of hypotonia and mechanical difficulty balancing the large head on a normal-sized trunk and short extremities. Intelligence is normal unless central nervous system complications develop. As the child begins to walk, the gibbus usually gives way to an exaggerated lumbar lordosis.

Infants and children with achondroplasia progressively fall below normal standards for length and height. They can be plotted against standards established for achondroplasia. Adult heights typically are 118-145 cm for men and 112-136 cm for women. Surgical limb lengthening and human growth hormone treatment have been used to increase height; both are controversial. C-type natriuretic peptide may stimulate bone growth in achondroplasia based on studies in animal models. Clinical studies are in the initial phases of testing.

Virtually all infants and children with achondroplasia have large heads, although only a fraction have true hydrocephalus. Head circumference should be carefully monitored using standards developed for achondroplasia, as should neurologic function in general. The spinal canal is stenotic, and spinal cord compression can occur at the foramen magnum and in the lumbar spine. The former usually occurs in infants and small children; it may be associated with hypotonia, failure to thrive, quadriparesis, central and obstructive apnea, and sudden death. Surgical correction may be required for severe stenosis. Lumbar spinal stenosis usually does not occur until early adulthood. Symptoms include paresthesias, numbness, and claudication in the legs. Loss of bladder and bowel control may be late complications.

Bowing of the legs is common and might need to be corrected surgically. Other common problems include dental crowding, articulation difficulties, obesity, and frequent episodes of otitis media, which can contribute to hearing loss.

Genetics

All patients with typical achondroplasia have mutations at *FGFR3* codon 380. The mutation maps to the transmembrane domain of the receptor and is thought to stabilize receptor dimers that enhance receptor signals, the consequences of which inhibit linear bone growth. Achondroplasia behaves as an autosomal dominant trait; most cases arise from a new mutation to normal parents.

Because of the high frequency of achondroplasia among dwarfing conditions, it is relatively common for adults with achondroplasia to

Figure 696-3 Achondroplasia phenotype at different ages. **A,** Infant with achondroplasia with macrocephaly, frontal bossing, midface hypoplasia, small chest, rhizomelic shortening of all the limbs, redundant skin folds, and extreme joint laxity. Note the trident hand with short fingers and abducted hips. **B,** Typical radiographic findings from a child with achondroplasia. All of the tubular bones are short, but the fibula is relatively long compared to the tibia. There is protrusion of the epiphysis into the metaphysis of the distal femur, creating the chevron deformity, and to a lesser extent of the proximal tibia. The iliac bones are rounded, the acetabular roof is horizontal, and the sacrosciatic notches are small. **C,** A 3 yr old with achondroplasia with the typical features shown in **A.** Note that the redundant skin folds are no longer present and that joint laxity has improved. Rhizomelic shortening of the extremities is more pronounced and accompanied by tibial bowing. *(From Horton WA, Hall JG, Hecht JT: Achondroplasia,* Lancet *370:162–172, 2007.)*

Figure 696-4 Radiograph of infant with achondroplasia, demonstrating interpedicular narrowing of the 1st through 5th lumbar vertebrae, short round iliac bones, and flat acetabular roofs. The tubular bones are short and show mild irregularities of the metaphyses.

marry. Such couples have a 50% risk of transmitting their condition, heterozygous achondroplasia, to each offspring, as well as a 25% risk of **homozygous achondroplasia**. The latter condition exhibits intermediate severity between TD and heterozygous achondroplasia and is usually lethal in the newborn period. Prenatal diagnosis is available and has been used to diagnose homozygous achondroplasia. Preimplantation genetic testing can be used to identify double dominant mutations.

Hypochondroplasia

Hypochondroplasia (MIM 146000) resembles achondroplasia but is milder. Usually, it is not apparent until childhood, when mild short stature affecting the limbs becomes evident. Children have a stocky build and slight frontal bossing of the head. Learning disabilities may be more common in this condition. Radiographic changes are mild and consistent with the mild achondroplastic phenotype. Complications are rare; in some patients the condition is never diagnosed. Adult heights range from 116-146 cm. An *FGFR3* mutation at codon 540 has been found in many patients with hypochondroplasia. Genetic heterogeneity exists in hypochondroplasia; that is, *SHOX* mutations are associated with a very similar clinical phenotype. Recombinant growth hormone therapy may enhance growth and improve body disproportion.

JANSEN METAPHYSEAL DYSPLASIA

Jansen metaphyseal chondrodysplasia (MIM 156400) is a rare, dominantly inherited chondrodysplasia characterized by severe shortening of limbs associated with an unusual facial appearance. Sometimes it is accompanied by clubfoot and hypercalcemia. At birth, a diagnosis can be made from these clinical findings and radiographs that show short tubular bones with characteristic metaphyseal abnormalities that include flaring, irregular mineralization, fragmentation, and widening of the physeal space. The epiphyses are normal.

The joints become enlarged and limited in mobility with age. Flexion contractures develop at the knees and hips, producing a bent-over posture. Intelligence is normal, although there may be hearing loss.

Jansen metaphyseal chondrodysplasia is caused by activating mutations of *PTHR1*. This G-protein–coupled transmembrane receptor serves as a receptor for both parathyroid hormone and parathyroid hormone-related peptide. Signaling through this receptor serves as a brake on the terminal differentiation of cartilage cells at a critical step in bone growth. Because the mutations activate the receptor, they enhance the braking effect and thereby slow bone growth. Loss-of-function mutations of *PTHR1* are observed in Blomstrand chondrodysplasia, whose clinical features are the mirror image of Jansen metaphyseal chondrodysplasia.

Chapter 697

Disorders Involving Ion Transporters

William A. Horton and Jacqueline T. Hecht

The disorders involving ion transporters result from the functional loss of the sulfate ion transporter called *diastrophic dysplasia sulfate transporter* (DTDST), which is also referred to as *SLC26A2* (solute carrier family 26, member 2). This protein transports sulfate ions into cells and is important for cartilage cells that add sulfate moieties to newly synthesized proteoglycans destined for cartilage extracellular matrix. Matrix proteoglycans are responsible for many of the properties of cartilage that allow it to serve as a template for skeletal development. The clinical manifestations result from defective sulfation of cartilage proteoglycans. In order of decreasing severity, the disorders include: achondrogenesis type 1B, atelosteogenesis type II, diastrophic dysplasia, and a rare recessive form of multiple epiphyseal dysplasia (MIM 226900).

A number of mutant alleles have been found for the *DTDST* gene; they variably disturb transporter function. The disorders are recessive traits requiring the presence of 2 mutant alleles. The phenotype is determined by the combination of mutant alleles; some alleles are present in more than one disorder.

DIASTROPHIC DYSPLASIA

Diastrophic dysplasia (MIM 22600) is a well-characterized disorder recognized at birth by the presence of very short extremities, clubfoot, and short hands, with proximal displacement of the thumb producing a hitchhiker appearance (Fig. 697-1). The hands are usually deviated in an ulnar direction. Bony fusion of the metacarpophalangeal joints (symphalangism) is common, as is restricted movement of many joints, including hips, knees, and elbows. The external ears often become inflamed soon after birth. The inflammation resolves spontaneously but leaves the ears fibrotic and contracted (cauliflower ear deformity). Many newborns have a cleft palate.

Radiographs reveal short and broad tubular bones with flared metaphyses and flat, irregular epiphyses (Fig. 697-2). The capital femoral epiphyses are hypoplastic, and the femoral heads are broad. The ulnas and fibulas are disproportionately short. Carpal centers may be developmentally advanced; the 1st metacarpal is typically ovoid, and the metatarsals are twisted medially. There may be vertebral abnormalities, including clefts of cervical vertebral lamina and narrowing of the interpedicular distances in the lumbar spine.

Complications are primarily orthopedic and tend to be severe and progressive. The clubfoot deformity in the newborn resists usual treatments, and multiple corrective surgeries are common. Scoliosis typically develops during early childhood. It often requires multiple surgical procedures to control, and it sometimes compromises respiratory function in older children. Despite the orthopedic problems, patients typically have a normal life span and reach adult heights in the 105-130 cm range, depending on the severity of scoliosis. Growth curves are available for diastrophic dysplasia.

Some patients are mildly affected and exhibit slight short stature and joint contractures, no clubfoot or cleft palate, and correspondingly mild radiographic changes. The mild phenotype tends to recur within families. The recurrence risk of this autosomal recessive condition is 25%. Ultrasonographic examination can be employed for prenatal diagnosis, but if *DTDST* mutations can be identified in the patients or parents, molecular genetic diagnosis is possible.

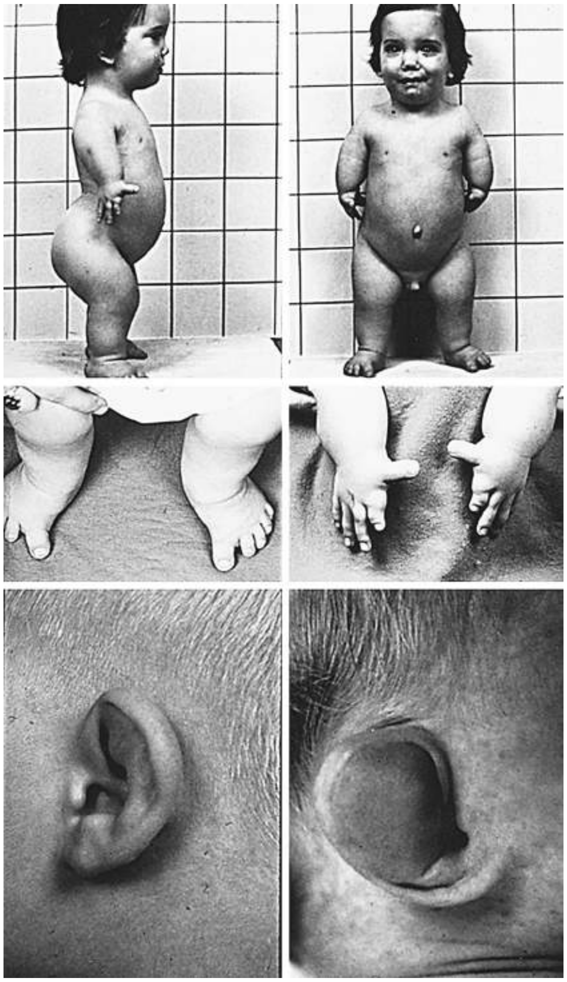

Figure 697-1 **Child with diastrophic dysplasia.** The extremities are dramatically shortened *(top).* Clubfoot is commonly observed *(middle left).* The fingers are short, especially the index finger; the thumb characteristically is proximally placed and has a hitchhiker appearance *(middle right).* The upper helix of the ears becomes swollen 3-4 wk postnatally *(lower left),* and this inflammation spontaneously resolves, leaving a cauliflower deformity of the pinnae *(lower right).*

Figure 697-2 **Radiograph of hands in diastrophic dysplasia.** The metacarpals and phalanges are irregular and short. The 1st metacarpal is ovoid.

ACHONDROGENESIS TYPE 1B AND ATELOSTEOGENESIS TYPE II

Achondrogenesis type 1B (MIM 600972) and atelosteogenesis type II (MIM 256050) are rare recessive lethal chondrodysplasias. The most serious is achondrogenesis type 1B, which demonstrates a severe lack

of skeletal development usually detected in utero or after a miscarriage. The limbs are extremely short, and the head is soft. Skeletal radiographs show poor to missing ossification of skull bones, vertebral bodies, fibulas, and ankle bones. The pelvis is hypoplastic, and the ribs are short. The femurs are short and exhibit a trapezoid shape with irregular metaphyses.

Infants with atelosteogenesis type II are stillborn or die soon after birth; prematurity is common. They exhibit very short limbs, especially the proximal segments. Clubfoot and dislocations of the elbows and knees may be detected. Hypoplasia of vertebral bodies, especially in the cervical and lumbar spine, is found on radiographs. The femora and humeri are hypoplastic and display a club-shaped appearance. The distal limb bones, including the ulna and fibula, are poorly ossified.

Both disorders carry a 25% recurrence risk and are potentially detectable in utero by mutation analysis if the mutant alleles are identified in the parents. Prenatal diagnosis is possible with fetal imaging and/or mutational testing, which is commercially available.

Chapter 698

Disorders Involving Transcription Factors

William A. Horton and Jacqueline T. Hecht

There are 3 well-delineated disorders involving transcription factors that result in bone dysplasias. **Campomelic dysplasia** is historically considered a chondrodysplasia while **cleidocranial dysplasia** and **nail-patella syndrome**, have been regarded as dysostoses, or abnormalities of single bones. The mutant genes that encode these transcription factors, *SOX9, RUNX2 (CBFA1*), and *LMX1B*, respectively, are members of much larger gene families. *SOX9* is a member of the *SOX* family of genes related to the *SRY* (sex-determining region of the Y chromosome) gene; *RUNX2 (CBFA1*) belongs to the runt family of transcription factor genes, and *LMX1B* is one of the LIM homeodomain gene family. All 3 disorders are a result of haploinsufficiency of the respective gene products; the disorders are dominant traits. For familial cases of cleidocranial dysplasia and nail-patella syndrome, prenatal diagnosis is possible if the mutations are identified. Campomelic dysplasia results from new mutational events and has a low risk of recurrence in subsequent pregnancies.

CAMPOMELIC DYSPLASIA

Campomelic dysplasia (MIM 114290) is apparent at birth owing to bowing of long bones (especially in the lower legs), short bones, respiratory distress, and other anomalies that include defects of the cervical spine, central nervous system, heart, and kidneys. In some cases, femoral bowing is minimal (acampomelic campomelic dysplasia). Cases of sex reversal of XY males have been reported; 75% of those with a male karyotype have partial or complete sex reversal. Radiographs confirm the bowing and often show hypoplasia of the scapulae and pelvic bones (Fig. 698-1). Affected infants usually die of respiratory distress in the neonatal period. Complications in children and adolescents who survive include short stature with progressive kyphoscoliosis, hip dislocation, recurrent apnea and respiratory infections, and mild to moderate learning difficulties. Mutational testing is commercially available.

CLEIDOCRANIAL DYSPLASIA

Cleidocranial dysplasia (MIM 114290) is recognized in infants because of drooping shoulders, open fontanelles, prominent forehead, mild short stature, and dental abnormalities (Fig. 698-2). Radiographs reveal hypoplastic or absent clavicles, delayed ossification of the cranial bones with multiple ossification centers (wormian bones), and delayed ossification of pelvic bones. The course is usually uncomplicated except for dislocations, especially of the shoulders, and dental anomalies (numerous teeth) that require therapy.

NAIL-PATELLA SYNDROME

Dysplasia of the nails, absence or hypoplasia of the patella, abnormalities of the elbow, and spurs or "horns" extending from the iliac bones characterize the nail-patella syndrome (MIM 119600), which is also called *osteo-onychodysostosis.* Some patients have nephritis that resembles chronic glomerulonephritis. There is a wide spectrum of severity; some patients present in early childhood, whereas others are asymptomatic as adults.

Chapter 699

Disorders Involving Defective Bone Resorption

William A. Horton and Jacqueline T. Hecht

Osteopetrosis, which has many subtypes, and pyknodysostosis result from defective bone resorption. Overall, bone dysplasias displaying increased bone density are rare.

OSTEOPETROSIS

Two main forms of osteopetrosis have been delineated: a severe autosomal recessive form (MIM 259700) with an incidence of approximately 1 in 250,000 births and a mild autosomal dominant form (MIM 166600) with an incidence of approximately 1 in 20,000 births. Intrinsic disturbances of osteoclast function due to mutations in genes encoding osteoclast-specific subunits of the vacuolar proton pump (*TCIRG1*, *CLCN7*) are found in most patients with the recessive form. Mutations of *CLCN7* are observed in the dominant form of osteopetrosis. Both types of mutations lead to disturbances of acidification needed for normal osteoclast function. Rarely, patients lack bioactive RANKL (receptor activator of nuclear factor kappa B ligand), the master osteoclastogenic cytokine produced mainly by osteoblasts.

Figure 699-1 Lateral radiograph showing bone-in-bone appearance that is characteristic of osteopetrosis.

The severe form is usually detected in infancy or earlier because of macrocephaly, hepatosplenomegaly, deafness, blindness, and severe anemia. Radiographs reveal diffuse bone sclerosis and low serum calcium and phosphorus levels with elevated parathyroid hormone levels and normal vitamin D levels. may be detected. Later films show the characteristic bone-within-bone appearance (Fig. 699-1). With time, infants typically fail to thrive and show psychomotor delay and worsening of cranial neuropathies and anemia. Dental problems, osteomyelitis of the mandible, and pathologic fractures are common. Untreated, the most severely affected patients die during infancy; less severely affected patients rarely survive beyond the 2nd decade. Those who survive beyond infancy usually have learning disorders but might have normal intelligence despite hearing and vision loss.

Clinical Manifestations

Most of the manifestations are from failure to remodel growing bones. This leads to narrowing of cranial nerve foramina and encroachment on marrow spaces, which results in secondary complications, such as optic and facial nerve dysfunction, and anemia accompanied by compensatory extramedullary hematopoiesis in the liver and spleen. The unusually dense bones are weak, leading to increased risk of fractures.

The autosomal dominant form of osteopetrosis (Albers-Schönberg disease, osteopetrosis tarda, or marble bone disease) usually manifests during childhood or adolescence with fractures and mild anemia and, less often, as cranial nerve dysfunction, dental abnormalities, or osteomyelitis of the mandible. Skeletal radiographs reveal a generalized

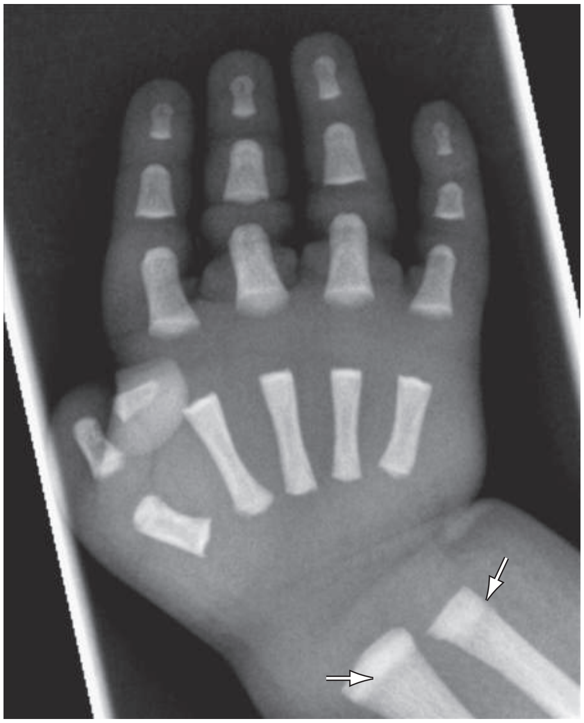

Figure 699-2 Right-hand radiograph of infant age 2 wk. Note metaphyseal lucent bands in the distal ulna and radius *(arrows)* and short tubular bones. *(From Stark Z, Savarirayan R: Osteopetrosis,* Orphanet J Rare Dis *4:5, 2009.)*

increase in bone density and clubbing of metaphyses. Alternating bands of lucent and dense bands produce a sandwich appearance to vertebral bodies. The radiographic changes are sometimes incidental findings in otherwise asymptomatic adolescents and adults.

Treatment

Most of the bone manifestations in severe osteopetrosis caused by intrinsic osteoclast defects can be prevented or reversed by hematopoietic stem cell transplantation, if carried out before development of irreversible secondary complications, such as visual impairment. RANKL replacement therapy may be useful in patients with RANKL deficiency. Calcitriol and interferon-γ have also been used with equivocal results. Symptomatic care, such as dental care, transfusions for anemia, and antibiotic treatment of infections, is important for patients who survive infancy.

PYKNODYSOSTOSIS

An autosomal recessive bone dysplasia, pyknodysostosis (MIM 265800) manifests in early childhood with short limbs, characteristic facies, an open anterior fontanel, a large skull with frontal and occipital bossing, and dental abnormalities. The hands and feet are short and broad, and the nails may be dysplastic. The sclerae may be blue. Minimal trauma often leads to fractures. Treatment is symptomatic and focused mainly on the management of dental problems and fractures. The prognosis is generally good, and patients typically reach heights of 130-150 cm.

Skeletal radiographs show a generalized increase in bone density. In contrast to many disorders in this group, the metaphyses are normal. Other changes include wide sutures and wormian bones in the skull, a small mandible, and hypoplasia of the distal phalanges (Fig. 699-2).

Several mutations have been found in the gene encoding cathepsin K, a cysteine protease that is highly expressed in osteoclasts. The mutations predict loss of enzyme function, suggesting that there is an inability of osteoclasts to degrade bone matrix and remodel bones.

Chapter 700

Disorders for Which Defects Are Poorly Understood or Unknown

William A. Horton and Jacqueline T. Hecht

Despite great advances in our understanding of the genetic basis of disease in recent years, many chondrodysplasias, or chondrodysplasia clinical phenotypes, remain for which the genetic cause or basic mechanism is poorly understood or not known. Many illustrate features not found in other disorders and have historical significance in the evolution of chondrodysplasia nomenclature and classification.

ELLIS–VAN CREVELD SYNDROME

The Ellis-van Creveld syndrome (MIM 225500), also known as **chondroectodermal dysplasia**, is a skeletal and an ectodermal dysplasia. The skeletal dysplasia presents at birth with short limbs, especially the middle and distal segments, accompanied by postaxial polydactyly of the hands and sometimes of the feet (Fig. 700-1). Nail dysplasia and dental anomalies (including neonatal, absent, and premature loss of teeth and upper lip defects) constitute the ectodermal dysplasia. Common manifestations also include atrial septal defects and other congenital heart defects.

Skeletal radiographs reveal short tubular bones with clubbed ends, especially the proximal tibia and ulna (Fig. 700-2). Carpal bones display extra ossification centers and fusion; cone-shaped epiphyses are evident in the hands. A bony spur is often noted above the medial aspect of the acetabulum.

Ellis-van Creveld syndrome is an autosomal recessive trait that occurs most often in the Amish. Mutations have been identified in 1 of 2 genes, *EVC (EVC1*) or *EVC2*, which map in a head-to-head configuration to chromosome 4p. Mutations of *EVC2* are detected in the allelic condition Weyers acrofacial dysostosis. EVC and EVC2 proteins are thought to influence hedgehog signaling in cilia.

Approximately 30% of patients die of cardiac or respiratory problems during infancy. Life span is otherwise normal; adult heights range from 119-161 cm.

ASPHYXIATING THORACIC DYSTROPHY (see also Chapter 417.3)

Asphyxiating thoracic dystrophy (MIM 208500), or **Jeune syndrome**, is an autosomal recessive chondrodysplasia that resembles Ellis-van Creveld syndrome. Newborn infants present with a long, narrow thorax and respiratory insufficiency associated with pulmonary hypoplasia. Neonates often die. Other neonatal manifestations include slightly short limbs and postaxial polydactyly. This condition results from a disturbance of primary cilia, most often from mutations of the gene encoding cytoplasmic dynein 2 heavy chain 1 (*DYNC2H1*).

Skeletal radiographs show very short ribs with anterior expansion. Tubular limb bones are short with bulbous ends; cone-shaped epiphyses occur in hand bones. The iliac bones are short and square with a spur above the medial aspect of the acetabulum.

If infants survive the neonatal period, respiratory function usually improves as the rib cage grows. Surgery that produces lateral thoracic expansion improves rib growth and enhances chest wall dimensions. Progressive renal dysfunction often develops during childhood. Intestinal malabsorption and hepatic dysfunction have also been reported.

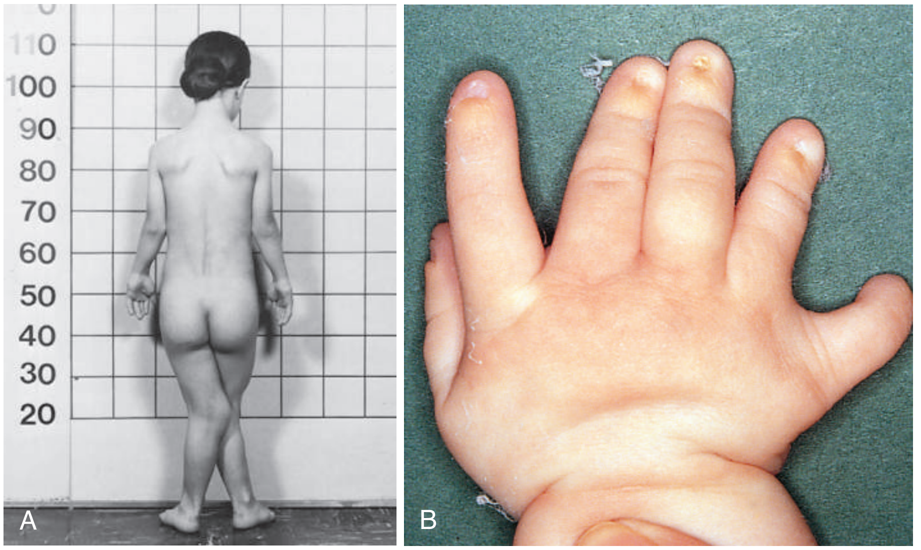

Figure 700-1 **A,** Ellis-van Creveld syndrome in a young woman. Note short stature, joint contractures at the elbows, and marked genu valgum. **B,** Multiple digits (polydactyly) in a different patient with Ellis-van Creveld syndrome. (*A from Zipes DP, Libby P, Bonow R, Braunwald E, editors:* Braunwald's heart disease: a textbook of cardiovascular medicine, *ed 7, Philadelphia, 2004, WB Saunders, Fig 70-6;* ***B*** *from Beerman LB, Kreutzer J, Allada V: Cardiology. In Zitelli BJ, McIntire SC, Nowalk AJ, editors:* Zitelli and Davis' atlas of pediatric physical diagnosis, *ed 6, Philadelphia, 2012, Elsevier, Fig 5-6.)*

Figure 700-2 Radiograph of lower extremities in Ellis-van Creveld syndrome. Tubular bones are short, and proximal fibula is short. Ossification is retarded in lateral tibia epiphyses, causing a knock-knee deformity.

Figure 700-3 Radiograph of lower extremities in cartilage-hair hypoplasia. The tubular bones are short and the metaphyses are flared and irregular. The fibula is disproportionately long compared with the tibia. The femoral necks are short.

SHORT-RIB POLYDACTYLY SYNDROMES

These conditions, which share the clinical features of constricted thoracic cage, short ribs, polydactyly, very short extremities, lethality during the newborn period and autosomal recessive inheritance, were originally grouped into 4 syndromes (SRP-I-IV). However, this classification is in flux as mutations that map to cilia-related genes *IFT80* and *DYNCH2H1* similar to those observed in Jeune syndrome have been detected in infants with SRP II and III. Mutations of two other cilia-related genes *NEK1* and *WDR34* have also been found in this group of disorders.

CARTILAGE-HAIR HYPOPLASIA

Cartilage-hair hypoplasia (CHH; MIM 250250) is also known as **metaphyseal chondrodysplasia–McKusick type**. It is recognized during the 2nd yr because of growth deficiency affecting the limbs, accompanied by flaring of the lower rib cage, a prominent sternum, and bowing of the legs. The hands and feet are short, and the fingers are very short with extreme ligamentous laxity. The hair is thin, sparse, and light colored, and nails are hypoplastic. The skin is hypopigmented.

Radiographs show short tubular bones with flared, irregularly mineralized, and cupped metaphyses (Fig. 700-3). The knees are more affected than are the hips, and the fibula is disproportionately longer

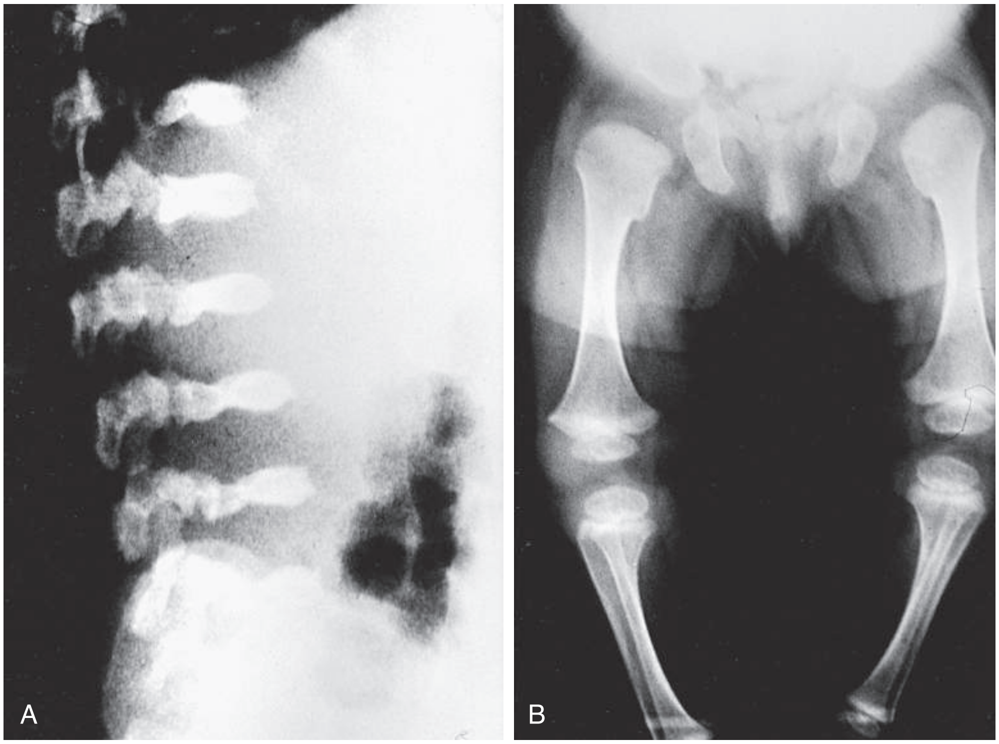

Figure 700-4 **A,** Radiograph of the lateral thoracolumbar spine in metatropic dysplasia showing severe platyspondyly. **B**, Radiograph of lower extremities in metatropic dysplasia showing short tubular bones with widened metaphyses. The femurs have a dumbbell appearance.

than the tibia. The metacarpals and phalanges are short and broad. Spinal radiographs reveal mild platyspondyly.

Nonskeletal manifestations associated with CHH include immunodeficiency (T-cell abnormalities, neutropenia, leukopenia, and susceptibility to chickenpox; children also may have complications from smallpox and polio vaccinations), malabsorption, celiac disease, and Hirschsprung disease. Adults are at risk for malignancy, especially non-Hodgkin lymphoma and skin tumors. Adults reach heights of 107-157 cm.

CHH shows autosomal recessive inheritance. Its highest prevalence is in the Amish and Finnish populations. It results from mutations of a gene coding for a large untranslated RNA component of an enzyme complex involved in processing mitochondrial RNA. Loss of this gene product interferes with processing of both messenger RNA and ribosomal RNA. Loss of ribosomal RNA processing correlates with the extent of bone dysplasia, whereas loss of messenger RNA processing correlates with degree of hair hypoplasia, immunodeficiency, and hematologic abnormality. Mutations of the RNA component of mitochondrial RNA processing are occasionally detected in patients with mild metaphyseal dysplasia lacking the extraskeletal features characteristic of CHH. Prenatal diagnosis is available if the mutation is identified either in the patient or parents.

METATROPIC DYSPLASIA

Metatropic dysplasia (MIM 156530) is an autosomal dominant disorder resulting from heterozygous mutations of *TRPV4* (transient receptor potential vanilloid family 4), which encodes a calcium-permeable cation channel. Newborn infants present with a long narrow trunk and short extremities. A tail-like appendage sometimes extends from the base of the spine. Odontoid hypoplasia is common and may be associated with cervical instability. Kyphoscoliosis appears in late infancy and progresses through childhood, often becoming severe enough to compromise cardiopulmonary function. The joints are large and become progressively restricted in mobility, except in the hands. Contractures often develop in the hips and knees during childhood. Although severely affected infants can die at a young age from respiratory failure, patients usually survive, although they can become disabled as adults from the progressive musculoskeletal deformities. Adult heights range from 110-120 cm.

Skeletal radiographs show characteristic changes dominated by severe platyspondyly and short tubular bones with expanded and deformed metaphyses that exhibit a dumbbell appearance (Fig. 700-4). The pelvic bones are hypoplastic and exhibit a halberd appearance because of a small sacrosciatic notch and a notch above the lateral margin of the acetabulum.

SPONDYLOMETAPHYSEAL DYSPLASIA, KOZLOWSKI TYPE

The Kozlowski type of spondylometaphyseal dysplasia (MIM 184252) is an autosomal dominant allelic disorder to metatropic dysplasia caused by *TRPV4* mutations. Mutations of *TRPV4* have also been identified in autosomal dominant brachyolmia, whose phenotype is dominated by progressive scoliosis and platyspondyly on x-rays.

The Kozlowski type of spondylometaphyseal dysplasia manifests in early childhood with mild short stature involving mostly the trunk and a waddling gait. The hands and feet may be short and stubby. Radiographs show flattening of vertebral bodies. The metaphyses of tubular bones are widened and irregularly mineralized, especially at the proximal femur. The pelvic bones manifest mild hypoplasia.

Scoliosis can develop during adolescence. The disorder is otherwise uncomplicated, and manifestations are limited to the skeleton. Adults reach heights of 130-150 cm.

DISORDERS INVOLVING FILAMINS

Mutations of genes encoding filamin A and filamin B proteins have been detected in diverse disorders of skeletal development: filamin A mutations in otopalatodigital syndromes type 1 and 2 frontometaphyseal dysplasia and Melnick-Needles syndrome (MIM 311300, 304120, 305620, 309350) and filamin B mutations in Larsen syndrome and perinatal lethal atelosteogenesis types I and III and Boomerang dysplasia (MIM 150250, 108720, 108721, 112310). Filamins functionally connect extracellular to intracellular structural proteins, thereby linking cells to their local microenvironment, which is essential for skeletal development and growth.

Table 700-1 Juvenile Osteochondroses

EPONYM	AFFECTED REGION	AGE AT PRESENTATION
Legg-Calvé-Perthes disease	Capital femoral epiphysis	3-12 yr
Osgood-Schlatter disease	Tibial tubercle	10-16 yr
Sever disease	Os calcaneus	6-10 yr
Freiberg disease	Head of second metatarsal	10-14 yr
Scheuermann disease	Vertebral bodies	Adolescence
Blount disease	Medial aspect of proximal tibial epiphysis	Infancy or adolescence
Osteochondritis dissecans	Subchondral regions of knee, hip, elbow, and ankle	Adolescence

JUVENILE OSTEOCHONDROSES

The juvenile osteochondroses are a heterogeneous group of disorders in which regional disturbances in bone growth cause noninflammatory arthropathies. Table 700-1 summarizes the juvenile osteochondroses. Some have localized pain and tenderness (Freiberg disease, Osgood-Schlatter disease [see Chapter 677.4], osteochondritis dissecans [see Chapter 677.3]), whereas others present with painless limitation of joint movement (Legg-Calvé-Perthes disease [see Chapter 678.3], Scheuermann disease [see Chapter 679.4]). Bone growth may be disrupted, leading to deformities. The diagnosis is usually confirmed radiographically, and treatment is symptomatic. The pathogenesis of these disorders is believed to involve ischemic necrosis of primary and secondary ossification centers. Although familial forms have been reported, these disorders usually occur sporadically.

CAFFEY DISEASE (INFANTILE CORTICAL HYPEROSTOSIS)

This is a rare disorder of unknown etiology characterized by cortical hyperostosis with inflammation of the contiguous fascia and muscle. It is often sporadic, but both autosomal dominant and autosomal recessive inheritance have been reported. In 3 unrelated families with autosomal dominant inheritance, a linkage to mutations of the *COL1A1* gene (codes for the α_1 chain of type I collagen) has been reported.

Prenatal and more often postnatal onset have been described. Prenatal onset may be mild (autosomal dominant) or severe (autosomal recessive). Severe prenatal disease is characterized by typical bone lesions, polyhydramnios, hydrops fetalis, severe respiratory distress, prematurity, and high mortality. Onset in infancy (younger than 6 mo; average: 10 wk) is most common; manifestations include the sudden onset of irritability, swelling of contiguous soft tissue that precedes the cortical thickening of the underlying bones, fever, and anorexia. The swelling is painful with a wood-like induration but with minimal warmth or redness; suppuration is absent. There are unpredictable remissions and relapses; an episode can last 2 wk to 3 mo. The most common bones involved include the mandible (75%) (Fig. 700-5), the clavicle, and the ulna. If swelling is not prominent or visible, the diagnosis might not be evident.

Laboratory features include elevated erythrocyte sedimentation rate and serum alkaline phosphatase as well as, in some patients, increased serum prostaglandin E levels. There may be thrombocytosis and anemia. The **radiographic features** include soft-tissue swelling and calcification and cortical hyperostosis (Fig. 700-6). All bones may be affected except the phalanges or vertebral bodies. The **differential diagnosis** includes other causes of hyperostosis such as chronic vitamin A intoxication, prolonged prostaglandin E infusion in children with ductal dependent congenital heart disease, primary bone tumors, and scurvy.

Complications are unusual but include pseudoparalysis with limb or scapula involvement, pleural effusions (rib), torticollis (clavicle), mandibular asymmetry, bone fusion (ribs or ulna and radius), and bone angulation deformities (common with severe prenatal onset).

Treatment includes indomethacin and prednisone (if there is a poor response to indomethacin).

Figure 700-5 Facies in infantile cortical hyperostosis. In almost all cases, the changes have appeared before the 5th mo of life. Unilateral swelling of the left cheek and left side of the jaw in an infant 12 wk of age. *(From Slovis TL:* Caffey's pediatric diagnostic imaging, *ed 11, Philadelphia, 2008, Mosby.)*

FIBRODYSPLASIA OSSIFICANS PROGRESSIVE

Fibrodysplasia ossificans progressive (FOP) (MIM 135100) is a rare and severely disabling disorder characterized by progressive extraskeletal bone formation in soft connective tissues including muscles, tendons, ligaments, fascia, and aponeuroses. With exception of deformity of the large toes, infants are normal at birth. Episodes of painful soft-tissue swelling with inflammation usually begin in early childhood initially involving the upper back and neck and later the entire trunk and extremities. Repeated episodes (flare-ups) slowly transform the soft tissues into bands or plates of bone that span joints and progressively limit movement and mobility. Episodes are often triggered by injury, intramuscular injections and viral infection. Most patients are wheelchair bound by their late teens. The average life span is approximately 40 yr, with death usually resulting from complications of thoracic insufficiency.

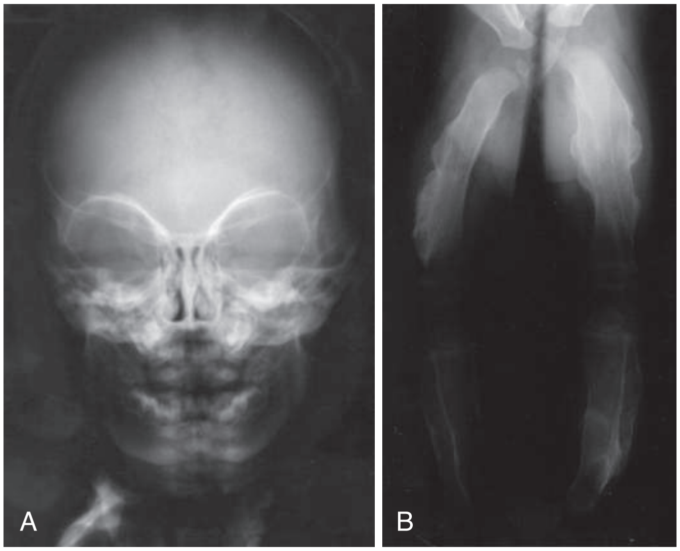

Figure 700-6 **A,** X-ray of a 5 mo old infant showing hyperostosis of the mandible. **B,** X-ray of a 5 mo old infant shoeing hyperostosis of both legs. *(From Kamoun-Goldrat A, le Merrer M: Infantile cortical hyperostosis (Caffey disease): a review.* J Oral Maxillofac Surg *66:2145–2150, 2008, Figs. 1 and 2.)*

FOP results from heterozygous activating mutations of the gene encoding the bone morphogenetic protein (BMP) type I receptor, activin A receptor type I (*ACVR1*). Patients with classic FOP have the same missense *ACVR1* mutation, which enhances BMP signaling, which, in turn, induces inflammation and aberrant endochondral ossification through mechanisms that are poorly understood. Environmental factors such as injury play an important role in triggering these events. *ACVR1* mutations usually occur sporadically, but autosomal dominant transmission has rarely been observed.

There is no definitive treatment for FOP. Supportive care includes avoidance of injury-prone physical activities, intramuscular injections including immunizations and overstretching of the jaw during dental procedures. Corticosteroids and other antiinflammatory agents reduce inflammation during flare-ups. Studies in FOP animal models suggest that BMP type I kinase inhibitors and retinoic acid receptor γ agonists, which block chondrogenesis, the initial step in endochondral ossification, may be useful therapies in the future.

Chapter 701

Osteogenesis Imperfecta

Joan C. Marini

Osteoporosis is fragility of the skeletal system and a susceptibility to fractures of the long bones or vertebral compressions from mild or inconsequential trauma. **Osteogenesis imperfecta** (**OI**) (brittle bone disease), the most common genetic cause of osteoporosis, is a generalized disorder of connective tissue. The spectrum of OI is extremely broad, ranging from forms that are lethal in the perinatal period to a mild form in which the diagnosis may be equivocal in an adult.

ETIOLOGY

Structural or quantitative defects in type I collagen cause the full clinical spectrum of OI (types I-IV). Type I collagen is the primary component of the extracellular matrix of bone and skin. Between 10 and 15% of patients clinically indistinguishable from OI do not have a molecular defect in type I collagen (Table 701-1).These cases are caused by defects in genes whose protein products interact with type I collagen. One group of patients has overmodified collagen, with similar biochemical findings to those with collagen structural defects and severe or lethal OI bone dysplasia. These cases are caused by recessive null mutations in any of the 3 components of the collagen prolyl 3-hydroxylation complex, prolyl 3-hydroxylase 1 (coded by the *LEPRE1* gene on chromosome 1p34.1) or its associated protein, CRTAP, or cyclophilin B (CyPB, encoded by *PPIB*). A second set of cases without collagen defects have biochemically normal collagen. Defects in *IFITM5* and *SERPINF1* account for defects in mineralization in types V and VI OI, while mutations in *SERPINH1*, encoding the collagen chaperone HSP47, and *FKBP10*, encoding the peptidyl-prolyl *cis-trans* isomerase FKBP65, cause types X and XI OI, respectively. Rare mutations in *BMP1*, *TMEM38B* and *WNT1* also cause recessive OI; the genetic defect in some individuals is still unknown.

EPIDEMIOLOGY

The autosomal dominant forms of OI occur equally in all racial and ethnic groups, whereas recessive forms occur predominantly in ethnic groups with consanguineous marriages. The West African founder mutation for type VIII OI has a carrier frequency of 1 in 200-300 among African-Americans. The incidence of OI detectable in infancy is approximately 1 in 20,000. There is a similar incidence of the mild form OI type I.

PATHOLOGY

The collagen structural mutations cause OI bone to be globally abnormal. The bone matrix contains abnormal type I collagen fibrils and relatively increased levels of types III and V collagen. Several noncollagenous proteins of bone matrix are also reduced. Bone cells contribute to OI pathology, with abnormal osteoblast differentiation and increased numbers of active bone resorbing osteoclasts. The hydroxyapatite crystals deposited on this matrix are poorly aligned with the long axis of fibrils, and there is paradoxical hypermineralization of bone.

PATHOGENESIS

Type I collagen is a heterotrimer composed of 2 α1(I) chains and 1 α2(I) chain. The chains are synthesized as procollagen molecules with short globular extensions on both ends of the central helical domain. The helical domain is composed of uninterrupted repeats of the sequence Gly-X-Y, where Gly is glycine, X is often proline, and Y is often hydroxyproline. The presence of glycine at every third residue is crucial to helix formation because its small side chain can be accommodated in the interior of the helix. The chains are assembled into trimers at their carboxyl ends; helix formation then proceeds linearly in a carboxyl to amino direction. Concomitant with helix assembly and formation, helical proline and lysine residues are hydroxylated by prolyl 4-hydroxylase and lysyl hydroxylase and some hydroxylysine residues are glycosylated.

Collagen structural defects are predominantly of 2 types: 80% are point mutations causing substitutions of helical glycine residues or crucial residues in the C-propeptide by other amino acids, and 20% are single exon splicing defects. The clinically mild OI type I has a quantitative defect, with null mutations in 1 α1(I) allele leading to a reduced amount of normal collagen.

The glycine substitutions in the 2 α chains have distinct genotype–phenotype relationships. One-third of mutations in the α_1 chain are lethal, and those in α2(I) are predominantly nonlethal. Two lethal regions in α1(I) align with major ligand binding regions of the collagen helix. Lethal mutations in α2(I) occur in 8 regularly spaced clusters along the chain that align with binding regions for matrix proteoglycans in the collagen fibril.

Table 701-1 Osteogenesis Type, Gene Defects, and Phenotypes

OSTEOGENESIS IMPERFECTA TYPE	GENE DEFECT	PHENOTYPE
DOMINANT INHERITANCE		
Classical Sillence Types		
I	*COL1A1* null allele	Mild, nondeforming
II	*COL1A1* or *COL1A2*	Lethal perinatal
III	*COL1A1* or *COL1A2*	Progressively deforming
IV	*COL1A1* or *COL1A2*	Moderately deforming
COL1-Mutation Negative		
V	*IFITM5*	Distinct histology
RECESSIVE INHERITANCE		
Mineralization Defect		
VI	*SERPINF1*	Distinct histology
3-Hydroxylation Defects		
VII	*CRTAP*	Severe to lethal
VIII	*LEPRE1*	Severe to lethal
IX	*PPIB*	Moderate to lethal
Chaperone Defects		
X	*SERPINH1*	Severe
XI	*FKBP10*	Progressive deforming, Bruck syndrome 1
C-Propeptide Cleavage Defect		
XII	*BMP1*	Severe, high bone mass case
UNCLASSIFIED		
Zinc-finger transcription factor defect	*SP7*	Moderate
Cation channel defect	*TMEM38B*	Moderate to severe
WNT signaling pathway defect	*WNT1*	Moderate, progressively deforming

From Marini JC, Blissett AR: New genes in bone development: what's new in osteogenesis imperfecta. J Clin Endocrinol Metab *98:3095–3103, 2013, Table 1, p. 3096.*

Classical OI (Sillence types I-IV) is an autosomal dominant disorder, as is type V OI. Some familial recurrences of OI are caused by parental mosaicism for dominant collagen mutations. Recessive OI accounts for 5-7% of new OI in North America. Three recessive types are caused by null mutations in the genes coding for the components of the collagen prolyl 3-hydroxylation complex in the endoplasmic reticulum (*LEPRE1*, *CRTAP*, or *PPIB*). It is not yet clear whether absence of the complex itself or of the modification is the crucial feature of these types of recessive OI. Other recessive types are caused by null mutations in genes whose products are involved in collagen folding (*SERPINH1, FKBP10*), or mineralization (*SERPINF1*).

CLINICAL MANIFESTATIONS

Classical OI was described with the triad of fragile bones, blue sclerae, and early deafness, although most cases do not have all of these features. The Sillence classification divides OI into 4 types based on clinical and radiographic criteria. Types V and VI were later proposed based on histologic distinctions. Subsequent types VII-XII were based on identification of the molecular defect, followed by clinical description.

Osteogenesis Imperfecta Type I (Mild)

OI type I is sufficiently mild that it is often found in large pedigrees. Many type I families have blue sclerae, recurrent fractures in childhood, and presenile hearing loss (30-60%). Both types I and IV are divided into A and B subtypes, depending on the absence (A) or presence (B) of **dentinogenesis imperfecta**. Other possible connective tissue abnormalities include hyperextensible joints, easy bruising, thin skin, joint laxity, scoliosis, wormian bones, hernia, and mild short stature compared with family members. Fractures result from mild to moderate trauma but decrease after puberty.

Osteogenesis Imperfecta Type II (Perinatal Lethal)

Infants with OI type II may be stillborn or die in the 1st yr of life. Birthweight and length are small for gestational age. There is extreme fragility of the skeleton and other connective tissues. There are multiple intrauterine fractures of long bones, which have a crumpled appearance on radiographs. There are striking micromelia and bowing of extremities; the legs are held abducted at right angles to the body in the frogleg position. Multiple rib fractures create a beaded appearance, and the small thorax contributes to respiratory insufficiency. The skull is large for body size, with enlarged anterior and posterior fontanels. Sclerae are dark blue-gray. The cerebral cortex has multiple neuronal migration and other defects (agyria, gliosis, periventricular leukomalacia).

Osteogenesis Imperfecta Type III (Progressive Deforming)

OI type III is the most severe nonlethal form of OI and results in significant physical disability. Birthweight and length are often low normal. Fractures usually occur in utero. There is relative macrocephaly and triangular facies (Fig. 701-1). Postnatally, fractures occur from inconsequential trauma and heal with deformity. Disorganization of the bone matrix results in a "popcorn" appearance at the metaphyses (Fig. 701-2). The rib cage has flaring at the base, and pectal deformity is frequent. Virtually all type III patients have scoliosis and vertebral compression. Growth falls below the curve by the 1st yr; all type III patients have extreme short stature. Scleral hue ranges from white to blue. Dentinogenesis imperfecta, hearing loss, and kyphoscoliosis may be present or develop over time.

Osteogenesis Imperfecta Type IV (Moderately Severe)

Patients with OI type IV can present at birth with in utero fractures or bowing of lower long bones. They can also present with recurrent fractures after ambulation and have normal to moderate short stature. Most children have moderate bowing even with infrequent fractures. Children with OI type IV require orthopedic and rehabilitation intervention, but they are usually able to attain community ambulation skills. Fracture rates decrease after puberty. Radiographically, they are osteoporotic and have metaphyseal flaring and vertebral compressions. Patients with type IV have moderate short stature. Scleral hue may be blue or white.

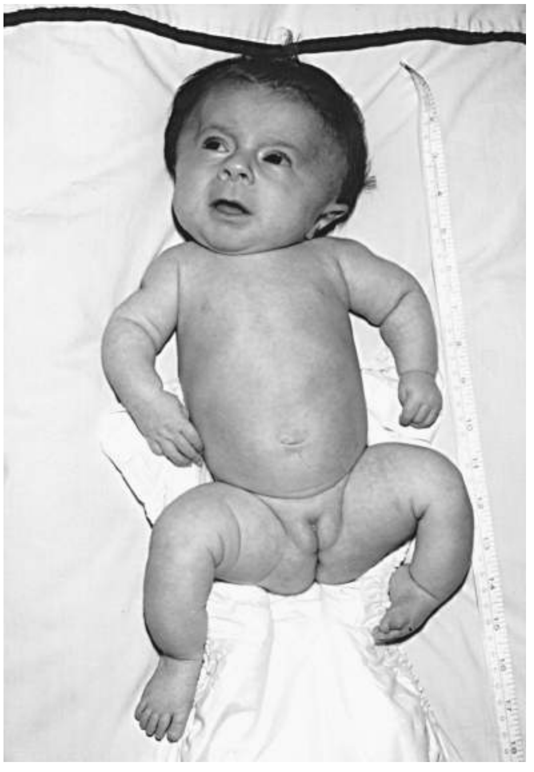

Figure 701-1 Infant with type III osteogenesis imperfecta displays shortened bowed extremities, thoracic deformity, and relative macrocephaly.

Osteogenesis Imperfecta Type V (Hyperplastic Callus) and Type VI Hyperosteoidosis (Mineralization Defect)

Types V and VI OI patients clinically have OI similar in skeletal severity to type IV, but they have distinct findings on bone histology. Type V patients also usually have some combination of hyperplastic callus, calcification of the interosseous membrane of the forearm, and/or a radiodense metaphyseal band. They constitute <5% of OI populations. All type V OI patients are heterozygous for the same mutation in *IFITM5*, which generates a novel start codon for the bone protein Bril. Ligamentous laxity may be present; blue sclera or dentinogenesis imperfect are not present. Patients with type VI OI have progressive deforming OI that does not manifest at birth. They have distinctive bone histology with broad osteoid seams and fish-scale lamellation under polarized light.

Osteogenesis Imperfecta Types VII, VIII, and IX (Autosomal Recessive)

Types VII and VIII patients overlap clinically with types II and III OI but have distinct features including white sclerae, rhizomelia, and small to normal head circumference. Surviving children have severe osteochondrodysplasia with extreme short stature and dual-energy x-ray absorptiometry L1-L2 z-score in the –6 to –7 range. Type IX OI is very rare (only 8 cases reported). The severity is quite broad, ranging from lethal to moderately severe. These children have white sclerae but do not have rhizomelia.

Osteogenesis Imperfecta Types X and XI (Autosomal Recessive)

Only 1 patient with type X OI has been reported; the child had severe OI with white sclerae and died of respiratory causes at age 3 yr. Type XI OI is a more prevalent recessive form with a moderate to severe skeletal phenotype, including white sclerae and normal teeth. Congenital contractures of large joints may occur with the same mutations that cause only skeletal fragility, even in sibships. At the opposite end of the spectrum, a deletion of a single tyrosine residue causes Kuskokwim syndrome, a congenital contracture disorder with very mild vertebral findings and osteopenia.

High Bone Mass Osteogenesis Imperfecta (Cleavage of the Procollagen C-Propeptide)

Autosomal dominant mutations in the C-propeptide cleavage site of procollagen or in the enzyme responsible for its cleavage cause bone fragility with normal or elevated dual-energy x-ray absorptiometry bone density z-scores. Individuals with dominant mutations have normal stature, white sclerae and teeth and mild to moderate OI. Null mutations in *BMP1* lead to a more severe skeletal phenotype with short stature, scoliosis and bone deformity, because *BMP1* has other substrates in addition to type I collagen.

Other Genes for Osteogenesis Imperfecta

A very small percentage of OI patients have bone dysplasia that cannot be accounted for by mutations in the genes described above.

LABORATORY FINDINGS

DNA sequencing is the first diagnostic laboratory test; several diagnostic labs offer panels to test for dominant and recessive OI. Mutation identification is useful to determine the type with certainty and to facilitate family screening and prenatal diagnosis. It is also possible to screen for type VI OI by determination of serum pigment epithelium-derived factor level, which is severely reduced in this type.

If dermal fibroblasts are obtained these can be useful for determining the level of transcripts of the candidate gene and also for collagen biochemical testing, which is positive in most cases of types I-IV and IX OI and all cases of VII/VIII OI. In OI type I, the reduced amount of type I collagen results in an increase in the ratio of type III to type I collagen on gel electrophoresis.

Severe OI can be detected prenatally by level II ultrasonography as early as 16 wk of gestation. OI and thanatophoric dysplasia may be confused. Fetal ultrasonography might not detect OI type IV and rarely detects OI type I. For recurrent cases, chorionic villus biopsy can be used for biochemical or molecular studies. Amniocytes produce false-positive biochemical studies but can be used for molecular studies in appropriate cases.

In the neonatal period, the normal to elevated alkaline phosphatase levels present in OI distinguish it from hypophosphatasia.

COMPLICATIONS

The morbidity and mortality of OI are cardiopulmonary. Recurrent pneumonias and declining pulmonary function occur in childhood, and cor pulmonale is seen in adults.

Neurologic complications include basilar invagination, brainstem compression, hydrocephalus, and syringohydromyelia. Most children with OI types III and IV have basilar invagination, but brainstem compression is uncommon. Basilar invagination is best detected with spiral CT of the craniocervical junction (Fig. 701-3).

TREATMENT

There is no cure for OI. For severe nonlethal OI, active physical rehabilitation in the early years allows children to attain a higher functional level than orthopedic management alone. Children with OI type I and some with type IV are spontaneous ambulators. Children with types III, IV, V, VI, and XI OI benefit from gait aids and a program of swimming and conditioning. Severely affected patients require a wheelchair for community mobility but can acquire transfer and self-care skills. Teens with OI can require psychologic support with body image issues. Growth hormone improves bone histology in growth-responsive children (usually types I and IV).

Orthopedic management of OI is aimed at fracture management and correction of deformity to enable function. Fractures should be promptly splinted or cast; OI fractures heal well, and cast removal should be aimed at minimizing immobilization osteoporosis. Correction of long bone deformity requires an osteotomy procedure and placement of an intramedullary rod.

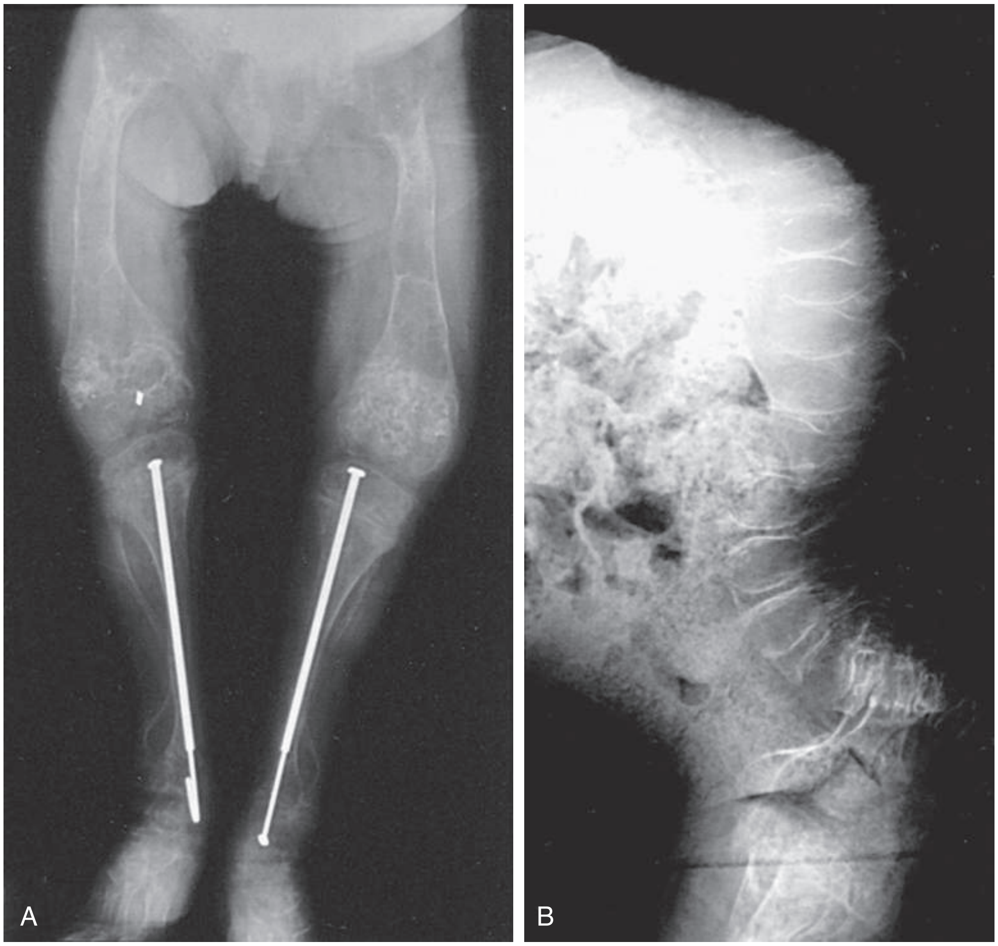

Figure 701-2 Typical features of type III osteogenesis imperfecta radiographs in a 6 yr old child. **A,** Lower long bones are osteoporotic, with metaphyseal flaring, "popcorn" formation at growth plates, and placement of intramedullary rods. **B,** Vertical bodies are compressed and osteoporotic.

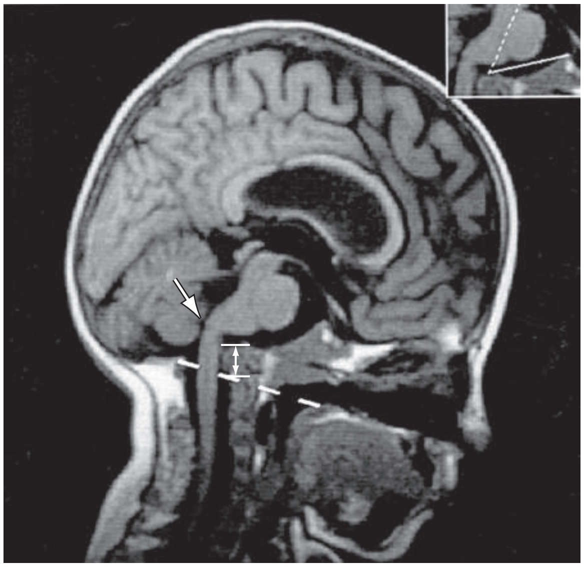

Figure 701-3 Typical feature of basilar invagination shown in the sagittal MRI of an asymptomatic child with type III osteogenesis imperfecta. There is invagination of the odontoid above the Chamberlain line, causing compression and kinking at the pontomedullary junction *(arrow)*.

A several-year course of treatment of children with OI with bisphosphonates (IV pamidronate or oral olpadronate or risedronate) confers some benefits. Bisphosphonates decrease bone resorption by osteoclasts; OI patients have increased bone volume that still contains the defective collagen. Bisphosphonates are more beneficial for vertebrae (trabecular bone) than long bones (cortical bone). Treatment for 1-2 yr results in increased L1-4 dual-energy x-ray absorptiometry and, more importantly, improved vertebral compressions and area, which can prevent or delay the scoliosis of OI. Relative risk of long bone fractures is modestly decreased. However, the material properties of long bones are weakened by prolonged treatment and nonunion after osteotomy is increased. There is no effect of bisphosphonates on mobility scores, muscle strength, or bone pain. Limiting treatment duration to 2-3 yr in mid-childhood can maximize benefits and minimize detriment to cortical material properties. Benefits appear to persist several years after the treatment interval. Side effects include abnormal long bone remodeling, increased incidence of fracture nonunion, and osteopetrotic-like brittleness to bone.

PROGNOSIS

OI is a chronic condition that limits both life span and functional level. Infants with OI type II usually die within months to a year of life. An occasional child with radiographic type II and extreme growth deficiency survives to the teen years. Persons with OI type III have a reduced life span with clusters of mortality from pulmonary causes in early childhood, the teen years, and the 40s. OI types I, IV, and V OI

are compatible with a full life span. The oldest reported individuals with type VIII are in their 3rd decade, and some with type XI are in their 4th decade. The long-term prognosis for most recessive types is still emerging, and many adults with OI have not had molecular testing.

Individuals with OI type III are usually wheelchair dependent. With aggressive rehabilitation, they can attain transfer skills and household ambulation. OI type IV children usually attain community ambulation skills either independently or with gait aids.

GENETIC COUNSELING

For autosomal dominant OI, the risk of an affected individual passing the gene to the individual's offspring is 50%. An affected child usually has about the same severity of OI as the parent; however, there is variability of expression, and the child's condition can be either more or less severe than that of the parent. The empirical recurrence risk to an apparently unaffected couple of having a second child with OI is 5-7%; this is the statistical chance that 1 parent has germline mosaicism. The collagen mutation in the mosaic parent is present in some germ cells and may be present in somatic tissues. If a parent is a mosaic carrier, the risk of recurrence may be as high as 50%.

For recessive OI, the recurrence risk is 25% per pregnancy. No known individual with severe nonlethal recessive OI has had a child.

Chapter 702

Marfan Syndrome

Alexander Doyle, Jefferson J. Doyle, and Harry C. Dietz III

Marfan syndrome (MFS) is an inherited, systemic, connective tissue disorder caused by mutations in the gene encoding the *extracellular matrix* (ECM) protein fibrillin-1. It is primarily associated with skeletal, cardiovascular, and ocular pathology. The diagnosis is based on clinical findings, some of which are age dependent.

EPIDEMIOLOGY

The incidence is reported to be 1 in 10,000 live births and approximately one-fourth of cases are sporadic. The disorder shows autosomal dominant inheritance, with high penetrance, but variable expression; both interfamilial and intrafamilial clinical variation is common. There is no racial or gender preference.

PATHOGENESIS

MFS is associated with abnormal production, matrix deposition and/or stability of fibrillin-1, a 350-kDa ECM protein that is the major constituent of microfibrils, with prominent disruption of microfibrils and elastic fibers in diseased tissues. The ***fibrillin-1 (FBN1)*** locus resides on the long arm of chromosome 15 (15q21), and the gene is composed of 65 exons. Linkage analysis suggests an absence of locus heterogeneity and the involvement of *FBN1* has been demonstrated in >90% of cases, with more than 1,000 disease-causing mutations identified to date (the majority of which are missense point mutations and unique to a given family). With the exception of an early onset and severe presentations of the disease associated with some mutations in exons 26-27 and 31-32, no clear genotype–phenotype correlation has been identified. Given that there is considerable intrafamilial variability, genetic, epigenetic, environmental or other unidentified factors may influence expression of the disease.

MFS was traditionally considered to result from a structural deficiency of connective tissues. Reduced fibrillin-1 was thought to lead to a primary derangement of elastic fiber deposition, because both skin and aorta from affected patients show decreased elastin, along with elastic fiber fragmentation. In response to stress (such as hemodynamic forces in the proximal aorta), affected organs were thought to manifest this structural insufficiency with accelerated degeneration. Additional research identified a cytokine-regulatory role for fibrillin-1 that appears to have important implications for MFS. The *transforming growth factor beta (TGF-β)* family of cytokines influences a diverse repertoire of cellular processes, including cell proliferation, migration, differentiation, survival and synthetic activity. The *TGF-β* ligands (*TGF-*β_1, -β_2, or -β_3) are synthesized as inactive precursor complexes and sequestered by ECM proteins, including fibrillin-1. Mice heterozygous for a mutation in the fibrillin-1 gene, typical of those that cause MFS in humans, display many of the classic features of MFS including aortic root aneurysm, which associates with a tissue signature for increased TGF-β signaling, suggesting that failed ECM sequestration of latent TGF-β by fibrillin-1 leads to increased TGF-β activation and signaling. Furthermore, pharmacologic antagonism of TGF-β signaling ameliorates aortic aneurysm in mouse models of MFS, demonstrating that high TGF-β signaling is a cause rather than a consequence of disease progression.

Aberrant TGF-β signaling might also play a role in the wider spectrum of manifestations of MFS. Increased TGF-β signaling has been observed in other tissues in MFS mice, including the developing lung, mitral valve, and skeletal muscle. Treatment of these mice with agents that antagonize TGF-β attenuates or prevents pulmonary emphysema, myxomatous degeneration of the mitral valve, and skeletal muscle myopathy. The prominent role of TGF-β dysregulation in the pathogenesis of MFS was further validated by the discovery and characterization of another aortic aneurysm syndrome, **Loeys-Dietz syndrome**, in which patients have mutations in the TGF-β receptors and share many overlapping clinical features with MFS (see "Differential Diagnosis" below).

CLINICAL MANIFESTATIONS

MFS is a multisystem disorder, with cardinal manifestations in the skeletal, cardiovascular, and ocular systems.

Skeletal System

Overgrowth of the long bones (dolichostenomelia) is often the most obvious manifestation of MFS and may produce a reduced *upper segment: lower segment ratio* (US:LS) or an arm span to height ratio >1.05 times. Abnormal ratios are US:LS <1 for ages 0-5 yr, US:LS <0.95 for ages 6-7 yr, US:LS <0.9 for ages 8-9 yr, and <0.85 above age 10 yr. Anterior chest deformity is likely the result of excessive rib growth, pushing the sternum either outward (pectus carinatum) or inward (pectus excavatum). Abnormal curvatures of the spine (most commonly thoracolumbar scoliosis) may also partly result from increased vertebral growth. Other skeletal features include an inward bulging of the acetabulum into the pelvic cavity (protrusio acetabuli), flatfeet (pes planus), and joint hypermobility or joint contractures. Long and slender fingers in relation to the palm of the hand (arachnodactyly) is generally a subjective finding. The combination of arachnodactyly and hypermobile joints is examined by the Walker-Murdoch or wrist sign, which is positive if there is full overlap of the distal phalanges of the thumb and fifth finger when wrapped around the contralateral wrist (Fig. 702-1), and the Steinberg or thumb sign, which is present when the distal phalanx of the thumb fully extends beyond the ulnar border of the hand when folded across the palm (Fig. 702-1). Contracture of the fingers (camptodactyly) and elbows is commonly observed. A selection of craniofacial manifestations may be present including a long narrow skull (dolichocephaly), deep-set eyes (enophthalmos), recessed lower mandible (retrognathia) or small chin (micrognathia), flattening of the midface (malar hypoplasia), a high-arching palate, and downward-slanting palpebral fissures (Fig. 702-2).

Cardiovascular System

Within the heart, thickening of the atrioventricular valves is common and often associated with valvular prolapse. Variable degrees of regurgitation may be present. In children with early onset and severe MFS,

Figure 702-1 Note the joint laxity **(A),** Steinberg thumb sign **(B),** ability to join thumb and fifth finger around the wrist (Walker-Murdoch sign) **(C),** pes planus **(D),** and striae over hips and back **(E).** *(From Jones KL, Jones MC, del Campo M:* Smith's recognizable patterns of human malformation*, ed 7, Philadelphia, 2013, WB Saunders, Fig. 2, p. 616;* ***A-D*** *courtesy Dr. Lynne M. Bird, Rady Children's Hospital, San Diego, CA.)*

insufficiency of the mitral valve can lead to congestive heart failure, pulmonary hypertension and death in infancy; this manifestation is the leading cause of morbidity and mortality in young children with the disorder. Supraventricular arrhythmias and ventricular dysrhythmias may be seen in association with mitral valve dysfunction, and there is an increased prevalence of prolonged QT interval. Dilated cardiomyopathy occurs with increased prevalence in patients with MFS, most often attributed to volume overload imposed by valve regurgitation. Aortic valve dysfunction is generally a late occurrence and attributed to stretching of the aortic annulus by an expanding aortic root aneurysm.

Aortic aneurysm, dissection and rupture, principally at the level of the sinuses of Valsalva (aortic root), remains the most life-threatening manifestations of MFS, prompting lifelong monitoring by echocardiography or other imaging modalities. In severe cases, the aneurysm may be present in utero, but in mild examples, it may be absent or never exceed dimensions that require clinical intervention. Aortic dimensions must be interpreted in comparison to age-dependent nomograms. The most important risk factor for aortic dissection are the maximal aortic root size and a positive family history. The characteristic histologic findings from aortae of patients with MFS include cystic medial necrosis of the tunica media and disruption of elastic lamellae. Cystic medial necrosis describes the focal apoptosis and disappearance of vascular smooth muscle cells and elastic fibers from the of the tunica media of the aortic wall, and subsequent deposition of mucin-like material in the cystic space. These changes produce a thicker, less distensible and stiffer aorta, which is more prone to aortic dissection. Most patients experiencing acute aortic dissection present with classic symptoms including sudden-onset, severe, tearing chest pain, often radiate into the back. The dissection typically starts at the aortic root and may remain confined to the ascending aorta (type II) or continue into the descending aorta (type I). Acute-onset congestive heart failure may occur if aortic valve function is compromised and patients may suffer cerebrovascular injury depending on the involvement of the carotid arteries. Involvement of the coronary arteries may herald sudden cardiac death, secondary to myocardial infarction or rupture into the pericardial sac with subsequent pericardial tamponade. Chronic aortic dissection usually occurs more insidiously, often without chest pain. Dilation of the main pulmonary artery is common but does not typically cause any clinical sequelae. Enlargement of the

Table 702-1 Diagnostic Criteria for Marfan Syndrome

In the absence of a family history of MFS, a diagnosis can be established in 4 distinct scenarios:
1. Aortic root Z score >2 *and* ectopia Lentis*
2. Aortic root Z score >2 *and* a bona fide *FBN1* mutation
3. Aortic root Z score >2 *and* a systemic score >7*
4. Ectopia lentis *and* a bona fide *FBN1* mutation known to cause aortic disease

In the presence of a family history of MFS, a diagnosis can be established in the presence of:
1. Ectopia lentis
2. A systemic score >7*
3. Aortic root Z score >2 if older than 20 yr or >3 if younger than 20 yr*

In the absence of a family history of MFS, alternative diagnoses include:
1. Ectopia lentis ± systemic score *and FBN1* mutation not known to associate with aortic aneurysm or no *FBN1* mutation = ectopia lentis syndrome
2. Aortic root Z score <2 *and* a systemic score >5 (with at least 1 skeletal feature) without ectopia lentis = MASS (mitral valve prolapse, myopia, borderline and nonprogressive aortic enlargement, and nonspecific skin and skeletal findings) phenotype
3. Mitral valve prolapse *and* aortic root Z score <2 *and* a systemic score <5 without ectopia lentis = mitral valve prolapse syndrome

*Denotes caveat that features suggestive of an alternative diagnosis must be excluded and appropriate alternative molecular testing should be performed.

Table 702-2 Scoring of Systemic Features in Points

- Wrist *and* thumb sign = 3 (wrist *or* thumb sign = 1)
- Pectus carinatum deformity = 2 (pectus excavatum or chest asymmetry = 1)
- Hind foot deformity = 2 (plain pes planus = 1)
- Pneumothorax = 2
- Dural ectasia = 2
- Protrusio acetabuli = 2
- Reduced US : LS *and* increased arm : height *and* no severe scoliosis = 1
- Scoliosis or thoracolumbar kyphosis = 1
- Reduced elbow extension = 1
- Facial features (3/5) = 1 (dolichocephaly, enophthalmos, down-slanting palpebral fissures, midface hypoplasia, retrognathia)
- Skin striae = 1
- Myopia >3 diopters = 1
- Mitral valve prolapse (all types) = 1

Maximum total: 20 points; score ≥7 indicates systemic involvement.
US:LS, upper segment:lower segment ratio.

descending thoracic or abdominal aorta can also occur, although relatively rarely.

Ocular System

Dislocation of the ocular lens (ectopia lentis) occurs in approximately 60-70% of patients, although it is not unique to the disorder. Other ocular manifestations include early and severe myopia, flat cornea, increased axial length of the globe, hypoplastic iris, and ciliary muscle hypoplasia, causing decreased miosis. Patients are also predisposed to retinal detachment and early cataracts or glaucoma.

Other Systems

There is an increased incidence of pulmonary disease in MFS: progressive anterior chest deformity or thoracic scoliosis may contribute to a restrictive pattern of lung disease. A widening of the distal airspaces predisposes patients to spontaneous pneumothorax, which occurs in up to 15% of patients. Assessment of pulmonary volumes and function should account for long bone overgrowth affecting the lower extremities, which can lead to a reduction in the normalized forced vital capacity and total lung capacity. If normalized to thoracic size or sitting height, pulmonary function testing is often normal in patients with the disorder.

MFS patients typically have normal skin texture and elasticity. The most common skin finding is stretch marks—pinkish, scar-like lesions that later become white (striae atrophicae), which occur in about one-third of patients (see Fig. 702-1). These may occur in the absence of obesity, rapid gain in muscle mass, or pregnancy, and at sites not associated with increased skin distention (i.e., the anterior shoulder or lower back). Another common manifestation is congenital or acquired inguinal hernia. There is also an increased risk of surgical and recurrent hernias in the Marfan population.

Widening of the dural sac or root sleeves (dural ectasia) is present in 63-92% of MFS patients. Although dural ectasia can result in lumbar back pain, it is often asymptomatic and should be assessed by lumbosacral imaging with CT or MRI.

DIAGNOSIS

Given the complexity of the clinical examination in MFS and the relevant differential diagnoses, evaluation should be coordinated by a professional with extensive experience, such as a geneticist, cardiologist, or ophthalmologist. The diagnosis is based on a defined set of clinical criteria drawn up by an international panel of experts: revised Ghent nosology for the MFS (Table 702-1).

In the absence of a conclusive family history of MFS, the diagnosis can be established in 4 distinct scenarios:

1. The presence of either aortic root dilation when standardized to age and body size (an aortic root Z score ≥2) or aortic dissection combined with ectopia lentis allows for the unequivocal diagnosis of MFS, irrespective of the presence or absence of any systemic features (Table 702-2), except when these are indicative of an alternate diagnosis.

Table 702-3 Criteria for Causal *FBN1* Mutation

• Mutation previously shown to segregate in a Marfan family
• Any 1 of the following de novo mutations (with proven paternity and absence of disease in parents):
  • Nonsense mutation
  • Inframe and out of frame deletion/insertion
  • Splice site mutations affecting canonical splice sequence or shown to alter splicing on mRNA/cDNA level
  • Missense mutation affecting/creating cysteine residues
  • Missense mutation affecting conserved residues of the EGF consensus sequence [(D/N)X(D/N)(E/Q)Xm(D/N)Xn(Y/F) with m and n representing variable number of residues; D representing aspartic acid; N representing asparagine; E representing glutamic acid; Q representing glutamine; Y representing tyrosine; F representing phenylalanine; X representing any amino acid]
  • Other missense mutations: segregation in family if possible *and* absence in 400 ethnically matched control chromosomes; if no family history, absence in 400 ethnically matched control chromosomes
  • Linkage of haplotype for n ≥6 meioses to the *FBN1* locus

cDNA, complementary DNA; mRNA, messenger RNA;

From Loeys BL, Dietz HC, Braverman AC, et al: The revised Ghent nosology for the Marfan syndrome. J Med Genet *47:476–485, 2010.*

2. The presence of aortic root dilation (Z score ≥2) or aortic dissection and the identification of a bona fide *FBN1* mutation (Table 702-3) are sufficient to establish the diagnosis even if ectopia lentis is absent.
3. When aortic root dilation (an aortic root Z score ≥2) or aortic dissection is present, but ectopia lentis is absent and the *FBN1* status is either unknown or negative, the diagnosis may be confirmed by the presence of sufficient systemic findings (a systemic score ≥7 points; see Table 702-2). However, features suggestive of an alternate diagnosis must be excluded and the appropriate alternative molecular testing should be performed.
4. In the presence of ectopia lentis, but absence of aortic root dilation or aortic dissection, an *FBN1* mutation, which has previously been associated with aortic disease, is required before the diagnosis can be made. If the *FBN1* mutation is not unequivocally associated with cardiovascular disease in either a related or unrelated proband, the patient should be classified as *isolated ectopia lentis syndrome*.

Despite these diagnostic criteria, on occasion young (<20 yr) sporadic cases may not fit in 1 of the 4 proposed scenarios detailed above. If insufficient systemic features (systemic score <7) and/or borderline aortic root measurements (Z score <3) are present without documented evidence of a bona fide *FBN1* mutation, the term *nonspecific connective tissue disorder* is recommended. In those instances when a *FBN1* mutation is identified, the term *potential MFS* should be used instead.

In an individual with a positive family history of MFS (where a family member has been independently diagnosed using the above criteria), the diagnosis can be established in the presence of:

1. Ectopia lentis
2. A systemic score >7 points (see Table 702-1)
3. Aortic root dilation with Z score ≥2 in adults (≥20 yr old) or Z score ≥3 in individuals younger than 20 yr old

In the case of scenarios 2 and 3, features suggestive of an alternative diagnosis must again be excluded and appropriate alternative molecular testing should be performed.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of MFS includes disorders with aortic aneurysm (Loeys-Dietz syndrome, familial thoracic aortic aneurysm syndrome, Shprintzen-Goldberg syndrome); ectopia lentis (ectopia lentis syndrome, Weill-Marchesani syndrome, and homocystinuria [see Chapter 85.3]); or systemic manifestations of MFS (congenital contractural arachnodactyly and MASS phenotype) (Table 702-4).

Aortic Aneurysm Syndromes

An important differential diagnosis is **Loeys-Dietz syndrome (LDS)**, a systemic connective tissue disorder characterized by the triad of arterial tortuosity and aggressive aneurysm disease, hypertelorism, and bifid uvula or cleft palate, as well as many of the craniofacial and skeletal features found in MFS. The diagnosis may be classified into LDS type 1 or LDS type 2 depending on whether the mutant locus resides in the *TGFBR1* or the *TGFBR2* gene, which encode the type 1 or the type 2 TGF-β receptors respectively. Two new LDS variants have been described, LDS type 3 and LDS type 4, which are caused by heterozygous mutations in the genes encoding the TGF-β intracellular signaling molecule SMAD3 and the extracellular ligand TGF-β_2, respectively. These new subtypes are also characterized by widespread arterial tortuosity and aneurysm disease, aortic dissection, as well as typical craniofacial and skeletal abnormalities. Patients with *SMAD3* mutations also appear predisposed to early onset osteoarthritis and supraventricular arrhythmias. Distinguishing between MFS and the various LDS subtypes is important because aneurysms tend to dissect at younger ages and smaller dimensions in LDS patients, necessitating more aggressive management.

Like MFS, **familial thoracic aortic aneurysm** syndrome segregates as an autosomal dominant trait characterized aortic root aneurysm and dissection. Other systemic manifestations of MFS are typically absent and the disorder has reduced penetrance. Disease-causing heterozygous mutations have been identified in several genes with roles in the vascular smooth muscle contractile apparatus, including *MYH11*, *ACTA2*, and *MYLK*, which encode smooth muscle myosin heavy chain 11, vascular smooth muscle α-actin, and myosin light chain kinase. However, these genes only account for a fraction of cases of nonsyndromic familial thoracic aortic aneurysm. In most cases, the management principles that have been generated for MFS have proved effective for this form of familial aortic aneurysm.

Shprintzen-Goldberg syndrome is a systemic connective tissue disorder that includes virtually all the craniofacial, skeletal, skin and cardiovascular manifestations of MFS and LDS, with the additional findings of craniosynostosis, hydrocephalus, mental retardation and severe skeletal muscle hypotonia. The majority of cases are caused by heterozygous mutations in the *SKI* gene, which encodes an intracellular repressor of TGF-β signaling. Vascular involvement tends to be less prevalent and less severe when compared to MFS or LDS.

Ectopia Lentis Syndromes

Both **ectopia lentis syndrome** and **Weill-Marchesani syndrome** may also be caused by heterozygous mutations in *FBN1*. Compound heterozygous or homozygous mutations at a second locus, *ADAMTSL4,* have been shown to cause ectopia lentis associated with slightly younger age at diagnosis. Interestingly, the same *FBN1* mutation produces classical MFS, ectopia lentis, and ectopia lentis combined with skin, but not cardiovascular, manifestations of MFS, suggesting that these presentations are part of a spectrum of clinical features of the same disease.

Weill-Marchesani syndrome is a systemic connective tissue disorder characterized by skin, skeletal, and ocular abnormalities, including microspherophakia, ectopia lentis, and myopia. Features inconsistent with the diagnosis of MFS include short stature and brachydactyly. As well as *FBN1* mutations (type 2), the syndrome may be caused by homozygous or compound heterozygous mutations in *ADAMTS10* (type 1) or homozygous mutations in *LTBP2* (type 3).

Homocystinuria is a metabolic disorder caused by homozygous or compound heterozygous mutations in the gene encoding cystathionine β-synthase, which leads to increases in both homocysteine and methionine. The clinical features of untreated homocystinuria include ectopia lentis and skeletal abnormalities resembling MFS. However, in contrast to MFS, affected persons often suffer from developmental delay, a predisposition to thromboembolic events, and a high incidence of coronary artery disease.

Table 702-4 Differential Diagnosis of Marfan Syndrome

DIFFERENTIAL DIAGNOSIS	CARDIAC FEATURES	VASCULAR FEATURES	SYSTEMIC FEATURES
AORTIC ANEURYSM SYNDROMES			
Loeys-Dietz syndrome (MIM 609192)	Patent ductus arteriosus Atrial septal defect Bicuspid aortic valve	Aortic root aneurysm Arterial tortuosity Widespread aneurysms Vascular dissection at relatively young ages and small aortic dimensions	Hypertelorism Cleft palate Broad or bifid uvula Craniosynostosis Midface hypoplasia Blue sclerae Arachnodactyly Pectus deformity Scoliosis Joint hypermobility Pes planus Rarely Easy bruising Dystrophic scars Translucent skin Rarely developmental delay
Familial thoracic aortic aneurysm (MIM 132900)	Generally none Rare forms with patent ductus arteriosus	Aortic root aneurysm Ascending aortic aneurysm	Generally none Rarely livedo reticularis and iris flocculi
Shprintzen-Goldberg syndrome (MIM 182212)	None	Aortic root aneurysm	Hypertelorism Craniosynostosis Arched palate Arachnodactyly Pectus deformity Scoliosis Joint hypermobility Developmental delay
Bicuspid aortic valve with aortic aneurysm (MIM: 109730)	Bicuspid aortic valve	Aortic root aneurysm Ascending aortic aneurysm	
Ehlers-Danlos syndrome, type IV (MIM: 130050)	Mitral valve prolapse	Aneurysm and rupture of any medium to large muscular artery No predisposition for aortic root enlargement	Joint hypermobility Atrophic scars Translucent skin Easy bruising Hernias Rupture of hollow organs
ECTOPIA LENTIS SYNDROMES			
Familial ectopia lentis (MIM 129600)	None	None	Nonspecific skeletal features
Homocystinuria (MIM 236200)	Mitral valve prolapse	Intravascular thrombosis	Tall stature Ectopia lentis Long-bone overgrowth Developmental delay
SYNDROMES WITH SYSTEMIC MANIFESTATIONS OF MFS			
MASS phenotype (MIM 604308)	Mitral valve prolapse	Borderline or nonprogressive	Nonspecific skin and skeletal findings Myopia

Syndromes with Systemic Manifestations of Marfan Syndrome

Congenital contractural arachnodactyly is a connective tissue disorder caused by heterozygous mutations in the gene encoding fibrillin-2 (*FBN2*). There are a number of clinical features overlapping with MFS including dolichostenomelia, anterior chest deformity, scoliosis, joint contractures, and arachnodactyly, as well as some craniofacial malformations, including highly arched palate and retrognathia. In addition, both may suffer from severe cardiovascular abnormalities leading to premature death, but the specific cardiac anomalies are quite different; valvular insufficiency and aortic root dilation in MFS whereas congenital heart defects are more common in congenital contractural arachnodactyly. Patients with congenital contractural arachnodactyly also suffer from crumpled auricular helices (a hallmark of this condition).

Many patients referred for possible MFS are found to have evidence of a systemic connective tissue disorder, including long limbs, deformity of the thoracic cage, striae atrophicae, mitral valve prolapse, and borderline but nonprogressive dilation of the aortic root, but do not meet diagnostic criteria for MFS. This constellation of features is referred to by the acronym **MASS** phenotype (mitral valve prolapse, myopia, borderline and nonprogressive aortic enlargement, and nonspecific skin and skeletal findings). The MASS phenotype can segregate in large pedigrees and remain stable over time. The diagnosis is particularly challenging in the context of a young, sporadic patient in whom careful follow-up is needed to distinguish MASS phenotype from emerging MFS. Familial mitral valve prolapse syndrome can also be caused by mutations in the gene encoding fibrillin-1 and include subdiagnostic systemic manifestations.

LABORATORY FINDINGS

Laboratory studies should document a negative urinary cyanide nitroprusside test or specific amino acid studies to exclude cystathionine β-synthase deficiency (homocystinuria). Although it is estimated that most, if not all, people with classic MFS have an *FBN1* mutation, the large size of this gene and the extreme allelic heterogeneity in MFS have frustrated efficient molecular diagnosis. The yield of mutation screening varies based on technique and clinical presentation. It

remains unclear whether the "missing" mutations are simply atypical in character or location within *FBN1* or located in another gene. Other differential diagnoses, such as MASS phenotype, ectopia lentis, Weill-Marchesani syndrome, and Shprintzen-Goldberg syndrome, are associated with mutations in the *FBN1* gene. It is often difficult or impossible to predict the phenotype from the nature or location of a *FBN1* mutation in MFS. Hence, molecular genetic techniques can contribute to the diagnosis, but they do not substitute for comprehensive clinical evaluation and follow-up. The absence or presence of an *FBN1* mutation is not sufficient to exclude or establish the diagnosis, respectively.

MANAGEMENT

Management focuses on preventing complications and genetic counseling. Referral to a multidisciplinary center where a geneticist with experience in MFS works in concert with subspecialists to coordinate a rational approach to monitoring and treatment is advisable given the complex nature of some patient's disease. Yearly evaluations for cardiovascular disease, scoliosis, or ophthalmologic problems are imperative.

CURRENT THERAPIES

Most therapies currently available or under investigation aim to diminish cardiovascular complications, which can be categorized into activity restrictions, aortic surgery, endocarditis prophylaxis, and current pharmacologic approaches.

Activity Restrictions

Physical therapy can improve cardiovascular performance, neuromuscular tone, and psychosocial health, and so aerobic exertion in moderation is recommended. However, strenuous physical exertion, competitive or contact sports and particularly isometric activities, which invoke a Valsalva maneuver, such as weight lifting, should be avoided.

Aortic Surgery

Surgical outcome is more favorable if undertaken on an elective rather than an urgent or emergent basis (mortality of 1.5% vs 2.6% and 11.7%, respectively). Therefore, aortic surgery should be recommended for adult patients when their aortic root diameter approaches 50 mm, and early intervention considered for those with a rapid rate of enlargement (>5-10 mm per year) or a family history of early aortic dissection. There are no definitive criteria guiding the timing of surgery in children in whom dissection is extremely rare, irrespective of aortic size. This has prompted many centers to adopt the adult criterion of 50 mm, although early surgery may be undertaken in the presence of a rapid rate of growth (>10 mm per year) or the emergence of significant aortic regurgitation. Preserving the native aortic valve at the time of repair is desirable to avoid the need for lifelong anticoagulation. Replacement of the aortic root with a pulmonary root autograft (a Ross procedure) is not recommended as the neoaorta can undergo progressive enlargement and autograft failure once exposed to the systemic blood pressure. Mitral valve repair or replacement is advised for severe mitral valve regurgitation with associated symptoms or progressive left ventricular dilation or dysfunction.

Pregnancy

There is higher risk of aortic dissection during pregnancy in women with MFS. However, improved awareness and more recent analyses have indicated the risk is low in patients with an aortic root diameter <40 mm. Prophylactic aortic root replacement can minimize the risk of aortic dissection and death in women with MFS who wish to become pregnant.

Endocarditis Prophylaxis

The American Heart Association no longer recommends the use of antibiotic prophylaxis for persons with structural or valvular heart disease, but exceptions are made for select groups at the greatest risk for bad outcomes from infectious endocarditis. The Professional Advisory Board of the National Marfan Foundation believes that patients with MFS should continue to receive prophylaxis for bacterial endocarditis, in part because it remains unknown, but possible, that the myxomatous valves typical of MFS are a preferred substrate for bacterial infection.

Current Pharmacologic Approaches

β-Blockers have traditionally been considered the standard of care in MFS and multiple small observational studies suggest there is a protective effect on aortic root growth, with the dose typically titrated to achieve a resting heart rate <100 beats/min during submaximal exercise. Given the putative role of hemodynamic stress in aortic dilation and aortic dissection in MFS, these effects are attributed to the negative inotropic and chronotropic effects of β-blockade.

EMERGING THERAPEUTIC STRATEGIES

Angiotensin II Receptor Type 1 Blockers

There is extensive evidence linking angiotensin II signaling to TGF-β activation and signaling. In a mouse model of MFS, the **angiotensin II receptor type 1 blocker losartan** completely prevents pathologic aortic root growth and normalizes both aortic wall thickness and architecture. In support of its relevance to humans, a retrospective study assessing the effect of angiotensin II receptor type 1 blockers in a small cohort of pediatric patients with MFS who had severe aortic root enlargement despite previous alternate medical therapy, showed that angiotensin II receptor type 1 blockers significantly slowed the rate of aortic root and sinotubular junction dilation (both of which occur in MFS), whereas the distal ascending aorta (which does not normally become dilated in MFS) remained unaffected. Further evidence of a beneficial effect from losartan therapy is provided by 3 prospective clinical trials that demonstrated that losartan treatment alone or in combination with β-blockade slows the progression of aortic root dilation in patients with MFS. Nonetheless when compared to atenolol, losartan therapy in children and young adults with Marfan syndrome and aortic root dilation demonstrated equivalent rates of aortic root dilation during a 3-yr study.

PROGNOSIS

The major cause of mortality is aortic root dilation, dissection, and rupture, with the majority of fatal events occurring in the 3rd and 4th decade of life. A reevaluation of life expectancy in MFS suggests that early diagnosis and refined medical and surgical management has greatly improved the prognosis for patients with the condition. Nevertheless, MFS continues to be associated with significant morbidity and selected subgroups are refractory to therapy and continue to show early mortality. In a review of 54 patients diagnosed during infancy, 89% had serious cardiac pathology; cardiac disease was progressive despite standard care (22% died during childhood, 16% before age 1 yr). In the more classic form of MFS, it is estimated that more than 90% of individuals will have a cardiovascular event during their lifetime, placing both physical and mental stresses on patients and their families. Awareness of these issues and referral for support services can facilitate a positive perspective toward the condition.

GENETIC COUNSELING

The heritable nature of MFS makes recurrence risk (genetic) counseling mandatory. Fathers of these sporadic cases are, on average, 7-10 yr older than fathers in the general population. This paternal age effect suggests that these cases represent new dominant mutations with minimal recurrence risk to the future offspring of the normal parents. Owing to rare reports of gonadal mosaicism in a phenotypically normal parent, the recurrence risk for parents of a sporadic case can be reported as low, but not zero. Each child of an affected parent, however, has a 50% risk of inheriting the MFS mutation and thus being affected. Recurrence risk counseling is best accomplished by professionals with expertise in the issues surrounding the disorder.

Section 4

Metabolic Bone Disease

Chapter 703

Bone Structure, Growth, and Hormonal Regulation

Russell W. Chesney

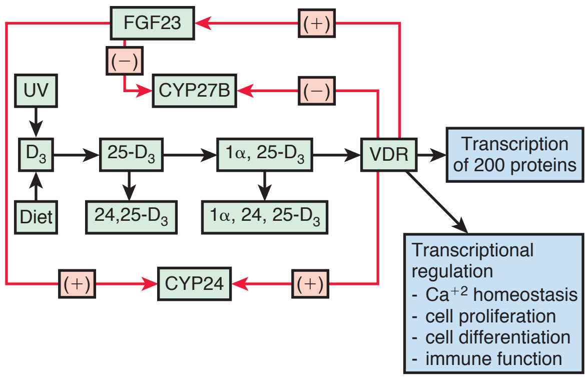

Figure 703-1 **Vitamin D metabolism.** Vitamin D can be synthesized in the skin under the influence of UV irradiation, or it can be absorbed from the diet. It is converted to 25(OH)D_3 (vitamin D_3) in the liver and then further converted by the kidney. The enzyme cytochrome P450 (CYP) 27B converts 25(OH)D_3 to 1α,25-$(OH)_2D_3$. 1,25$(OH)_2D_3$ binds to vitamin D receptor (VDR), which, after transport to the nucleus, acts to induce the transcription of more than 200 proteins. The functions of some of the proteins are indicated. VDR activation leads to productions of fibroblast growth factor 23 (FGF23). FGF23 induces phosphaturia (not shown), upregulates CYP 24, and downregulates CYP 27B.

See also Chapters 51 and 570.

Bone is a rigid organ but metabolically active in that it is constantly being formed **(modeling)** and reformed **(remodeling).** It is capable of rapid turnover, bearing weight, and withstanding the stresses of various physical activities. Bone is the major body reservoir for calcium, phosphorus, and magnesium. Other functions of bone include organ protection, structure, movement, and sound transmission. It is also an endocrine organ that produces fibroblast growth factor 23 (FGF23), which regulates renal phosphate handling. Disorders that affect this organ and the process of mineralization are designated **metabolic bone diseases.**

The human skeleton consists of a protein matrix, largely composed of a collagen-containing protein, osteoid, on which is deposited a crystalline mineral phase. Collagen-containing osteoid accounts for 90% of bone protein; other proteins, including osteocalcin, which contains γ-carboxyglutamic acid, are also present. Synthesis of osteocalcin depends on vitamin K and vitamin D; in states with high bone turnover, serum osteocalcin values are often elevated. Osteocalcin itself acts on insulin secretion and reduction of fat stores.

The microfibrillar matrix of osteoid permits deposition of highly organized calcium phosphate crystals, including hydroxyapatite $[C_{10}(PO_4)_6{\cdot}6H_2O]$ and octacalcium phosphate $[Ca_8(H_2PO_4)_6{\cdot}5H_2O]$, plus less-organized amorphous calcium phosphate, calcium carbonate, sodium, magnesium, and citrate. Hydroxyapatite is deep within bone matrix, whereas amorphous calcium phosphate coats the surface of newly formed or remodeled bone.

Because bone growth and turnover rates are high during childhood, many clinical and osseous features of metabolic bone diseases are more prominent in children than in adults.

The growth pattern of bones is an acceleration of bone growth (length) of the limbs during prepubescence, increased growth (length) of the trunk (spine) during early adolescence, and increased bone mineral deposition in late adolescence. The use of dual-energy x-ray absorptiometry or quantitative CT permits measurement of both mineral content and bone density in healthy subjects and in children with metabolic bone disease. Dual-energy x-ray absorptiometry scanning exposes the patient to less radiation than a chest radiograph.

Bone growth occurs in children by the process of calcification of the cartilage cells present at the ends of bone. In accord with the prevailing extracellular fluid calcium and phosphate concentrations, mineral is deposited in chondrocytes or cartilage cells set to undergo mineralization. The main function of the vitamin D–parathyroid hormone (PTH)–FGF23–endocrine axis is to maintain the extracellular fluid calcium and phosphate concentrations at appropriate levels to permit mineralization.

Other hormones also appear to regulate the growth and mineralization of cartilage, including growth hormone acting through insulin-like growth factors, thyroid hormones, insulin, leptin, ghrelin, and androgens and estrogens during the pubertal growth spurt. Supraphysiologic concentrations of glucocorticoids impair cartilage function and bone growth and augment bone resorption.

Rates of bone formation are coordinated with alterations in mineral metabolism in both the intestine and kidneys, where a number of hormones regulate the processes. Inadequate dietary intake or intestinal absorption of calcium causes a fall in serum levels of calcium and its ionized fraction. This serves as the signal for PTH synthesis and secretion, resulting in greater bone resorption (which raises the serum calcium level), enhanced distal tubular reabsorption of calcium, and promotes higher rates of renal synthesis of $1,25(OH]_2D$ or calcitriol, the most active metabolite of vitamin D (Fig. 703-1). Calcium homeostasis thus is controlled by the intestine because the availability of $1,25(OH)_2D$ ultimately determines the fraction of ingested calcium that is absorbed.

Phosphate homeostasis is regulated by the kidneys because intestinal phosphate absorption is nearly complete and renal excretion determines the serum level of phosphate. Excessive intestinal phosphate absorption causes a fall in serum levels of ionized calcium and a rise in PTH secretion, resulting in phosphaturia, thus lowering the serum phosphate level and permitting the calcium level to rise. Hypophosphatemia blocks PTH secretion and promotes renal 1,25-dihydroxyvitamin D $[1,25(OH]_2D]$ synthesis. This latter compound also promotes greater intestinal phosphate absorption. The important role of FGF23 in phosphate homeostasis is described below.

Vitamin D can be synthesized in the skin under the influence of UV irradiation, or it can be absorbed from the diet. It is converted to $25(OH)D_3$ (vitamin D_3) in the liver and then further converted by the kidney. An understanding of the metabolism of vitamin D is necessary to appreciate mineral homeostasis and metabolic bone disease and rickets. The skin contains 7-dehydrocholesterol, which is converted to vitamin D_3 $[25(OH)D_3]$ by UV radiation; other inactive vitamin D sterols are also produced (see Chapter 51). Vitamin D_3 is then transported in the bloodstream to the liver by a vitamin D–binding protein (DBP); DBP binds all forms of vitamin D. The plasma concentration of free or nonbound vitamin D is much lower than the level of DBP-bound vitamin D metabolites.

Vitamin D also can enter the metabolic pathway by ingestion of dietary vitamin D_2 (ergocalciferol) or vitamin D_3 (cholecalciferol), both of which are absorbed from the intestine because of the action of bile salts. After absorption, ingested vitamin D is transported by chylomicrons to the liver, where, along with skin-derived vitamin D_3, it is converted to 25-hydroxyvitamin D [25(OH)D] by the action of a hepatic microsomal enzyme requiring oxygen, nicotinamide adenine dinucleotide phosphate, and magnesium to hydroxylate vitamin D at the 25th carbon atom. The 25(OH)D is next transported by DBP to the kidneys, where it undergoes further metabolism. 25(OH)D is the main circulating vitamin D metabolite in humans (Table 703-1). Because the synthesis of 25(OH)D is weakly regulated by feedback, its plasma level rises in summer and falls in winter. High vitamin D intake raises the plasma level of 25(OH)D to many times above normal, but the parent vitamin D compound itself is absorbed by adipose tissue.

In the kidneys, 25(OH)D undergoes further hydroxylation, depending on the prevailing serum concentration of calcium, phosphate, PTH and FGF23. If the calcium or phosphate level is reduced or the PTH level is elevated, the enzyme 25(OH)D-1-hydroxylase is activated and $1,25(OH)_2D$ is formed. The enzyme cytochrome P450 (CYP) 27B1 converts $25(OH)D_3$ to $1\alpha,25\text{-}(OH)_2D_3$. $1,25(OH)_2D_3$ binds to vitamin D receptor, which, after transport to the nucleus, acts to induce the transcription of 200-400 proteins and peptides. The functions of some of the proteins are known.

Another class of proteins important in the regulation of mineral balance and vitamin D synthesis are the phosphatonins. Among these are FGF23, sFRP-4 (secreted Frizzled-related protein 4), and MEPE (matrix extracellular phosphoglycoprotein). Overexpression of FGF23 results in hypophosphatemia, phosphaturia, reduced serum $1,25(OH)_2D$ values, and some forms of rickets. Disorders of phosphate balance, including hyper- and hypophosphatemia, can relate to loss or gain of function of these phosphatonins (see Fig. 703-1).

Vitamin D receptor activation by $1,25(OH)_2D$ leads to production of FGF23. FGF23 is produced by osteocytes and targets another organ, the kidney, to promote phosphaturia. FGF23 reduces expression/insertion of 2 sodium phosphate transporters into the renal proximal tubule, resulting in higher levels of urinary phosphate excretion. This bone-derived hormone also inhibits renal hydroxylase activity (CYP 27B1) and promotes 24-hydroxylase activity. Consequently, circulating $1,25(OH)_2D$ levels fall.

A gene termed *Klotho* codes for a single-pass transmembrane protein that is an aging suppressor in mice. Klotho protein also influences interaction of FGF23 with its receptor FGF23R. FGF23 is then able to inhibit the action of CYP27B1 and the sodium-dependent phosphate transporter in the kidney. The net result of Klotho FGF23 interaction is reduced $1,25(OH)_2D$ values and phosphaturia.

The active metabolite, $1,25(OH)_2D$, circulates at a level that is only 0.1% of the level of 25(OH)D (see Table 703-1) and acts on the intestine to increase the active transport of calcium and stimulate phosphate absorption. Because 1α-hydroxylase is a mitochondrial enzyme that is tightly feedback regulated, the synthesis of $1,25(OH)_2D$ declines after serum calcium or phosphate values return to normal. Excessive $1,25(OH)_2D$ is converted to an inactive metabolite. In the presence of normal or elevated serum calcium or phosphate concentrations, the renal 25(OH)D-24-hydroxylase is activated, producing 24,25-dihydroxyvitamin D [$24,25(OH)_2D$], which is a pathway for the removal of excess vitamin D; serum levels of $24,25(OH)_2D$ (1-5 ng/mL) increase after ingestion of large amounts of vitamin D (see Fig. 703-1), or in the presence of increased concentrations of FGF23. Although hypervitaminosis D and production of inactive metabolites can occur after oral dosing, extensive skin exposure to sunlight does not usually produce toxic levels of $25(OH)D_3$, suggesting natural regulation of the production of this metabolite in cutaneous tissue.

Serum $1,25(OH)_2D$ levels are higher in children than in adults, are not as subject to seasonal variability, and peak in the 1st yr of life and again during the adolescent growth spurt. These values must be interpreted in light of the prevailing serum calcium, phosphate, and PTH values, and with regard to the entire vitamin D metabolite profile.

Mineral deficiency prevents the normal process of bone mineral deposition. If mineral deficiency occurs at the growth plate, growth slows and bone age is retarded, a condition called *rickets.* Poor mineralization of trabecular bone resulting in a greater proportion of unmineralized osteoid is the condition of osteomalacia. Rickets is found only in growing children before fusion of the epiphyses, whereas osteomalacia is present at all ages. All patients with rickets have osteomalacia, but not all patients with osteomalacia have rickets. These conditions should not be confused with osteoporosis, a condition of equal loss of bone volume and mineral (see Chapter 707).

Rickets may be classified as calcium-deficient or phosphate-deficient rickets. Because both calcium and phosphate ions constitute bone mineral, the insufficiency of either type in the extracellular fluid that bathes the mineralizing surface of bone results in rickets and osteomalacia. The 2 types of rickets are distinguishable by their clinical manifestations (Table 703-2). Rickets can also occur in the face of mineral deficiency, despite adequate vitamin D stores. True dietary calcium deficiency rickets is found in some parts of Africa but rarely in North America or Europe. A form of phosphate-deficiency rickets can occur in infants given prolonged administration of phosphate-sequestering aluminum salts as a treatment for colic or gastroesophageal reflux. This results in the phosphate depletion syndrome.

Table 703-1 Vitamin D Metabolic Values in Plasma of Normal Healthy Subjects

METABOLITE	PLASMA VALUE
Vitamin D_2	1-2 ng/mL
Vitamin D_3	1-2 ng/mL
$25(OH)D_2$	4-10 ng/mL
$25(OH)D_3$	26-70 ng/mL
TOTAL 25(OH)D	30-80 ng/mL [The 2010 Institute of Medicine report states that a value of 25(OH)D above 20 ng/mL is the lower limit of normal.]
$24,25(OH)_2D$	1-4 ng/mL
$1,25(OH)_2D$	
Infancy	70-100 pg/mL
Childhood	30-50 pg/mL
Adolescence	40-80 pg/mL
Adulthood	20-35 pg/mL

Chapter 704

Primary Chondrodystrophy (Metaphyseal Dysplasia)

Russell W. Chesney

Skeletal dysplasias are classified under 3 major categories: **osteodysplasias, chondrodysplasias,** and **dysostoses.** The osteodysplasias affect bone density and often lead to osteopenia. The chondrodysplasias are genetic disorders of cartilage and result in deficient linear growth. The dysostoses affect a single bone.

In primary chondrodystrophy, which is an autosomal dominant condition, bowing of the legs, short stature, and a waddling gait appear in the absence of abnormalities of serum levels of calcium and phosphate, alkaline phosphatase activity, or vitamin D metabolites. Metaphyseal chondrodysplasia **(Jansen type)** is very rare and is typified by cupped and ragged metaphyses, which develop mottled calcification at the distal ends of bone over time (Fig. 704-1). Hypercalcemia, with serum values of 13-15 mg/dL, can occur. The spine can also be deformed by the irregular growth of vertebrae. Three different mutations, resulting in ligand independent activation, have been identified in parathyroid hormone receptor type I as the molecular cause of this syndrome, as have some of the downstream target genes that can contribute to the pathogenesis of the disease. The **Schmid type** of metaphyseal chondrodysplasia is less severe, although the radiographic appearance of the knees and extreme bowing of the lower limbs resemble signs seen in patients with familial hypophosphatemia. It is associated with defects in collagen type X, alpha 1, and the hip abnormalities are more debilitating than in Jansen metaphyseal chondrodysplasia. Patients with both types of metaphyseal chondrodysplasia have lifelong short stature.

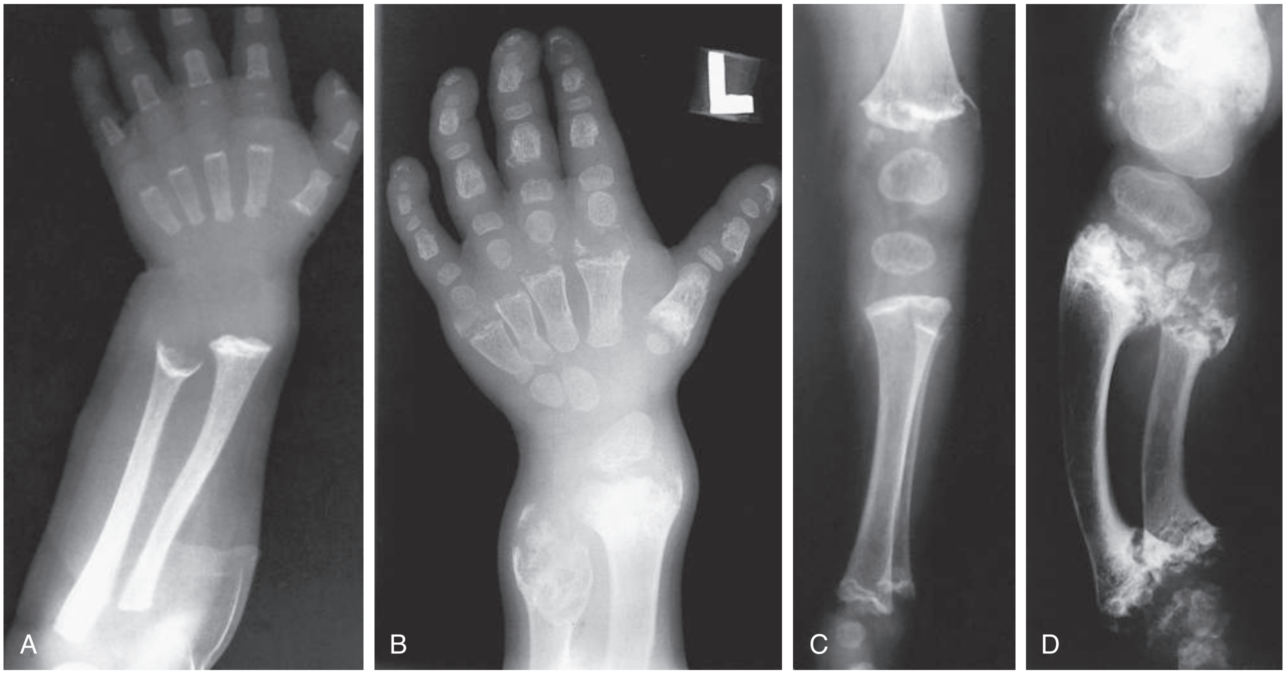

Figure 704-1 Radiographic findings in Jansen-type metaphyseal chondrodysplasia. **A,** At age 1 yr there is severe metaphyseal cupping and splaying at the wrists and also in the hand bones. **B,** At age 7 yr there is increasing metaphyseal change at the wrists with enlarged epiphysis; enlarged epiphyses with wide epiphyseal plates are also present in the hands. **C,** At age 1 yr there are severe metaphyseal irregularities at knees and ankles (femur, tibia, and fibula) and enlarged, rounded epiphyses. **D,** At age 7 yr there are severely fragmented, sclerotic metaphyses, wide epiphyseal plates, and enlarged epiphyses. Radiographic findings in Jansen-type metaphyseal chondrodysplasia. *(From Slovis TL, editor:* Caffey's pediatric diagnostic imaging*, ed 11, Philadelphia, 2008, Mosby.)*

Metaphyseal dysostosis, or **Pyle disease,** results from defects in endochondral bone formation and metaphyseal modeling. The long ends of bones are splayed, resulting in an "Erlenmeyer flask" defect. Short stature is not necessarily characteristic, and serum chemical levels are normal. Leonine features often develop if the facial bones are involved. Metaphyseal dysostosis may also be a clinical feature of Shwachman-Diamond syndrome, a rare autosomal recessive disorder characterized by neutropenia, pancreatic exocrine insufficiency, bone marrow dysfunction, and sometimes severe hematologic complications (see Chapter 448). Allogeneic bone marrow transplantation has been used as a therapeutic approach, with mixed results.

There are no other currently available forms of treatment known to be effective for the chondrodystrophies or dysostosis.

Chapter 705

Hypophosphatasia

Russell W. Chesney

Hypophosphatasia, which radiographically resembles rickets, is defined by low serum alkaline phosphatase activity and mainly affects the skeleton and teeth. This inherited disorder (with both autosomal recessive and dominant forms) is an inborn error of metabolism in which activity of the tissue-nonspecific (liver, bone, kidney) alkaline phosphatase isoenzyme (TNSALP) is deficient, although activity of the intestinal and placental isoenzymes is normal. Single-point mutations of the gene prevent expression of the activity of this enzyme in vitro and indicate its necessity for normal skeletal mineralization. A large proportion of the more than 100 mutations of the gene identified to date are missense mutations, although splice-site mutations, small deletions, and frameshift mutations also have been found. The only phenotype associated with these mutations is hypophosphatasia. Some patients have a regulatory defect involving this enzyme rather than a mutation.

There is considerable heterogeneity in the severity of the disease and 6 forms of the condition are described. Some cases appear at birth, and diagnosis has even been made in utero by radiographic examination of a fetus. The disease can appear in a lethal neonatal or perinatal form **(congenital lethal hypophosphatasia),** a severe infantile form, or a milder form occurring in childhood or late adolescence **(hypophosphatasia tarda)** (Fig. 705-1). The lethal form is characterized by a moth-eaten appearance at the ends of the long bones, severe deficiency of ossification throughout the skeleton, and marked shortening of the long bones. Patients with mild disease can present with bowing of the legs and variable statural shortening. Hypercalcemia is common in the neonatal and infantile forms, and because calcium accumulation by mature chondrocytes does not occur, patients might appear to have rickets.

Unusual clinical manifestations include wormian bones in the calvariae; poor calcification of the frontal, parietal, and occipital bones; and premature loss of deciduous or permanent teeth, due to hypoplasia of dental cementum. Because of the hypercalcemia in the infantile form, nephrocalcinosis is also found.

In the childhood form, bone pain, frequent fractures, and milder skeletal deformities are evident, as well as premature tooth loss. The metaphyseal defect consists of irregular ossification, punched-out areas, and metaphyseal cupping.

There is an adult form, manifesting in middle age, which is characterized by recurrent metaphyseal stress fractures and femoral pseudofractures. The lethal and infantile forms are autosomal recessive. The milder forms can be either autosomal recessive or dominant.

In hypophosphatasia, large quantities of phosphoethanolamine are found in the urine because this compound cannot be degraded in the absence of TNSALP activity. Plasma inorganic pyrophosphate and pyridoxal-5-phosphate levels are also elevated for the same reason. Pyridoxal-5-phosphate levels tend to be lower than normal in most

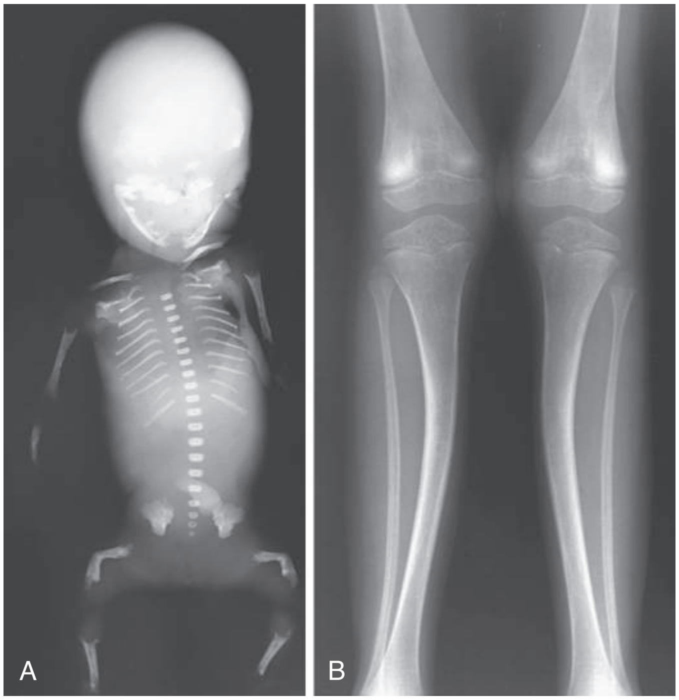

Figure 705-1 **A,** Fetus with congenital lethal hypophosphatasia showing thin wavy ribs, platyspondyly, missing cervical vertebrae, ossification, and bent femurs. **B,** A 7 yr old with hypophosphatasia tarda showing osteopenia, bent tibias, and punched-out metaphyseal lesions.

other bone diseases and hence can aid in the differential diagnosis of hypophosphatasia. Seizures in patients with the lethal and infantile forms of the disease may be related to impaired pyridoxine metabolism. Although no satisfactory therapy has been found, infusion of plasma rich in alkaline phosphatase activity has been helpful in healing bone in short-term studies. Enzyme replacement therapy with recombinant human TNSALP improves skeletal healing and mineral content, pulmonary status, and overall physical activity. Bone marrow transplantation has been successful using donors with normal TNSALP values. The clinical course of this condition often improves spontaneously as an affected child matures, although early death from renal failure or flail chest leading to pneumonia can occur in the severe infantile form of the disorder.

Rare patients presenting with identical clinical and radiographic patterns have normal serum alkaline phosphatase activity. Their disease has been labeled **pseudohypophosphatasia** and might represent the presence of a mutant alkaline phosphatase isoenzyme that reacts to artificial substrates in an alkaline environment (in a test tube) but not in vivo with natural substrates.

Chapter 706
Hyperphosphatasia

Russell W. Chesney

Hyperphosphatasia is defined by excessive elevation of the bone isoenzyme of alkaline phosphatase in serum and significant growth failure. Osteoid proliferation in the subperiosteal portion of bone results in separation of the periosteum from the bone cortex. Bowing and thickening of the diaphyses are common, along with osteopenia (Fig. 706-1). The disease usually has its onset by 2-3 yr of age, when painful deformity developing in the extremities leads to abnormal gait and sometimes fractures. Other common findings include pectus carinatum, kyphoscoliosis, and rib fraying. The skull is large, and the cranium is thickened (widened diploë) and may be deformed. Skull involvement can lead to progressive and profound hearing loss. Radiographically, the bony texture is variable; dense areas (showing a teased cotton-wool appearance) are interspersed with radiolucent areas and general demineralization. Long bones appear cylindrical, lose metaphyseal modeling, and contain pseudocysts that show a dense, bony halo. There exist several clinical phenotypes.

Figure 706-1 Hyperphosphatasia showing bowing and thickening of the diaphyses and osteopenia. *(From Slovis TL, editor:* Caffey's pediatric diagnostic imaging, *ed 11, Philadelphia, 2008, Mosby, Fig. 167-26, p. 2744.)*

In this autosomal recessive disorder, serum levels of both calcium and phosphate are normal, whereas urinary leucine amino acid peptidase activity and serum acid phosphatase levels are increased. This disorder is often called **juvenile Paget disease** because, as in adult-onset Paget disease, calcitonin can reduce the rapid bone turnover found in this disorder; in children, the disorder is more generalized and symmetric. This disorder is distinct from Paget disease because histology of bone reveals a lack of normal cortical bone remodeling and an absence of the classic mosaic pattern of lamellar bone found in the adult condition. Hence, the term *juvenile Paget disease* is inappropriate. A case has been reported in which intense intravenous bisphosphonate (ibandronate) therapy administered over a 3 yr period arrested progression of idiopathic hyperphosphatasia, preventing deformity and disability and improving hearing.

Transient hyperphosphatasia occurs between 2 mo and 2 yr of age, has no associated manifestations other than some mild gastrointestinal symptoms; it is usually detected during routine (screening) laboratory evaluation for some unrelated complaint. Liver and bone isoenzyme fractions are elevated; there are no other manifestations of hepatic or bone dysfunction. Serum alkaline phosphatase values as high as 3,000-6,000 IU/L may be encountered. The cause is unknown. Resolution usually occurs within 4-6 mo.

Familial hyperphosphatemia, an autosomal dominant trait, is another benign condition that is distinguished from the transient infantile form by persistent and asymptomatic elevations of serum alkaline phosphatase levels.

A more serious autosomal dominant variant, expansile skeletal hyperplasia, is characterized by early-onset deafness, premature loss of teeth, progressive hyperostotic widening of long bones causing painful phalanges in the hands, episodic hypercalcemia, and enhanced bone

remodeling. A defect in the gene that encodes receptor activation of nuclear factor γB is relevant. This gene appears to be necessary for osteogenesis, and the defect leads to increased activity of nuclear factor γB in the skeleton.

Chapter 707
Osteoporosis

Russell W. Chesney

Osteoporosis, the most common bone disorder in adults, is relatively uncommon in children. This disorder is characterized by diminished bone volume and a marked increase in the prevalence of fractures. In contrast to osteomalacia, which shows undermineralization and normal bone volume, histologic sections of bone in all forms of osteoporosis reveal a normal degree of mineralization but a reduction in the volume of bone, especially trabecular bone (vertebral bone). There is a reduction in trabecular bone turnover as well. In osteoporosis, by definition, there is a reduced amount of bone tissue (termed *osteopenia*), which is associated with atraumatic (pathologic) fractures. Osteoporosis in children may be primary or secondary (Table 707-1). The primary osteoporoses can be divided into heritable disorders of connective tissue, including osteogenesis imperfect (see Chapter 701), Bruck syndrome, osteoporosis-pseudoglioma syndrome, Ehlers-Danlos syndrome (see Chapter 659), Marfan syndrome (see Chapter 702), homocystinuria, and idiopathic juvenile osteoporosis. Secondary forms of osteoporosis include various neuromuscular disorders, chronic illness, endocrine disorders, and drug-induced and inborn errors of metabolism, including lysinuric protein intolerance and Gaucher disease.

When no obvious primary or secondary cause can be detected, **idiopathic juvenile osteoporosis** should be considered, especially if the following clinical features are evident: onset before puberty, long-bone and lower back pain, vertebral fractures, long-bone and metatarsal fractures, a washed-out appearance of the spine and appendicular skeleton, and improvement after puberty. Trabecular bones such as the spine and metatarsals are particularly affected by atraumatic fractures.

In general, blood values of minerals, vitamin D metabolites, alkaline phosphatase, and parathyroid hormone are normal. Evaluation of bone mineral content and bone density by dual-energy x-ray absorptiometry or, less often, quantitative CT shows markedly reduced values. Several modes of therapy (including oral calcium supplements, calcitriol, bisphosphonates, and calcitonin) have been used with some success in individual conditions, but the effect of these treatments is difficult to gauge because spontaneous recovery occurs after the onset of puberty in more than 75% of cases.

Osteoporosis-pseudoglioma is an autosomal recessive disorder manifested by variable age at onset, low bone mass, fractures in childhood, and abnormal eye development; the defective gene has been

Table 707-1 Risks for Osteoporosis

ENDOCRINE DISORDERS	**CONNECTIVE TISSUE/BONE DISORDERS**
Female Hypogonadism	Juvenile osteoporosis
Turner syndrome	Osteogenesis imperfecta
Hypothalamic amenorrhea (athletic triad)	Ehlers-Danlos syndrome
Anorexia nervosa	Marfan syndrome
Premature and primary ovarian failure	Homocystinuria
Depot medroxyprogesterone acetate therapy	Fibrous dysplasia
Estrogen receptor α *(ESR1)* mutations	Previous or recurrent low impact fractures
Hyperprolactinemia	Early onset osteoporosis with *WNT1* mutations
Male Hypogonadism	X-linked osteoporosis with fractures with *PLS3* mutations
Primary gonadal failure (Klinefelter syndrome)	**DRUGS**
Secondary gonadal failure (idiopathic hypogonadotropic hypogonadism)	Alcohol
Delayed puberty	Heparin
Hyperthyroidism	Glucocorticosteroids
Hyperparathyroidism	Thyroxine
Hypercortisolism (therapeutic or Cushing disease)	Anticonvulsants
Growth hormone deficiency	Gonadotropin-releasing hormone agonists
Thyrotoxicosis	Cyclosporine
INFLAMMATORY DISORDERS	Chemotherapy
Dermatomyositis	Cigarettes
Chronic hepatitis	**MISCELLANEOUS DISORDERS**
Systemic lupus erythematosus	Immobilization (cerebral palsy, spinal muscular atrophy, Duchenne dystrophy)
GASTROINTESTINAL DISORDERS	Rheumatoid arthritis
Malabsorption syndromes (cystic fibrosis, celiac disease, biliary atresia)	Renal disease
True or perceived milk intolerance	Glycogen storage disease type 1
Inflammatory bowel disease	Chronic hepatitis
Chronic obstructive jaundice	Low calcium dietary intake
Primary biliary cirrhosis and other cirrhoses	Gaucher disease
Alactasia	Severe congenital neutropenia
Subtotal gastrectomy	
BONE MARROW DISORDERS	
Bone marrow transplant	
Lymphoma	
Leukemia	
Hemolytic anemias (sickle cell anemia, thalassemia)	
Systemic mastocytosis	

mapped to chromosome 11q12-13. The mutation is a loss of function in the gene for low-density lipoprotein receptor-related protein 5. Interestingly, gain-of-function mutations result in a gene product that increases bone density.

The life-cycle implications of either significant demineralization or osteoporosis in childhood need to be stressed. Events in childhood influence peak bone mass, and late adolescence is a period of rapid bone mineral accretion. Peak bone mass is achieved by 20-35 yr of age (depending on the bone measured), and the contribution during childhood is considerable. A number of measures influence bone mass: vitamin D (400-800 IU daily), calcium intake (≥1,200 mg/day in adolescents), and weightbearing exercise throughout childhood. Weightbearing exercise enhances bone formation and reduces bone resorption. Other factors that can prevent acquisition of peak bone mass include use of alcohol and tobacco. Excellent sources of dietary calcium include mainly dairy products but also bony fish, green vegetables, and calcium-supplemented drinks (e.g., orange juice). Yogurt and cheeses can be used in lactase-deficient children. Because it appears that adult-onset osteoporosis is the result of a number of genetic factors, thus forming a complex trait interaction, specific interventions during childhood to influence bone mass are not available.

The treatment of secondary osteoporosis is best achieved by treating the underlying disorder when feasible. Hypogonadism should be treated with hormone replacement therapy, especially in thin athletic women (see Chapter 691). Calcium intake should be increased to 1,500-2,000 mg/day. In glucocorticoid-induced osteoporosis, an emphasis on the lowest possible dose to prevent disease activity (inflammatory bowel disease) with alternate-day or topical therapy and the use of inhaled glucocorticoids in asthma is essential. Special diets for inborn errors of metabolism are also appropriate. Celiac disease may be overrepresented in adults with osteoporosis and should be screened for and treated appropriately (see Chapter 338.2). Treatment with bisphosphonates that inhibit bone resorption in certain secondary (glucocorticoid-induced) and adult-onset osteoporosis has been successful. Bisphosphonate therapy is also beneficial in osteogenesis imperfecta and cerebral palsy.

Rehabilitation Medicine

PART XXXIII

Chapter 708

Principles of Rehabilitation Medicine

Dennis J. Matthews

Pediatric rehabilitative medicine is dedicated to improving the lives and daily function of children with acute and chronic disabilities and to maximizing their potential. It is based on an understanding of the importance of early intervention among those children identified as needing or potentially needing additional support; the development of simpler, culturally relevant surveillance systems that function well in all nations and within all populations within nations; and expanding intervention programs in the scope of services offered and reach of programs.

EPIDEMIOLOGY

The Centers for Disease Control estimates that the prevalence of developmental disabilities in the United States increased by 17% between 1997-1999 and 2006-2008 (Table 708-1). Over the past 3 decades, mortality rates have plummeted among children in lower- and middle-income nations (see Chapter 1). A least a portion of those who formerly would not have survived early childhood have disabilities; it is estimated that more than 200 million children from lower- and middle-income nations have developmental delays or disabilities.

APPROACH

Rehabilitation requires knowledge of the enabling/disabling process and the interrelationships of pathology, impairment, functional ability, and social participation, superimposed on normal development. Rehabilitation management of children with impairments requires the integration and identification of their functional capabilities and selection of the best rehabilitation intervention strategies. A well-designed rehabilitation program can reverse many disabling conditions and can help patients cope with deficits that cannot be reversed by medical care. *The goal of rehabilitation is to maximize an individual's function and participation in society*.

Pediatric rehabilitation medicine uses an interdisciplinary approach to address the prevention, diagnosis, treatment, and management of congenital and childhood-onset impairments, including related or secondary medical, physical, functional, cognitive, psychosocial, and vocational limitations or conditions, with an understanding of the life course of the disability. It requires identifying and managing common pediatric rehabilitation medical conditions and complications, including nutrition, bowel management, bladder management, gastroesophageal reflux, skin protection, pulmonary hygiene and protection, sensory impairments, sleep disorders, spasticity, swallowing dysfunction, and behavioral problems.

Therapeutic treatment includes (1) early intervention, (2) age-appropriate functional training, (3) programs of therapy, (4) play, (5) therapeutic exercise, (6) electrical stimulation and other modalities, (7) communication strategies, (8) oral motor interventions, (9) educational and vocational planning, (10) transitional planning, (11) adjustment to disability support, and (12) prevention strategies.

SCOPE OF PRACTICE

Rehabilitation management of common pediatric problems includes musculoskeletal disorders and trauma, cerebral palsy, spinal dysraphism and other congenital anomalies, spinal cord injury, traumatic and other acquired brain injuries (see Chapter 710), limb deficiency/amputation, neuromuscular disorders, peripheral nerve injuries, and spasticity management.

A significant deleterious effect of childhood disability is inactivity. This is defined as a reduced functional capacity of musculoskeletal and other body systems. It should be considered a distinct diagnosis from the original condition that has led to a curtailment of normal physical function. The main adverse effects are muscle atrophy and weakness, joint contracture, and immobilization osteoporosis.

PREVENTION OF MUSCLE WEAKNESS

Muscle weakness can be reduced by prescribing progressive resistance, stretching, and aerobic exercises. A minimum of once-a-day muscle contraction at 30-50% of maximal strength for 3-5 min, 3 times per wk for a single muscle group, may suffice to prevent muscle loss and weakness. For chronic disuse atrophy with weakness and stiffness, strengthening and stretching exercises may be required for many months, and even then, the child is unlikely to gain normal strength and range of motion.

Stretching to maintain optimal muscle resting length as well as viscoelastic properties is important for maintaining muscle function. Muscles that cross 2 joints, such as the hamstring, gastrocnemius, biceps, and long back extensor muscles, are particularly prone to stiffness. Once a contracture has developed, the treatment is active and passive range-of-motion exercises combined with a sustained terminal stretch on a daily basis. The daily stretching can prevent the loss of sarcomeres in series of immobilized muscles and maintain elongation properties of muscle fibers and surrounding connective tissue, maintaining range of motion.

Stretching techniques include ballistic, static, or passive and neuromuscular facilitation. Prevention of injury and treatment of specific joint injury, as well as the presence and effects of pain or muscle spasms, require modification. The intensity should be a mild degree of tightness without discomfort. Static stretches are held 15-60 sec. Passive and neuromuscular facilitation is a 6 sec contraction followed by 10-30 sec of assisted stretch. Stretching is generally more successful when used in combination with the application of deep heat (i.e., ultrasound). Sustained stretching lasting 2 hr can be obtained by splinting (orthotics, serial casting). In patients with spasticity, chemical denervation (botulinum toxin, phenol blocks) may improve positioning inside the cast or orthotic to improve the tolerance for wearing.

Dynamic splinting provides tension in the desired direction with the use of springs or elastic bands. This type of splinting is often used in the hand and arm because it allows a measure of function while providing stretching. To achieve optimal joint position, it is sometimes necessary to surgically lengthen the contracted tendon.

Maintenance of skeletal mass depends largely on mechanical loading applied to the bone by muscle pull and the force of gravity. Bone mass only increases with repeated loading and increase in muscle strength. Disuse osteoporosis can be prevented by regular use of isotonic exercises, weight bearing, and functional training. Passive loading and standing are of little benefit.

A variety of therapeutic exercise techniques have been developed to address central nervous system dysfunction. Most commonly used are neurodevelopmental techniques using reflex inhibitory patterns to inhibit increased tone along with advanced postural reactions to stimulate recovery. Other therapeutic programs include proprioceptive neuromuscular facilitation. There is no convincing evidence that any

Table 708-1	Specific Developmental Disabilities in U.S. Children Ages 3-17 Yr
DISABILITY	**PERCENT CHANGE BETWEEN 1997-1999 AND 2006-2008**
Any developmental disability	17.1%*
Attention-deficit/ hyperactivity disorder	33.0%*
Autism	289.5%*
Blind/unable to see at all	18.2%
Cerebral palsy	—
Moderate to profound hearing loss	–30.9%
Learning disability	5.5%
Intellectual disability	–1.5%
Seizures, past 12 mo	9.1%
Stuttered or stammered, past 12 mo	3.1%
Other developmental delay	24.7%*

*Statistically significant trend over 4 time periods: 1997-1999, 2000-2002, 2003-2005, and 2006-2008.

of these methods actually alter the natural history of recovery. These approaches to therapy seem to be most useful in enabling the child to develop compensatory techniques. Using these methods, patients improve performance in and gain independence with such tasks as making transfers, stretching, bed mobility, and safe ambulation.

OTHER ASSIST DEVICES

Rehabilitation often includes prescribing age-appropriate assistive devices and technology to assist environmental accessibility, including orthotics, prosthetics, wheelchairs, positioning, activities of daily living aids, interfaces and environmental controls, and augmentative communication devices. The goal of all assistive devices is to overcome the limitations and improve function and community participation.

Rehabilitation management of children with developmental or acquired disabilities is best accomplished through a medical home and team approach seeking to maximize the child's level of motor, intellectual, emotional, and social functioning.

Chapter 709

Evaluation of the Child for Rehabilitative Services

Michael A. Alexander

CHILD CHARACTERISTICS

A rehabilitation evaluation starts with *determining physiologic impairments and strengths.* The strengths may turn out to be pivotal in how well the individual compensates for his or her actual impairments. Physiologic impairments are the biologic shortfalls, which limit the child. Many assessment tools are available and professional organizations have developed compendiums of such tools.

The assessment begins with **cognitive issues**. Where is the child in the developmental spectrum in language, social, and emotional abilities? How does the child function in the family, school, and community? Does the presence of an impairment act as an impediment to social acceptance? Poor impulse control, stuttering, or speaking loudly, perhaps because of hearing loss, will all distance a child from other children of the same age group.

Sensory issues need to be evaluated. Are vision, hearing, and other senses present and meeting the needs of the child? Impairment of the sense of touch and position sense may affect the child's extremity function, particularly in the area of fine motor activities. Deficiencies in these skills can also affect how others perceive the child.

For a child who has significant disabilities, the evaluation team needs to include educators, neuropsychologists, social workers, physical therapists, occupational therapists, speech therapists, augmentative communication and device technicians, and seating and adaptive equipment specialists, as well as the physician. The pediatric rehabilitation evaluation is a process that not only looks at the actual impairments but looks to see how they affect the functioning of the individual. Functional substitutions and adaptive equipment and strategies need to be applied by the team to minimize the overall impact of the child's impairments on the child's function, maturation, and separation from family and, ultimately, on the child's function as an adult.

Upper-extremity function is assessed to determine strength, range of motion, and agility. Obviously, weakness of both the arms and legs will result in a greater degree of dysfunction than weakness of only the arms or only the legs. Lower-extremity function affects movement in other environments as well.

For one child, a manual wheelchair may enhance mobility. But children with arm weakness may need electric wheelchairs, with their associated complications. Problems of accessibility, transport, and cost can become significant issues for the family. Fine motor and prehension (the highly complex motor and sensory tasks performed by the hand) tasks are closely assessed because some of these children may need to rely on their ability to interface with access joysticks and computers and strength in these areas may compensate for physical weaknesses.

Skeletal deformities, range-of-motion limitations, and contractures may affect gross motor function, balance, sitting, walking, and climbing. Scoliosis, kyphosis, and pelvic obliquity may limit sitting balance and tolerance, which can secondarily affect upper-extremity function and the amount of time a child is able to socialize.

FAMILY CHARACTERISTICS

The education, vocation, and mental well-being of the parents or caregivers have a dramatic impact on the child. We know that if a child with impairment is to reach maximum potential, a stable and loving family structure facilitates the child's outcome. Does the family have other stressors, such as illness, death, divorce, and legal problems? What are their health care resources?

THE PHYSICAL ENVIRONMENT

Environment assessment begins with the child's room and home. Access to and inside the home should be discussed. How is this child transported? If the child uses power mobility, does the chair travel with the child or does it need to reside at the school or home or elsewhere? How is the child mobile in environments in which the power chair is not available? Is the transport of the child the problem? What is the adequacy, cost, and reliability of the van that is being used by the family? How the child gets in and out of the wheelchair is a significant part of the evaluation. Does the child assist with this, or is the child totally and passively dependent on an adult to move the child from, for example, a toilet seat back to the wheelchair?

In the school, does the child have access to all of the building and can the child participate in all activities in the building, such as those in the art and music rooms, cafeteria, science lab, and stage? Does the

child participate in clubs, teams, and other activities outside of the home?

THE PREVIOUSLY HEALTHY CHILD

For children who have established themselves in the general community and functioned in their environment in a normal capacity but then acquire a significant impairment, it becomes incredibly important to understand what their world looked like before they were affected by this new set of problems. If the child is old enough to remember what life had been like, the loss of function can be devastating. Coping with “what could have been” coupled with what was lost will require the help of skilled psychosocial clinicians.

Chapter 710
Severe Traumatic Brain Injury
Linda E. Krach

Medical rehabilitation is an integral part of the process of assisting families and their children in transitioning from acute medical care after a severe traumatic brain injury (TBI) to reintegration into the community. Table 710-1 lists the quality of care indicators for inpatient pediatric TBI rehabilitation based on a review of evidence and the application of the RAND/UCLA modified Delphi Method.

ETIOLOGY
The cause of TBI varies by age. For young children, ages 0-4 yr, falls and nonaccidental trauma are the most common causes. The major cause of TBI among adolescents >14 yr is motor vehicle traffic. TBI is more common in males than females at all ages.

PATHOPHYSIOLOGY
Brain injury from trauma results from a combination of primary and secondary injury. The mechanism of injury can be different in children because of factors that differentiate them from adults; very young children have open sutures, so they can accommodate some increase in intracranial pressure by an increase in their head circumference or widening of the sutures. Compared with adults, children also have a larger head size compared to their neck musculature, higher brain water content, and less myelination, all of which are thought to contribute to greater brain distortion with resultant injury.

Table 710-1 Quality of Care Indicators for Pediatric Rehabilitation Care After Traumatic Brain Injury

- Dedicated pediatric specialty unit that has at least 1 inpatient with a TBI 90% of the time
- Physical accommodations for family to remain on-site 24 hr/day
- Age-appropriate therapeutic and adaptive equipment
- On-site classroom
- Medical director experienced in pediatric rehabilitation medicine
- Therapists with pediatric training/certification
- Pediatric clinical psychologist, at least 1 certified rehabilitation registered nurse
- 24 hr access to:
  - pharmacy
  - respiratory therapy
  - neurosurgery
  - neurology
  - radiology

ACUTE REHABILITATION
The acute rehabilitation course for children with severe TBI includes addressing multiple medical issues related to the injury in addition to the provision of rehabilitation services. One of these issues is the possibility of seizure activity. Although it is common practice to initiate prophylactic anticonvulsant therapy early after injury, it is appropriate to consider discontinuing this treatment if late seizures have not occurred. Among children, early seizures do not correlate with the later development of epilepsy. The severity of injury, the presence of severe edema, and a very young age at injury increase the likelihood of the later development of **posttraumatic seizures**.

Sleep disturbance is common after TBI and can have an effect on the individual's ability to function (Fig. 710-1). Various approaches, including sleep hygiene, sleep aids, strategic stimulants, cognitive behavioral therapy, strategic caffeine, and naps, can be tried for both the initiation and maintenance of sleep. Other chronotherapy techniques (coordinating the biologic rhythms of a child's body with his/her medical therapy) may be necessary to address sleep–wake cycle abnormalities.

Children with severe TBI may also experience **autonomic dysfunction** characterized by elevated temperature, heart rate, respiratory rate, and blood pressure, accompanied by diaphoresis and posturing. Autonomic dysfunction is a diagnosis of exclusion and is associated with poor outcome after acquired brain injury in children. Autonomic dysfunction develops in approximately 13% of children with acquired brain injury, 10% of those with TBI, and 31% of those with injury as a result of cardiac arrest. Autonomic dysfunction is associated with longer hospital lengths of stay and poorer outcomes.

Acute inpatient rehabilitation emphasizes functional goals and community reintegration. The child and family are integral members of the rehabilitation team. Community reintegration involves careful consultation and planning with the school system to facilitate the transition from hospital to school. In the United States, federal law requires that a physician document that a child had a TBI to qualify for special education services under this disability category. Rehabilitation team consultation with the school team is essential for optimal and expeditious transition back to the school setting. Participation in school is essential for peer interaction and a step toward normalization of the child's life. Schools can adapt to the child's needs rather than providing services in an isolating homebound manner.

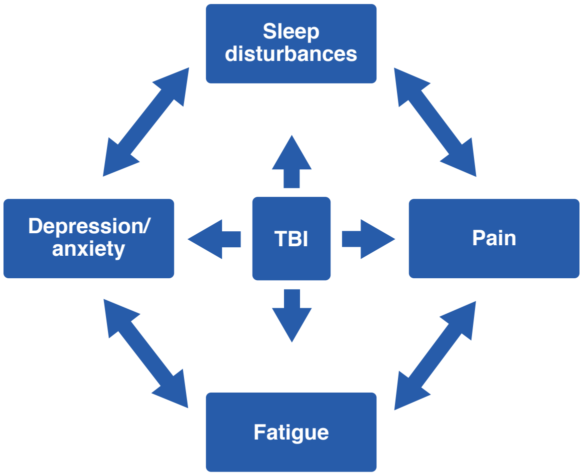

Figure 710-1 Relationship of sleep-related issues among patients recovering from traumatic brain injury. *(From Viola-Saltzman M, Watson NFL: Traumatic brain injury and sleep disorders.* Neurol Clin *30(4):1299–1312, 2012, Flowchart 2.)*

OUTCOMES ASSOCIATED WITH SEVERE TRAUMATIC BRAIN INJURY

The most disabling consequences of TBI are cognitive, particularly those associated with executive function.

In severe TBI, cognition is often the most affected area of functioning and outcomes are associated with preinjury adaptive functioning and family function. Attentional skills may remain impaired in children 10 yr after sustaining a TBI. Subsets of attention appear to be more impaired after TBI, particularly divided and sustained attention.

Other areas of long-term impairment of cognitive performance after pediatric TBI include overall intellectual performance, learning, metamemory, working memory, social competence, and a variety of behavioral concerns. Impairments have been noted in ability to perform self-care activities, communicate, and participate in community and social activities.

PEDIATRIC TRAUMATIC BRAIN INJURY AND PLASTICITY

In the past there has been an assumption that sustaining a TBI at a young age compared to more advanced age would allow for better outcomes because of plasticity. In fact, plasticity may actually be related to poorer outcomes in those injured at a very young age. The major task of childhood is development and learning; a significant TBI can impact the child's ability to learn. Likewise, children do not have overlearned material to fall back on as do adults. There is some evidence that the anticipated changes associated with brain maturation, including cortical thinning of specific regions, do not occur in children who have had TBI at a young age. There are potentially critical periods in development during which a child is more at risk for the effects of a brain injury. Because children are expected to develop cognitive skills over time, the full extent of the impairment from injury might not be recognized until a significant amount of time has elapsed following the injury. For example, if executive function were impaired, one wouldn't expect to see the manifestations of that until adolescence.

Chapter 711

Spinal Cord Injury and Autonomic Crisis Management

David W. Pruitt and Mary A. McMahon

EVALUATION

The most accurate way to assess a patient who has sustained a **spinal cord injury (SCI)** is by performing a standardized physical examination as endorsed by the International Standards for Neurological and Functional Classification of Spinal Cord Injury (Fig. 711-1). These standards provide the basic definitions of the terms utilized by clinicians caring for patients with SCI. Caution is recommended in utilizing and trusting the anorectal examination portion of this examination in children and youth because of poor interrater reliability.

CLINICAL MANIFESTATIONS

Children with neurologic levels of injury at T6 or above are particularly at risk for interruption and decentralization of the autonomic nervous system. The most common manifestations include bradycardia, hypotension, temperature dysregulation, and, once spinal shock has resolved, **autonomic dysreflexia (AD).** Children and adolescents with cervical and upper level SCI have lower baseline blood pressure compared with the general population. Blood pressure elevations of 20-40 mm Hg above baseline may be considered a sign of AD. AD is a sustained sympathetic response in relation to a noxious stimulus *below* the level of injury. Symptoms resulting from AD typically include hypertension, bradycardia, headache, and flushing of skin above the level of injury. Noxious stimuli are most often localized to bladder or rectal distention, but may include a number of other causes (Table 711-1). Identification and treatment of the noxious stimulus is

Table 711-1 Potential Etiologies of Noxious Stimuli Causing Autonomic Dysreflexia

Urinary System • Bladder distention • Bladder or kidney stones • Blocked/kinked catheter • Detrusor sphincter dyssynergia • Urinary tract infection • Urologic instrumentation • Shock wave lithotripsy	Gastrointestinal System • Bowel distention • Bowel impaction • Gallstones • Appendicitis • Gastric ulcers • Gastritis • Gastrointestinal instrumentation • Hemorrhoids	Integumentary System • Constrictive clothing, shoes, or orthotics • Blisters • Burns, sunburn, or frostbite • Ingrown toenail • Insect bites • Pressure ulcers
Musculoskeletal System • Fractures • Heterotopic ossification • Functional electrical stimulation	Reproductive System–Male • Epididymitis • Scrotal compression (sitting on scrotum) • Sexual intercourse • Sexually transmitted infections	Reproductive System–Female • Menstruation • Pregnancy, especially labor and delivery • Vaginitis • Sexual intercourse • Sexually transmitted infections
Hematologic System • Deep vein thrombosis • Pulmonary embolus	Other Systemic Causes • Boosting (an episode of autonomic dysreflexia intentionally caused by an athlete with spinal cord injury in an attempt to enhance physical performance). • Excessive alcohol intake • Excessive caffeine or diuretic intake • Over-the-counter or prescribed stimulants • Substance abuse	

From Consortium for Spinal Cord Medicine: Acute management of autonomic dysreflexia: individuals with spinal cord injury presenting to health-care facilities, Washington, DC, 2001, Paralyzed Veterans of America, pp 10-11.

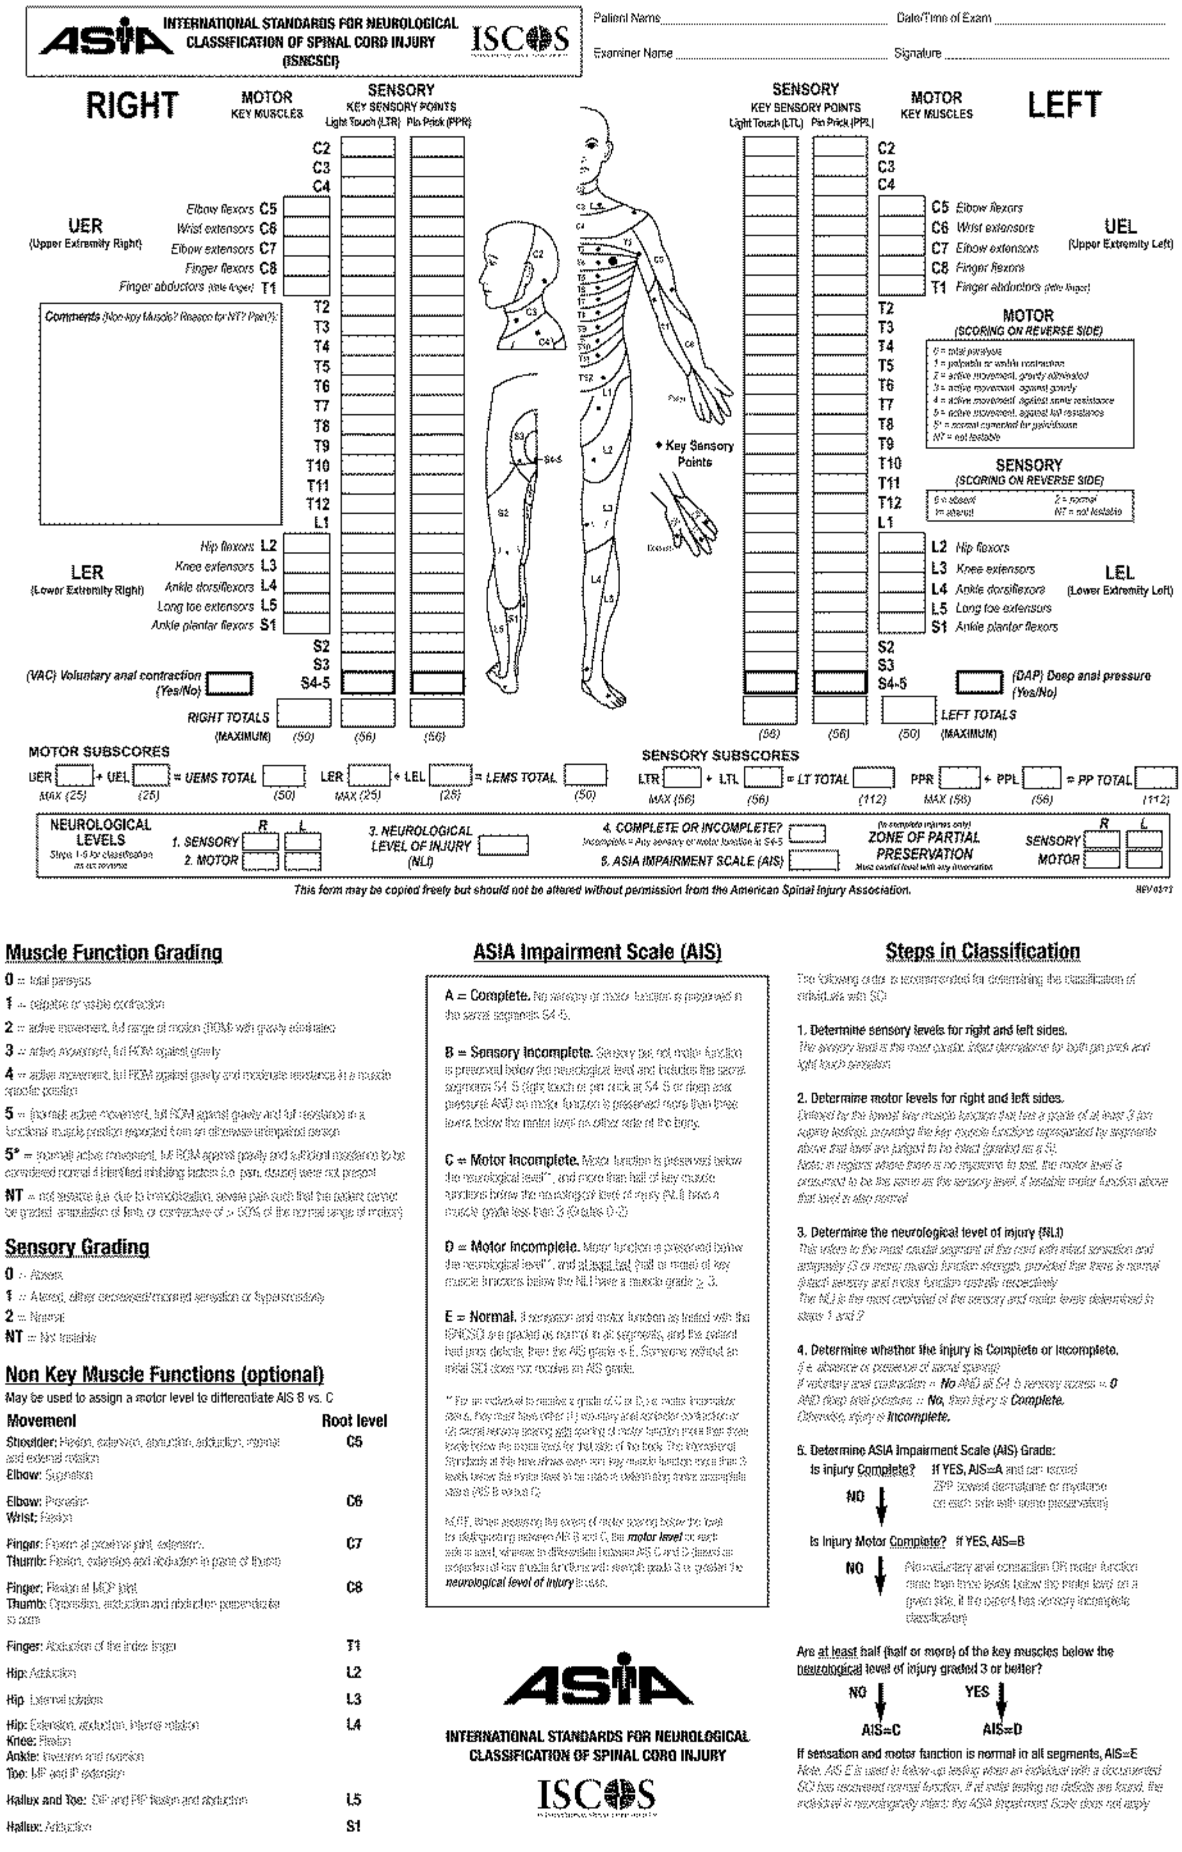

Figure 711-1 American Spinal Injury Association flow sheet. *(From American Spinal Injury Association/International Medical Society of Paraplegia. International standards for neurological and functional classification of spinal cord injury patients. Chicago, 2013, http://www.asia-spinalinjury.org/elearning/ISNCSCI.php.)*

typically associated with resolution of symptoms without the use of antihypertensive medication. If necessary, antihypertensive agents with a rapid onset and short duration, including nifedipine and nitropaste, are advocated (Fig. 711-2). Emergent management of AD is necessary owing to the risk of cerebrovascular accident and additional organ damage as a result of sustained hypertension.

Deep venous thrombosis and **pulmonary embolism** are common, potentially life-threatening conditions in patients with SCI. In children and youth, deep venous thromboses are more common in postpubertal children. Prophylactic treatment, including low-molecular-weight heparin and calf compression pumps, during acute rehabilitation is recommended. Late-occurring deep venous thrombosis most commonly occurs with increased immobilization related to illness or surgery and prophylactic measures should be considered during these situations as well.

Following SCI, the **bladder** can be **areflexic** or **hyperreflexic** and detrusor sphincter dyssynergia is possible. Clean intermittent catheterization is typically used 4-6 times/day to keep bladder volumes below capacity. Anticholinergic medications can improve bladder storage. Asymptomatic bacteriuria, without vesicoureteral reflux, is generally not treated.

Bowel continence requires optimal consistency through the use of diet and medications and planned evacuation, employing aids including gastrocolic reflex, digital stimulation, suppositories, and enemas. Individuals with SCI have increased risk for dysphagia, delayed gastric emptying, ileus, gastric ulceration, pancreatitis, and superior mesenteric artery syndrome.

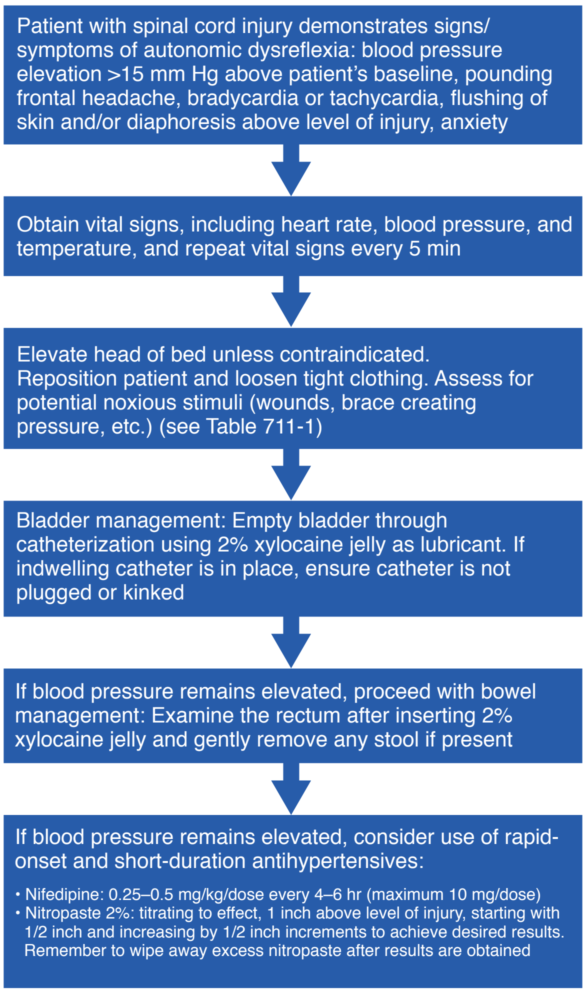

Figure 711-2 Algorithm for management of autonomic dysreflexia.

Frequent monitoring for **skin breakdown** and **pressure ulcers** is necessary both acutely as well as lifelong in individuals with SCI. Common locations include the occiput, elbows, sacrum, ischium, and heels. Devices such as halo vests and splints increase risk. Frequent inspection and repositioning are important means of minimizing risk.

Depending upon the level of the lesion, paralysis of the diaphragm or intercostal and abdominal muscles can result in restrictive ventilatory impairment and ineffective cough. Respiratory muscle training, abdominal binders, and noninvasive ventilation and airway clearance devices, such as the insufflator–exsufflator cough assist device, should be considered in select patients.

Immediately following SCI there is a period of **spinal shock** with low tone and absent reflexes. Eventually, signs of an upper motor neuron lesion will increase, including spasticity and involuntary muscle spasms. Symptoms typically increase with noxious stimulation and can interfere with sleep, comfort, positioning, and care. Management includes pharmacologic therapy, stretching, splinting, and positioning. Focal spasticity can be treated with chemodenervation using botulinum toxin or phenol. Intrathecal baclofen should be considered for severe generalized spasticity.

Increased bone resorption occurs as a result of immobilization. If excessive calcium is not adequately excreted by the kidneys, insidious onset of abdominal pain, nausea, vomiting, lethargy, polydipsia, and polyuria may occur. This **immobilization hypercalcemia** is managed with intravenous fluid hydration at 1.5-2 times the maintenance rate, as well as use of furosemide to hasten the renal excretion of calcium. Complications include nephrocalcinosis, urolithiasis, and renal failure.

Osteopenia begins immediately after an SCI occurs and plateaus 6-12 mo later. **Pathologic fractures** occur as a consequence of loss of bone mineral density. The most common sites of fracture include the supracondylar region of the femur and the proximal tibia; fracture is often associated with gait training, minor trauma, and range of motion. Treatment should include use of removable splints or casts that are well padded over bony prominences to prevent skin breakdown. Prevention through weight bearing and calcium and vitamin D supplementation is encouraged.

Development of spine deformity and scoliosis is prevalent in patients sustaining SCI prior to puberty and many of these individuals will require surgical correction. Because of the high incidence of scoliosis, radiographs of the thoracolumbar-sacral spine should be obtained every 6 mo prior to skeletal maturity and every 12 mo thereafter.

An SCI will impact the child's social-emotional development, so adjustment should be monitored closely. Positive coping strategies and strong social supports are associated with greater social participation. Education regarding sexual development and function with SCI injury should be provided.

PROGNOSIS

Prognosis for recovery of neurologic deficits resulting from SCI depends on the neurologic level of injury and level of completeness. Examination at least 72 hr after injury has been determined a better indicator of the prognosis than examinations done earlier. It is prudent for those determining and communicating the diagnosis to understand the particularities and limitations of the anorectal examinations, and thus completeness of injury, unique to children. Those individuals with incomplete injury tend to have increased likelihood of neurologic recovery. The neurologic level of injury can be assistive in determining the level of independence with functional activities (Table 711-2).

Chapter 712

Spasticity

Joyce L. Oleszek and Loren T. Davidson

Spasticity is a component of the upper motor neuron syndrome characterized by velocity-dependent resistance to passive range of motion resulting in tonic stretch reflexes and accompanied by exaggerated tendon jerks. Spasticity management is determining what degree of spasticity may be tolerable and of functional benefit vs counterproductive and potentially injurious. When devising a treatment plan, both the positive and negative effects of spasticity on function must be considered; treatment should maximize function while minimizing sedation and adverse effects.

ORAL MEDICATIONS

Oral medications are often used as an early treatment for generalized spasticity (Table 712-1). Although efficacy of certain antispasmodics has been demonstrated, their use should be contingent upon functional benefit as adverse effects are quite common. Frequently used medications include baclofen, benzodiazepines (diazepam, clonazepam), dantrolene sodium, tizanidine, and clonidine.

GABAergic Medications

γ-Aminobutyric acid (GABA) is an inhibitory neurotransmitter of the central nervous system. The 2 most relevant GABA receptors for the purposes of pharmacologic management of spasticity are $GABA_A$ and $GABA_B$. **Benzodiazepine medications** exert their effect through

Table 712-1 Dosing Guidelines, Pharmacologic Actions, and Adverse Event Profile of Commonly Prescribed Oral Antispasmodic Medications for Children

ORAL MEDICATION (DOSE/FREQ., AGE/ WEIGHT RANGE)	MODE OF ACTION	ADVERSE EVENTS/PRECAUTIONS
Baclofen (0.125-1 mg/kg/day) *Dosing guideline* *2-7 yr* 2.5-10 mg tid-qid (10-40 mg/day) *8-12 yr* 5-15 mg tid-qid (15-60 mg/day) *12-16 yr* 5-20 mg tid-qid (20-80 mg/day) *Note:* Caution advised with renal impairment, consider reducing dose.	Centrally acting, structural analog of γ-aminobutyric acid (GABA), binds to $GABA_B$ receptors of presynaptic excitatory interneurons (and postsynaptic primary afferents) causing presynaptic inhibition of monosynaptic/polysynaptic spinal reflexes. Rapid absorption, blood level peaks in 1 hr, half-life 5.5 hr. Renal (70-80% unchanged) and hepatic (15%) excretion.	Central nervous system (CNS) depression (sedation, drowsiness, fatigue), nausea, headache, dizziness, confusion, euphoria, hallucinations, hypotonia, ataxia, paresthesias. **Note: Abrupt withdrawal** may cause seizures, hallucinations, rebound muscle spasms, and hyperpyrexia.
Diazepam (0.12-0.8 mg/kg/day) *Dosing guideline* 6 mo-12 yr 0.12-0.8 mg/kg/day PO divided q6-8h >12 yr 2-10 mg PO bid-qid *Note:* Prescription of a *qhs* dose only or proportionately larger dose at bedtime may limit excessive daytime sedation.	Centrally acting; binds to $GABA_A$ receptors mediating presynaptic inhibition in brainstem reticular formation and spinal polysynaptic pathways. Rapid absorption; blood level peaks in 1 hr, with half-life of 30-60 hr. Metabolized in liver, producing pharmacologically active metabolites with long duration of action. Increased potential for adverse effects with low albumin levels as a result of being 98% protein bound.	CNS depression (sedation, impaired memory and attention), ataxia. Dependence/potential for substance abuse/overdose. Withdrawal syndrome (including anxiety, agitation, irritability, tremor, muscle twitching, nausea, insomnia, seizures, hyperpyrexia).
Dantrolene Sodium (3-12 mg/kg/day) *Dosing guideline (for children >5 yr old):* *6-8 mg/kg/day PO divided bid-qid* In children >5 yr old Start 0.5 mg/kg qd-bid for 7 days, then 0.5 mg/kg tid for 7 days, then 1 mg/kg tid for 7 days, then 2 mg/kg tid to a maximum of 12 mg/kg/day or 400 mg/day.	Peripheral action, blocking release of calcium from sarcoplasmic reticulum with uncoupling of nerve excitation and skeletal muscle contraction. Blood level peaks in 3-6 hr (active metabolite 4-8 hr), with half-life of approximately 15 hr. Metabolized largely in liver, with 15-25% of nonmetabolized drug excreted in urine.	Malaise, fatigue, nausea, vomiting, diarrhea, muscle weakness with high dose. *Note:* Hepatotoxicity (baseline liver function tests **must** be checked prior to starting dantrolene, tested weekly during dose titration, and regularly every 1-2 mo thereafter). Drug *should be discontinued* promptly if liver enzymes become elevated.
Tizanidine *Dosing guideline* In children <10 yr: Commence 1 mg orally at bedtime initially, increasing to 0.3-0.5 mg/kg in 4 divided doses. In children >10 yr: Commence 2 mg orally at bedtime initially, increased according to response, maximum 24 mg/day in 3-4 divided doses.	Centrally acting, α_2-adrenoceptor agonist activity at both spinal and supraspinal sites. Prevents release of excitatory amino acids, facilitating presynaptic inhibition. Good oral absorption, blood level peaks in 1-2 hr, with a half-life of 2.5 hr. Extensive first-pass hepatic metabolism with urinary excretion of inactive metabolites.	Dry mouth, drowsiness, tiredness, headache, dizziness, insomnia, anxiety, aggression, mood swings, visual hallucinations, risk of hypotension (although 10 times less antihypertensive potency than clonidine), nausea, vomiting, and constipation. Liver function tests should be monitored at baseline, 1, 3, and 6 mo. Then periodically.
Clonidine *Dosing guideline* 0.025-0.1 mg in 2-3 divided doses. *Note:* A retrospective chart review of literature about clonidine in children reported an average dosage based on weight was 0.02-0.03 mg/kg/day (0.4-0.5 mg/day), with a range of 0.0014-0.15 mg/kg/day.	Centrally acting, mixed α-adrenoceptor agonist with predominant α_2 activity causing membrane hyperpolarization at multiple sites in brain, brainstem, and dorsal horns of spinal cord. Inhibition of substance P may also contribute to tone reduction via an antinociceptive effect. Rapidly absorbed orally, blood level peaks in 1-1.5 hr, with a half-life of 6-20 hr.	Drowsiness, dry mouth, bradycardia, orthostatic hypotension. Abrupt cessation may result in rebound hypertension.

$GABA_A$ receptors by increasing the affinity of GABA for the $GABA_A$ receptor. This results in presynaptic inhibition and a net inhibitory effect at both spinal and supraspinal levels. Of the benzodiazepines, **diazepam** is the oldest and most commonly used medication to treat spasticity because of its long half-life and need for less-frequent administration. In children <2 yr of age, **clonazepam** is a good option because of the availability of a liquid formulation and dosing guidelines. The cognitive effects of benzodiazepines limit its use in persons with severe spasticity as dose escalation results in increased sedation. Furthermore, sedation and cognitive slowing limit the usefulness of benzodiazepines in persons with spasticity of cerebral origin as it may impede recovery in acquired brain injury and cognitive development in congenital developmental delay. The use of benzodiazepines may lead to physiologic dependence, and, thus, abrupt discontinuation should be avoided to prevent withdrawal.

Baclofen is a $GABA_B$ agonist and is a preferred agent in the treatment of spasticity of spinal origin. Baclofen exerts an inhibitory effect on both monosynaptic and polysynaptic spinal reflexes. Unfortunately, supraspinal receptor sites also exist, resulting in sedation, which is common to all GABAergic medications. In most instances, daytime dosing of oral baclofen is better tolerated than benzodiazepines with regard to sedation. Intrathecal administration of baclofen via a baclofen pump (see below) allows greater selectivity of spasticity reduction while minimizing adverse cognitive effects. Abrupt cessation of both oral and intrathecal baclofen therapy *must be avoided* as it may result in a life-threatening withdrawal response.

α_2-Adrenergic Agents

Clonidine and **tizanidine** are examples of centrally acting α_2-adrenergic agents that decrease spasticity and have an antinociceptive effect. Clonidine is the older of the 2 agents and is used more frequently as an antihypertensive agent. Clonidine exerts its effect on spasticity via both presynaptic inhibition of sensory afferents, as well as release of glutamate at the level of the spinal cord. Adverse effects of clonidine that limit its use as an antispasmodic include hypotension, bradycardia, sedation, cognitive impairment, and xerostomia.

Tizanidine is an α_2-noradrenergic agonist that is as effective as diazepam and baclofen in tone reduction. In comparison to clonidine, tizanidine has less-potent hemodynamic effects, which is desirable when it is used primarily for spasticity reduction. The half-life of tizanidine is approximately 2.5 hr, requiring frequent dosing to maintain a steady state. Adverse effects of tizanidine include hypotension, sedation, xerostomia, dizziness, hallucination, and hepatotoxicity.

Peripherally Acting Calcium Blockers

Dantrolene sodium works at the level of skeletal muscle to block calcium release from the sarcoplasmic reticulum. Despite its peripheral site of action, dantrolene may induce sedation, although to a lesser degree than other centrally acting agents. Dantrolene is effective at decreasing both clonus and spasticity but achieves this by weakening skeletal muscle in a nonselective fashion. The resultant generalized weakness seen with dantrolene use limits its utility in ambulatory patients. Dantrolene has a rare but significant adverse event of fatal hepatotoxicity in less than 1% of patients. Hepatotoxicity risk increases with increasing age, increasing dose, and female sex.

Pediatric dosing of spasticity medications is quite variable and needs to be tailored to the response of the child. The choice of medication is often based on personal experience and the impact of benefit vs potential adverse effects. See Table 712-1 for dosing guidelines.

SURGICAL MANAGEMENT

Surgical management of spasticity should be considered when spasticity causes significant functional impairments that are refractory to more conservative management. Combining treatment options such as injections and systemic medications can be very effective.

Botulinum toxin (BTX) intramuscular injections and **phenol/alcohol neurolysis** are used to treat focal areas of spasticity. These injections are most effective in children with hypertonia localized to specific muscles and those without significant contracture. BTX blocks signal transmission at the neuromuscular junction by preventing the release of acetylcholine from the presynaptic axon of the motor end plate. Treatment with BTX type A is most common but BTX type B is also used. The period of clinically useful relaxation is usually 12-16 wk and it is recommended that injections be spaced a minimum of 3 mo apart because of concern for neutralizing antibody formation. Adverse events related to BTX are rare and include injection-site pain and focal muscle weakness. The FDA requires black box labeling on BTX products cautioning that the effects of the BTX may spread from the area of injection to other areas of the body, causing symptoms similar to botulism. Coadministration of BTX and aminoglycosides or other agents interfering with neuromuscular transmission (curare-like nondepolarizing blockers, lincosamides, polymyxins, quinidine, magnesium sulfate, anticholinesterases, succinylcholine chloride) should be performed with caution as the effect of the toxin may be potentiated. BTX-A is an effective and generally safe treatment for spasticity of the upper and lower extremities; evidence regarding functional improvement is conflicting. Long-term use of BTX-A with repeated rounds of injections in children with cerebral palsy is safe and efficacious. BTX-A injections into the gastrocnemius can be combined with serial casting to help improve ankle range and gait.

Phenol perineural injections are typically performed in the large proximal muscles (biceps brachii, hip adductors, hamstrings) and duration of clinical effect may be longer than BTX, varying between 3 and 18 mo. Phenol injection of the anterior branch of the obturator nerve in children with cerebral palsy is safe and effective. The low cost of phenol is a significant advantage over BTX, but the need for electrical stimulation guidance and general anesthesia may offset any cost savings. Combining phenol injections with BTXs allows an increased number of affected muscles to be injected at the maximal recommended dose during one procedure. Phenol is safe in children, but transient sensory dysesthesias occur rarely.

Intrathecal baclofen (ITB) is highly effective in treating severe spasticity. ITB is delivered to the intrathecal space via a surgically implanted infusion pump and catheter. This method of delivery confers an advantage over enteral baclofen in that central nervous system depressive effects are minimized and dosages can be titrated to functional effect. A preoperative screening bolus dose of baclofen can be delivered via lumbar puncture and is used to evaluate responsiveness and impact on functional abilities. Goals of treatment, whether they are to improve function, comfort, and/or care, need to be firmly established. Cost and maintenance can be prohibitive for some families. Catheter tips are typically positioned at C5-T2 but can be placed intraventricularly for severe dystonia. ITB is effective in children with cerebral palsy; there may be a significant reduction in upper- and lower-extremity spasticity for up to 10 yr. Speech, communication, and saliva control can improve after ITB. The most frequent and serious adverse events related to device and implant procedures are catheter dislodgement from the intrathecal space, catheter break/cut, and implant site infection, including meningitis. Electromagnetic interference and MRI may cause transient operational changes to the pump and changes in flow rate. Although baclofen pumps do not prohibit MRI imaging, it is recommended that the pump be "interrogated" by a programmer after MRI as a precaution. ITB pumps need to be replaced every 5-7 yr for end of battery life. The pump comes in a 20 mL and 40 mL size, both of which measure 8.75 cm in diameter. The baclofen pump requires regular refills at 2-6 mo intervals depending on dose rate and pump size, and refills are readily performed in an outpatient clinic setting. **ITB withdrawal** is a medical emergency and needs to be identified early and managed aggressively. Sequelae can include high fever, altered mental status, exaggerated rebound spasticity, and muscle rigidity that, in rare cases, can advance to rhabdomyolysis, multiple organ–system failure, and death. Prevention of abrupt discontinuation of ITB requires careful attention to programming and monitoring of the infusion system, refill scheduling, and pump alarms. Caregivers need to be educated about the early symptoms of baclofen withdrawal.

Selective dorsal rhizotomy (SDR) is a surgical procedure that has been widely used as a treatment for spasticity. The surgical technique

involves single-level or multilevel osteoplastic laminectomies exposing the L2-S1 nerve roots. Typically, 25-70% of dorsal rootlets are selectively cut with the aid of electrophysiologic monitoring. Children 3-8 yr of age with spastic diplegia, minimal upper-limb involvement, good selective motor skills and strength, and minimal contractures are the best candidates for SDR. The preoperative ability to rise from a squatted position with minimal support or a younger child's ability to crawl on hands and knees are positive predictors for a good outcome with SDR. Children must have the cognitive and social capacity for the requisite intensive postoperative therapy program. Long-term outcomes 5 and 20 yr after SDR in children show an improvement in spasticity, motor function, and gait pattern. SDR can reduce the need for orthopedic surgeries, with 35% of children avoiding surgery; this might be more likely if SDR is performed before the age of 5 yr. Long-term complications such as sensory dysfunction, bladder or bowel dysfunction, or back pain are infrequent. A concern with multilevel laminectomies is the potential increased risk of spinal deformities, but there is no clear evidence to support this.

Chapter 713

Birth Brachial Plexus Palsy

Maureen R. Nelson

Birth brachial plexus palsy (BBPP) may cause significant arm weakness and subsequent functional deficits in children. The nerves to the arm are affected with variable degrees of weakness and sensory loss. Most children will have good recovery spontaneously, but functional deficits will remain in 20-30% of children with BBPP (see Chapter 99.7).

The mechanism for birth brachial plexus injury appears to be a lateral stretch of the plexus for the vast majority of cases. Anatomic variations in bones, blood vessels, and tendons lead to a very small number of cases. The incidence of BBPP is reported as 0.5-4.6 per 1,000 live births, with variability thought to be attributable to the type of obstetric care and the size of infants around the world.

Risk factors for birth brachial plexus injury include prior infants with BBPP, shoulder dystocia, birthweight greater than 4 kg, multiparous mothers, mothers with excessive weight gain, and diabetic mothers. Delivering twins or triplets, as well as cesarean sections, have been described as protective from BBPP.

Nerve injuries include neurapraxia, neurotmesis, and axonotmesis. *Neurapraxia* is the least severe of these types and is a reversible loss of nerve conduction. This type will recover. *Neurotmesis* is the most severe and is a total and complete disruption of the nerve; an *avulsion* describes a rupture of a preganglionic lesion, and a *rupture* describes the same event in a postganglionic lesion. *Axonotmesis* is the intermediate form and the most difficult to delineate. There is disruption of the epineurium with variable injury to the axons (Fig. 713-1). Nerves are made of groups of fascicles, which, in turn, are made of groups of axons. This type of lesion contributes greatly to the diagnostic dilemma and difficulty in prediction of recovery.

The brachial plexus consists of the anterior primary rami, or roots, from C5, C6, C7, C8, and T1 (Fig. 713-2). The trunks of the brachial plexus consist of C5-C6 forming the upper trunk, C7 forming the middle trunk, and C8-T1 forming the lower trunk; each trunk has anterior and posterior divisions. The posterior cord is formed from the posterior division of each trunk. The medial cord comes from the anterior division of the lower trunk. The lateral cord is formed from the anterior divisions of the upper and middle trunks. Evaluation of the roots, trunks, and cords from which the nerves arise helps determine the site of injury.

Erb palsy is generally described as the upper trunk or C 5-6 palsy. It is by far the most common injury seen in birth brachial plexus injury, present in three fourths of infants. It also demonstrates the greatest recovery rate at >80% with a functional arm. *Klumpke palsy,* C8-T1, is extremely rare in BBPP, likely not occurring except in the case of anatomic variation. If a baby presents with a C8-T1 deficit, the baby most likely originally had a complete C5-T1 BBPP and then had recovery of the upper portion of the plexus. This can happen because C4, C5, C6, and sometimes C7 are protected coming out from the spinal cord, held in a gutter along the transverse processes by connective tissue, whereas C8 and T1 are not. The sensory fibers are also relatively protected compared to the motor fibers because the sensory fibers run together until outside of the spinal cord into the dorsal root ganglion where their cell bodies lie. The motor fibers have the cell bodies within the spinal cord and so are not as cohesive in their path. Therefore the sensory fibers may be spared while motor fibers show clinical deficits. A C8-T1 deficit may also result from a spinal cord injury. Consequently, it is important to check for any other indications of spinal cord injury throughout the body. Consideration also must be given to the potential of an anatomic variation, such as an anomalous rib, that may actually cause a C8-T1 deficit alone.

Because various parts of the brachial plexus have different risks of injury, the clinical presentation can be quite variable, causing the diagnosis to be challenging. The phrenic nerve may also be involved with its innervation from C3, C4, and C5, with potential respiratory concerns.

Included in the differential diagnosis of an infant with an arm deficit is the possibility of a fracture of the humerus or clavicle, osteomyelitis, a tumor, or congenital varicella infection, all of which may lead to the limited ability to move the arm.

PHYSICAL EXAMINATION

The physical examination of the child begins with observation. Examination for sensation, particularly examining for sharp sensation, useful in its own right, will also frequently help with active motor evaluation in infants. Assessment of muscle stretch reflexes is important in that infants with a brachial plexus palsy will be areflexive or hyporeflexive in the involved arm. Evaluation of primitive reflexes, particularly the Moro reflex, is helpful as most of these infants will have C5-6 involvement and therefore the Moro may show shoulder abduction and elbow flexion on 1 side but not the involved side. Range-of-motion examination is critical. Deficits are commonly seen because of the imbalance of muscles that are active and those that are not. Shoulder adduction and internal rotation is a common position, as is elbow flexion, forearm pronation, and wrist and finger flexion. The size of the involved arm may also be smaller because of muscle atrophy and sometimes shorter length and smaller diameter of the bone. In children with very severe deficits, the arm may be cooler because of the sympathetic nervous system outflow at T1. **Torticollis** is commonly present and almost always with the face turned away from the involved arm.

Among older infants and children, compensatory movements of the arm may be noted. Common examples are use of trunk momentum to move (particularly to rotate) the proximal arm, hyperlordosis of the lumbar spine to position the arm more advantageously, use of the pectoralis muscle to flex the shoulder, and use of the knee to physically flex the elbow. Examination of the back for symmetry, along with the scapulae for winging, is also relevant. Having the older child manipulate buttons, snaps, or zippers, throw and catch a ball, and write, print, or color may be revealing.

LABORATORY EXAMINATION

Radiographic evaluation may be needed. Plain films can be viewed immediately if there is reason to consider clavicle or humerus fracture, infection, osteomyelitis, or tumor. Ultrasound shows the nerves and this is improving as technology advances. MRI and CT myelogram are used for evaluation of nerve roots and nerves.

Electrodiagnostic evaluation may also contribute to the diagnosis. Sensory nerve conduction studies are very useful in a child with severe

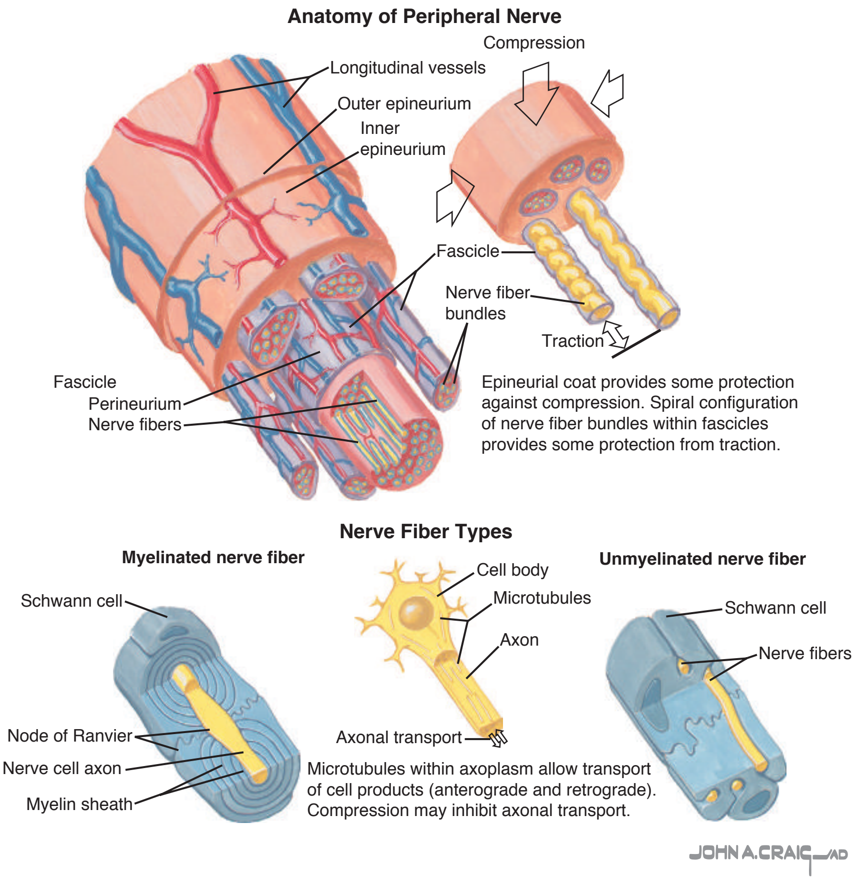

Figure 713-1 Anatomy of peripheral nerve. *(Netter illustration from www.netterimages.com. Elsevier, Inc. All rights reserved.)*

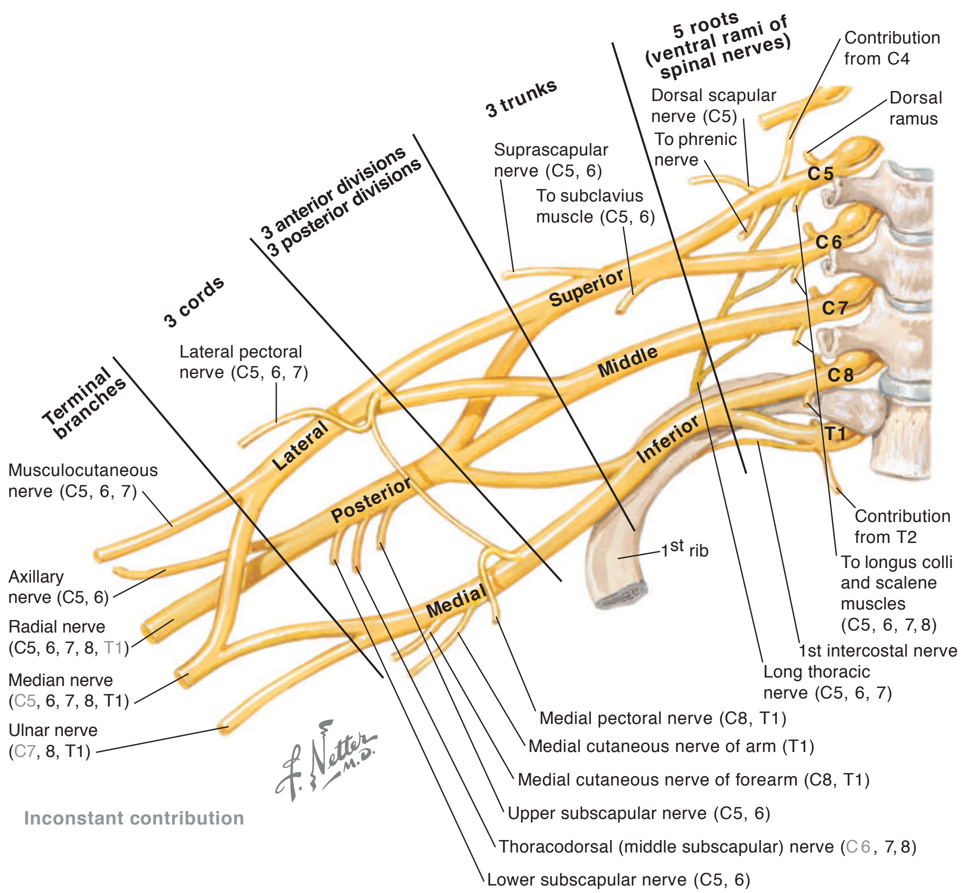

Figure 713-2 Schematic of the brachial plexus. *(Netter illustration from www.netterimages.com. Elsevier, Inc. All rights reserved.)*

injury who has insensate areas. Normal sensory response in areas where the child cannot feel indicates a *preganglionic neurotmesis* (avulsion). Motor nerve conduction studies are useful to check for continuity of nerve fibers to muscles that are weak or paralyzed. F waves are useful in evaluating proximally as these responses go from peripheral nerves to the spinal cord and back. **Somatosensory evoked potentials** are difficult to perform with infants because of motor artifact obliterating the responses with movement and are imprecise because of overlapping responses to peripheral stimulation. These are used intraoperatively as stimulation can be performed on the nerve roots themselves to determine proximal continuity. **Electromyography** can show activation in muscles with paralysis or severe weakness. It is important that these studies be performed by someone who is experienced in the examinations of infants and young children, both for the most precise evaluation and the most comfortable experience for the youngster. There are changes in nerve conduction velocities that occur with age, distances are nonclassic for traditional studies, and electrode placement is challenging because of the very small hands and limbs.

TREATMENT

Treatment begins on initial evaluation with instruction to the parents for positioning and early stretching exercises to begin at 10-14 days of age. They are also told of the critical task of maintaining infant awareness of the involved arm, initially by manually mimicking activities with the affected arm that the baby performs with the contralateral arm. The parents also are informed of the higher risk of BBPP for future infants, and so the families are encouraged to speak with the obstetrician about optimal management in future deliveries.

The baby will start with occupational or physical therapy at approximately 2 wk of age. The therapist will evaluate the baby as described above. The therapist will reiterate the importance of maximizing the awareness of the involved arm and will teach range-of-motion exercises. The therapist will often do splinting, commonly for wrist extension in a baby with wrist-drop, and possibly extending the fingers and abducting the thumb as well. Over time other splinting needs may be evident. There may be a supinator strap used during the therapeutic activities to turn the arm from a pronated position to supination. Therapeutic taping may be done for supination, wrist extension, or, most commonly, for shoulder positioning to minimize an adducted, internally rotated posture. The family is instructed in a home exercise program to be carried out on a daily basis, including stretching exercises, strengthening as a child is able, positioning, and use of splints.

After a few months of age the child may be able to tolerate electrical stimulation. Electrical stimulation to the muscles minimizes atrophy and promotes increased size, and therefore strength, of muscle fibers. Specific parameters for its use have not yet been determined but a 20-30 min twice-daily program is effective. Electrical stimulation to the nerves remains an area of contention, with some maintaining that it improves recovery while others stating that it impairs it. There are also proponents of the use of **constraint-induced movement training** to increase the active use of the involved hand. This is useful for a short-term increase in active use of the arm but less certain are long-term improvements.

Biofeedback has been used to attempt to retrain muscles in those with BBPP. Botulinum toxin injections are also used to help balance out muscles that are overpowering weak muscles to minimize contractures.

Functional assessments are not widely used in children with BBPP. Computer adaptive testing using selected items from large item banks relevant to the child's function may provide a meaningful evaluation tool. Hand function was evaluated with testing of children with upper-plexus involvement compared to their contralateral hand; 80% of the children had significantly greater-than-predicted decreased performance from the opposite hand. This indicated the hand function is impaired even in children who only have upper-plexus involvement.

Secondary problems can increase the negative impact of functional deficits in children with BBPP. Contractures from imbalance due to muscle weakness or paralysis, including shoulder adduction and internal rotation, elbow flexion, forearm pronation, and wrist and finger flexion, are all seen and interfere with function. A decrease in growth of the affected arm in length and atrophy of muscles are often seen. Lack of awareness of the arm, sometimes called *developmental disregard*, in children can have a significant impact on active use of the arm, with functional loss as a consequence. Pain is not usually seen in birth brachial plexus as opposed to injuries, which occur later in life. Scapular winging can be problematic both socially and clinically. The change in child development overall can be problematic. Toddlers with sensory loss sometimes chew on their fingers, causing injury.

Because the shoulder joint develops as the infant and toddler grows, deficits frequently develop. Shoulder deformity is a common musculoskeletal complication of BBPP. Muscular imbalance across the developing shoulder results in deformity of the skeletally immature glenohumeral joint. The weakness of shoulder external rotation, combined with strong internal rotation, leads to this difficulty. There can be progressive glenohumeral dysplasia, with increased glenoid retroversion, humeral head flattening, and posterior subluxation of the humeral head. The natural history of this deformity is progression if left untreated. This leads to further functional limitations even with a strong hand. Treatment aims to minimize this progression. Treatment options include botulinum toxin injections, arthroscopic surgeries, release of contracture, muscular tendinous lengthening (frequently a subscapularis slide), tendon transfers (commonly transfer of the latissimus dorsi to increase external rotation and abduction strength), and derotational humeral osteotomy.

Infants who do not show satisfactory improvement in muscle strength are candidates for surgical intervention. Classically the lack of elbow flexion to three fifths or greater strength merits referral for nerve surgery. The specific criteria and timing remain under debate. Those with a complete brachial plexus palsy with a flaccid arm and lack of sensation are under consideration for surgery between 2 and 4 mo of age, and those with upper-plexus involvement are considered between 3 and 6 mo of age. The surgical strategy for complete palsy is early microsurgery with the focus first on hand reinnervation. If the shoulder and elbow have continued deficits later, they will undergo secondary musculotendinous procedures.

Nerve transfers, nerve grafting, and neurolysis all are commonly performed. Intraoperative electrical nerve studies can help guide the procedure. The somatosensory evoked potentials and nerve conduction studies, both nerve-to-nerve and nerve-to-muscle, are commonly performed. These can assist in determining functional electrical continuity of nerve fibers. Nerve grafting is commonly performed using sural nerve fascicles, with several fascicles attached at each root level. For those with no intact nerve roots, intercostal nerve and other peripheral nerve transfers or grafts, or a cross C7 graft (from the contralateral plexus), may be performed.

Recovery of muscle function can occur with extremely varied nerve grafts and transfers providing innervation, showing the amazing adaptability of the body and its recuperative power. Postoperative improvement in hand and arm function has been shown to have a negative correlation with age at surgery, and therefore early intervention is recommended.

For older babies and children, muscle tendon and bony procedures are generally performed, sometimes combined with a peripheral nerve procedure. The Oberlin procedure, using a portion of the ulnar nerve to the musculocutaneous nerve, just as it enters the biceps, is a classic peripheral nerve procedure. The Steindler flexorplasty is sometimes used to obtain elbow flexion by moving the flexor and pronator muscles from the medial epicondyle to the more proximal humerus. A subscapularis release with latissimus dorsi transfer is commonly used for shoulder abduction and external rotation. Shoulder joint procedures are becoming more common. For those with very severe arm involvement, the gracilis is sometimes used by taking this muscle along with the nerve and vascular supply for transfer to the arm for elbow flexion and/or wrist extension. A derotational osteotomy of the humerus is an older procedure that is still performed for changing the position of the shoulder and arm.

Meningomyelocele (Spina Bifida)

Pamela Wilson and Janet Stewart

See also Chapter 591.

Meningomyelocele, or spina bifida, is a congenital neural tube defect that results in the malformation of the spine and spinal cord. It is the second most common disability in children and can range from spina bifida occulta (see Chapter 591.2) to anencephaly (see Chapter 591.6).

ETIOLOGY

See Chapter 591.1.

PREVENTION

See Chapter 591.1.

PRENATAL SCREENING

Prenatal screening is recommended for all pregnant women to detect neural tube defect. A simple blood test is done in the 2nd trimester to evaluate α-fetoprotein, human chorionic gonadotropin, estriol, and inhibin. If a neural tube defect is present, the α-fetoprotein is often elevated and further screening using high-resolution ultrasound is indicated. Ultrasound may reveal not only a spinal defect but also abnormal brain development, including the *lemon* and *banana signs*. The lemon sign is related to the shape of the head, whereas the banana sign is associated with hindbrain herniation of the cerebellum into the foramen magnum. The importance in early identification allows families to plan for delivery and consider fetal interventions, mainly prenatal closure of the defect. The Management of Meningomyelocele trial studied the safety and efficacy of prenatal spinal defect closure and the results suggest that prenatal closure may decrease the need for a shunt and lower the incidence of severe Arnold-Chiari malformations along with improved motor outcomes. However, study data show an increased incidence of preterm delivery and a risk for uterine dehiscence.

CLINICAL IMPLICATIONS

Spina bifida is often a multisystem problem that is most frequently associated with central nervous system abnormalities. The neurologic lesion is assessed by the actual anatomic level and then neurologic or functional level. Lesions associated with spina bifida are often grouped together as thoracic, upper lumbar (L1-2), midlumbar (L3), lower lumbar (L4-5), and sacral. Based on this information 1 can make inferences on the functional capabilities of the child and answer pertinent questions during the initial encounters (Table 715-1). The most basic question all families ask is: "Will my child walk?"

The first issue that must be dealt with after delivery is closure of the back defect. This is generally done the 1st day of life. Once the back is closed the child will be monitored to see if hydrocephalus develops. Hydrocephalus is very common in spina bifida and is related to hindbrain herniation. Hydrocephalus may develop most rapidly in the 1st postnatal mo; ventricular dilation may precede a change in head circumference or signs of increased intracranial pressure. The occurrence of hydrocephalus has been noted to be anywhere from 77-95% and does appear to have an association with level of lesion. Treatment is placement of a ventricular shunt or endoscopic third ventriculostomy. The risk for shunt revision in the 1st 2 yr is 30-50%, which decreases to 10% after 2 yr.

Hindbrain herniation or the **Chiari type II malformation** is seen in 80-90% of individuals with myelomeningocele. The classic manifestations include caudal displacement of the cerebellum, pons, and medulla and elongation of the fourth ventricle. This can impede cerebrospinal fluid flow and is involved in the development of hydrocephalus. The Chiari II malformation is symptomatic (from brainstem herniation/compression) in approximately 20% of children. Respiratory symptoms may be seen at birth or develop in the 1st few mo. These include stridor, vocal cord dysfunction, and central or obstructive apnea. Swallowing and feeding problems may require gastrostomy tube placement. If the child has a symptomatic Chiari II malformation, surgical

Table 715-1 Prognosticating in Myelomeningocele

MOTOR LEVEL SPINAL CORD SEGMENT	CRITICAL MOTOR FUNCTION PRESENT	MOBILITY: SCHOOL AGE	RANGE: ADULT	ACTIVITY: ADOLESCENT
T12	Totally paralyzed lower limbs	Standing brace, wheelchair	Wheelchair	Wheelchair, no ambulation
L1-2	Hip flexor muscles	Crutches, braces, wheelchair	Wheelchair, household ambulation	Wheelchair, nonfunctional ambulation
L3-4	Quadriceps muscles	Crutches, braces, household ambulation, wheelchair	Crutches, household ambulation, wheelchair	50% Wheelchair, household ambulation with crutches
L5	Medical hamstrings, anterior tibial muscles	Crutches, braces, community ambulation	Crutches, community ambulation	Community ambulation with crutches
S1	Lateral hamstring and peroneal muscles	Community ambulation	Community ambulation	Community ambulation 50% crutch or cane
S2-3	Mild loss of intrinsic foot muscles possible	Normal	Normal	Limited endurance because of late foot deformities

From Braddon RL, editor: Physical medicine & rehabilitation, *ed 4, Philadelphia, 2011, WB Saunders, Table 54-1, p. 1284.*

decompression is indicated. All children with spina bifida are at risk for **tethered cord syndrome**. After shunt malfunction, this is the second most common cause for neurologic decline. Clinical manifestations of tethered cord syndrome include any change in gait or bowel or bladder function, increasing scoliosis, back pain, or orthopedic changes. Surgical detethering procedures are indicated in those with neurologic decline but the success rate is variable.

The **orthopedic complications** of myelomeningocele are common and have predictable patterns. The spine deformities include scoliosis, lordosis, and kyphosis (see Chapter 679). The development of scoliosis has an association with the neurologic level. Children with thoracic level defects have an 80-100% risk, whereas those with a sacral level are at very low risk. Spine deformities tend to increase more rapidly during growth and puberty. Treatment of scoliosis includes both nonsurgical and surgical options. Braces, such as **thoracic-lumbar-sacral orthotics**, therapy, and proper seating options may be beneficial. Surgically implanted growing rods to support the developing spine have been used in younger children. Spine surgery should definitely be considered if the scoliotic spine curvature reaches 45 degrees; the child who is nearing skeletal maturity is a better candidate for spine surgery. Realistic expectations need to be discussed with the child and family. Correction of the spine may improve sitting, posture, and pelvic obliquity, but may have a negative impact on function and ambulation.

The **development of the hip** is also influenced by neurologic level (see Chapter 678). The risk for dislocation is highest in the L3 level followed by the L1-L2. Unilateral hip dislocations should be fixed surgically as they may result in pelvic obliquity and problems with sitting, whereas bilateral dislocations generally do not require interventions. Contractures of soft tissues are commonly seen in children with higher lesion levels. Hip flexors and knee flexors are commonly involved.

Abnormalities in the foot occur in approximately 90% of children and adolescents. The goal of treatment is to achieve a plantar grade foot for weight bearing and allow shoe wear. Clubfoot deformities are common in babies and treatment commonly includes serial casting and orthotics (see Chapter 674.3). The results are often suboptimal and surgery may be needed. In addition congenital vertical talus (rocker-bottom feet) are often encountered and need to be addressed (see Chapter 674.4).

Osteoporosis (see Chapter 707) begins to develop in childhood and is more severe in the higher-level injuries. Fractures of the lower extremities are most common in the femur followed by the tibia. Preventive treatment includes use of supplemental calcium and vitamin D. Those with documented fractures should undergo a diagnostic evaluation (see Table 707-1), including dual-energy x-ray absorptiometry. The use of bisphosphonates may be considered if the diagnostic evaluation does not reveal other underlying causes. The utility of early weight bearing has been advocated, but passive standing may have little impact on bone density.

Neurogenic bladder and bowel can be anticipated (see Chapters 543 and 606.1). The goals of treatment interventions are to protect kidney function and achieve social continence. The introduction of clean intermittent catheterization is the mainstay of management. It is not atypical for newborn babies to be started on a clean intermittent catheterization program. Urodynamics and renal ultrasounds are routinely used to monitor for hydronephrosis and track intravesicular pressures. Medications may be used to reduce bladder contractions and improve volume capacity. Surgical techniques are being used to improve continence, including bladder augmentation and the Mitrofanoff procedure (appendicovesicostomy). Symptomatic urinary tract infections should be treated with appropriate antibiotics. These children tend to have colonized bladders and should only be treated for symptoms and not the urinalysis or culture. A good bowel program is generally needed to achieve bowel continence. Nonsurgical interventions include adequate hydration, dietary manipulation, fiber regulation, and use of laxatives. Surgical interventions, such as the antegrade continence enema, have improved continence in many of these children and adolescents.

Latex allergies are fairly common in this population. The etiology may be multifactorial but increased exposure may play a role in development of severe reactions (see Chapter 149). Care providers need to be keenly aware of products that contain latex or that have a cross reactivity such as foods mixed with avocado, bananas or Kiwi fruit. **Radioallergosorbent testing** is used for identification of potential severe allergens.

Spina bifida is known to be associated with specific **neuropsychologic problems**. Various cerebral neuronal dysplasias may be present. The hallmark is a nonverbal learning disorder characterized by difficulties in math reasoning, visual spatial perception, and time concepts. In addition there are weaknesses in executive function, processing speed, and organizational skills. Children with spina bifida typically fall within the average IQ range although those with a higher lesion tend to cluster on the lower range. Hydrocephalus itself has an impact on cognition as noted by deficits in learning, memory, and executive function. Young children with spina bifida tend to do well early on as they have good verbal skills but as the academic demands increase school problems become more obvious. It is important to have appropriate neuropsychologic/educational testing done to identify difficulties each child or adolescent may encounter. Appropriate early intervention and support programs should be put in place and **individual education plans** or 504 plans developed (see Chapter 36). Structure in the home environment plays a key role in teaching self-care, dressing, and mobility skills. The importance of these early interventions cannot be underestimated as they will impact the quality of life and independence in adolescence and transition to an independent adulthood.

ADOLESCENCE AND TRANSITION INTO ADULTHOOD

Clinical care has increased the life span of individuals with spina bifida and the majority are living into adulthood. The physical problems in association with the learning disorders make the transition into independent living and competitive employment very difficult. The pediatrician in conjunction with specialty services plays a pivotal role in developing future planning. It is important to discuss early on strategies to encourage developmentally appropriate independence and self-help skills. Long-term financial arrangements, such as Special Needs Trusts, should be discussed. Transitioning primary and specialty care will need to be researched and introduced to the individual and family. Young adults may have depression and suicidal ideation.

Chapter 716

Ambulation Assistance

Marisa Osorio and Susan Apkon

Assistive devices, such as orthoses, prostheses, walkers, crutches, and wheelchairs, are key components of the therapeutic prescription for children with physical disabilities. The type of device chosen depends on the underlying diagnosis, functional level of the child, prognosis for improvement, tone abnormalities, range of motion, strength, and the overall gait pattern. Physicians, licensed independent practitioners, and physical therapists perform the evaluation of a child requiring mobility assistance. The physician or licensed independent practitioner is ultimately responsible for writing the prescription for the assistive device.

ORTHOSES

An orthosis is a device that is applied to the surface of the body to maintain alignment or position, to prevent or assist movement of the body part, or to provide support. Orthoses can be static, indicating the brace is rigid and does not allow movement, or they can be dynamic,

allowing movement of the limb to occur. Orthoses are named for the body parts covered. For example, "AFO" stands for *ankle–foot orthosis*, a brace worn on the foot that extends from the toes to the midcalf position (Fig. 716-1). Orthoses are custom made by an orthotist and can be obtained either directly through the orthotist or through the child's physical therapist. The orthosis is replaced during periods of growth or changes in function. All braces must be prescribed by a physician or licensed independent practitioner.

The type of lower-extremity orthosis prescribed is based on evaluation of the child's gait, strength, tone, and range of motion. There are many types of braces that have specific functions to improve gait. Table 716-1 lists examples of these orthoses and their potential uses.

Solid and articulated AFOs are the most commonly prescribed braces. Solid AFOs are used for children with hypertonicity, as they help to biomechanically reduce tone and provide stability with standing. Solid-ankle AFOs are also used in children who are nonambulatory to maintain range of motion of the ankle.

Articulated (hinged) AFOs allow the child with active ankle dorsiflexion to achieve heel strike and a more typical-appearing gait pattern by allowing forward movement of the tibia. This design makes ambulating on uneven surfaces and using stairs easier because of the movement allowed at the ankle, while still supporting the foot position and medial-lateral stability of the ankle. Articulated AFOs should not be used in children with cerebral palsy, spina bifida, or other disorders if they have a crouched gait pattern because the braces do not prevent crouching and may, in fact, allow further crouching. With crouched gait the hips and knees are held in flexion and ankles in dorsiflexion throughout the gait cycle.

Figure 716-1 Hinged ankle-foot orthosis. *(Courtesy of Ultraflex Systems, Inc., Pottstown, PA.)*

PROSTHESES

A prosthesis is a device that replaces a missing body part, such as an arm or a leg. Lower-extremity prostheses are used to improve mobility, while upper-limb prostheses are not always needed to improve function as children can be quite independent with a single upper limb. Lower-limb prostheses are used in children with congenital amputations, limb deficiencies such as fibular longitudinal deficiency, and acquired amputations as a result of trauma or cancer.

There are multiple components to lower-limb prostheses, which include the socket and foot, but may also include a hip and knee joint depending on the level of amputation. A prosthetist works with the child and family to fabricate the prosthesis. A physician or licensed independent practitioner with experience in prostheses provides the prescription for this device.

The type of prosthesis and the age at which a child is fit for the device depends on the etiology of the amputation, healing after surgery, and weight-bearing restrictions. In very young children, use of a lower-extremity prosthesis follows developmental milestones, with the first prosthesis prescribed at the time the child is pulling to stand. Addition of joints to the prosthesis also occurs when developmentally appropriate, such as use of a knee joint around the age of 3 when the child is learning to use stairs.

Advances in technology are helping children who use prostheses achieve a fluid gait pattern that makes their prosthetic use virtually undetectable to the untrained eye. New components and designs allow amputees to lead active lifestyles, including running, swimming, biking, and mountain climbing.

ASSISTIVE DEVICES

The purpose of assistive devices is to provide a wider base of support to improve stability during ambulation. The least supportive device is a traditional single-point cane commonly used following an orthopedic injury. For most children with gait abnormalities secondary to neurologic disorders, this is not a functional option. More supportive gait aids, such as forearm or Lofstrand crutches, are appropriate in these children; however, use of these devices requires good coordination and strength. Children with cerebral palsy and spina bifida may benefit from these devices.

Walkers provide more support than crutches and canes; they do not require as much strength and coordination to operate. Children with cerebral palsy, for example, may use a reverse walker, which they pull behind them. This reverse configuration provides a wide base of support and stability, helps to maintain an erect posture, and allows the child to engage with the environment without the barrier of the walker in front of them. Having the walker behind them also reduces the risk for more serious injury after a forward fall.

Table 716-1 Orthotic Options

ORTHOSIS	FUNCTION	COMMENTS
Foot orthosis	Provides support of foot only	Not typically customized
Supramalleolar orthosis	Provides medial-lateral support	Appropriate for children with low tone such as in Down syndrome
Ankle–foot orthosis	Provides support at the ankle and reduces footdrop or plantarflexion tone	Commonly used for ambulatory and nonambulatory children
Ground reaction ankle–foot orthosis	Provides knee extension moment to reduce crouching	Appropriate for children with spina bifida who crouch when walking
Knee–ankle–foot orthosis	Provides support at the knee when there is quadriceps weakness	Less commonly used because of large size of brace

Figure 716-2 Gait trainer. *(Photo copyright 2013 by Rifton Equipment, http://www.rifton.com.)*

For children who require a significant amount of support, gait trainers are often used. These devices allow the child to work on leg movements while the trunk and pelvis are stabilized (Fig. 716-2).

WHEELCHAIRS

Wheelchairs should be considered as a means of mobility when ambulation is not possible or is difficult outside of the home setting. Children with spinal cord injuries, spina bifida, neuromuscular diseases, or cerebral palsy may benefit from the use of a wheelchair. The goal is to provide a wheelchair that will allow the child to move independently about the environment, including home, school, and the community. Children as young as age 2 yr can self-propel a manual wheelchair and drive a power wheelchair. The type of wheelchair will depend on the child's underlying diagnosis, cognitive abilities, vision, motor skills such as head and trunk control, ability to manually propel a wheelchair, strength and endurance, musculoskeletal deformities if present, and medical comorbidities. One must also consider future growth or anticipated changes in function over time as well as the family's ability to transport the chair. Unique to pediatric wheelchairs is the adjustability to accommodate growth. A typical wheelchair may last 3-5 yr with periodic adjustments to growth by a seating specialist. There are many components that can be added in order to provide more support in the wheelchair, including head rests, lateral trunk support, hip guides, antitippers that prevent the wheelchair from tipping backwards, and specialized tires. The seating system is considered a separate item from the wheelchair itself and should be properly fit for the child's current size and seating needs. Seats that are too large for the child can cause pressure ulcers, worsen scoliosis, and make it more difficult for the child to maneuver or propel.

Chapter 717

Health and Wellness for Children with Disabilities

Margaret A. Turk

See also Chapter 42.

The number of children with developmental disabilities in the United States has increased by 17% in the past 20 yr, with nearly 3 million being of school age. Despite available medical support, many of these children and their families do not receive recommended childhood preventive care and anticipatory guidance, health education, discussions about appropriate activity and exercise, or an opportunity to engage in or learn about health promotion.

The expansion of the disability definition to include children with special healthcare needs, chronic conditions, and activity limitations from any cause (e.g., limitations in usual daily activities such as age-appropriate self-care, mobility, communication, and cognition) has made the health issues of the more traditional childhood disability types (e.g., cerebral palsy, intellectual disability, spina bifida, congenital musculoskeletal disorders) more difficult to identify. U.S. data identify developmental, emotional, and behavioral conditions as the leading conditions with activity or functional limitations, with physical health conditions comprising a smaller proportion of self-identified disabilities (although mobility and motor control issues may be noted among the aforementioned nonphysical conditions). Childhood cognitive, mental, and physical health problems contribute to continued economic and health problems into adulthood. Because these problems can respond to childhood and adolescent health promotion interventions, monitoring children with disabilities throughout their development is helpful in providing information and support to children and adolescents, their parents, and families to promote health over a lifetime.

HEALTH PROMOTION DEFINITIONS AND BACKGROUND FOR DISABILITY

The World Health Organization defines *health promotion* as “the process of enabling people to increase control over, and to improve, their health.” For people with disabilities, this concept is important because they are both underserved and have comparatively large health disparities. The World Health Organization further defines health promotion approaches as including more than health education, and consisting of community action, supportive and accessible environments, policy changes, health service modifications, and development of personal skills. Health and wellness programs also include traditional preventive management strategies, such as anticipatory guidance. There is ample evidence that engaging in specific areas of health promotion results in improvement, although the evidence for its influence on adult health is less robust.

Children with disabilities encounter many barriers to healthy behaviors (Table 717-1). Both broad and focused health promotion programs consider severity of condition, barriers and resources, and self-efficacy and resiliency, to achieve health-promoting behaviors. Children with disabilities may also require modeling or assistance to apply healthy behaviors to their particular disability or economic, social, and environmental circumstances.

Children and adults (and their families) often view health differently than those without disabilities. Disability may influence health and vice versa, but their perception of their own health and wellness does not equate with their level of disability. Children with congenital or

Table 717-1 Barriers and Facilitators for Children to Engage in Healthy Behaviors

BARRIERS	FACILITATORS
• Lack of knowledge and skills • Fear of injury or failure • Negative attitudes by parents, peers, healthcare providers • Poor parental healthy behaviors • Stress in the close family network • Personal choices • Fatigue • Lack of initiative • Limited function or capability • Inability to control behaviors • Inaccessible facilities or resources • Needing adult or aid assistance • Economic restrictions • Policies and procedures of facilities or programs	• Education or knowledge about healthy behaviors • Engaging child in discussions and decisions • Promotion of activities by rehabilitation and other healthcare professionals • Family support and participation • Involvement of friends and peers in activities • Desire to be active • Models or directions for participation with adaptations • Creative and knowledgeable professionals • Making activities a part of the routine—repetition and consistency promote ongoing activities • Accessible facilities and opportunities, with knowledgeable staff • Policies and resources promoting participation

acquired disabilities have a narrow view of healthy living, concentrating on nutrition and secondarily on physical activity, with little understanding of how they apply to their own condition. Experiences as a child with a disability often foreshadow adult behaviors, especially negative attitudes toward therapy, exercise, and activity. Beliefs of parents, families, and healthcare providers also influence the views of health by children with disabilities. Health promotion programs for these children must (1) understand and support the role and well-being of parents, (2) recognize that parents of children with more functional limitations may require more resources and support, (3) involve children with disabilities in design of programs and decisions about participation, and (4) address barriers to participation, perceived and real (see Table 717-1). Because many healthcare providers have a poor understanding of the needs of people with disabilities, engaging experienced rehabilitation health professionals in designing and promoting a health and wellness agenda is an important strategy.

An effective health and wellness program should involve multiple approaches and opportunities for success, including partnerships with families, school staff, and rehabilitation providers. Competency requires addressing any mismatch between the child's positive sense of health and well-being and that expected by the healthcare providers; limitations of an education-only model; engaging the child in discussions about the importance of healthy behaviors, ways to engage in healthy behaviors related to the child's disability and circumstances, and decisions about participation; and parent and family involvement coupled with sensitivity for the already overwhelming support a family provides for the child with a disability.

ANTICIPATORY GUIDANCE, COUNSELING, AND PREVENTIVE CARE

Preventive healthcare through health education, anticipatory guidance, and participation in screening and immunization schedules is the mainstay of pediatric public health programs (see Chapter 16). *Bright Futures,* developed by the American Academy of Pediatrics and their collaborators and supported by the Maternal and Child Health Bureau, Health Resources and Services Administration, provides a knowledge base for pediatric healthcare providers and the public about anticipatory guidance, health promotion, and prevention for children and adolescents; but it has few references to disability. Anticipatory guidance refers to general information related to growth/development and healthy practices. Counseling refers to advice given regarding specific conditions, which could include discussions of applications of general guidance to children with disabilities. For the general population, 25% of parents receive no information and <50% receive all recommended guidance. Although parents of children with special healthcare needs (the broad inclusive definition of disabilities) report similar or better receipt of general preventive information, it is not clear whether those with higher severity of functional limitations receive this guidance or counseling, and whether it is provided in the context of disability and other circumstances.

Children with special healthcare needs require typical prevention, as well as more specific counseling related to their disability. Some of this more specific counseling can be managed by specialty care providers, although children with special healthcare needs have difficulty obtaining appropriate specialty outpatient services. Additional barriers to care, especially with increasing age of the child, are the lack of accessible medical equipment and facilities. Although discussions of health risks with adolescents about smoking, drinking, and protected sexual activity should be undertaken, the discussions may require a different focus for adolescents with disabilities. Higher violence and abuse rates toward children with disabilities are reported for which providers must be vigilant.

The recommendation is to recognize the need for modifications to typical guidance, to be alert for any signs of violence, and to broaden counseling to include questions and discussions about conditions associated with the specific disabilities (e.g., epilepsy or cognitive impairments often seen with cerebral palsy, or neurogenic bladder and bowel in spinal cord dysfunction) or secondary conditions, such as pain, osteoporosis/fractures, or fatigue seen in many children and adolescents with disabilities. Although the patient-centered medical home may provide this inclusive support, it risks decreased access to the specialty physicians and healthcare providers who will provide much of this information.

PHYSICAL ACTIVITY AND EXERCISE

National health guidelines recommend at least 60 min of physical activity daily for children, and they suggest that specific advice from health professionals is needed for children with disabilities. Exercise and activity have shown to increase aerobic capacity, functional ability, and quality of life for children with many kinds of disabilities and chronic diseases (e.g., cerebral palsy, spinal cord dysfunction, cystic fibrosis, asthma, intellectual disabilities, diabetes). The vast majority of study participants noted benefits. And yet, most healthcare providers expect sedentary lifestyles for children and adolescents with disabilities, whatever their functional abilities. For children with disabilities, school physical education and recess programs can support activities at or greater than the recommendation, and school requirements can reinforce activity expectations. Despite this potential, most children with disabilities engage in very limited physical activity even in supported school environments. School and public playgrounds are not sufficiently accessible to support community physical activity.

Physical activity for children and adolescents improves fitness and quality of life for youth with developmental disabilities (Table 717-2). The described exercise and fitness programs require 2-3 mo of participation at least twice a week to achieve any changes, and many of the changes achieved are longer lasting than expected. These programs are not traditional therapy, and participation in therapy is not a substitute. The focused fitness and exercise programs cited here generally required the support and direction of rehabilitation professionals, although programs can be community based in nonmedical surroundings.

Table 717-2 Examples of Effective Exercise Programs for Children with Disabilities

PROGRAM	DESCRIPTION	OUTCOMES/COMMENTS
Center-based fitness program and home program*	Children with a variety of disabilities Group exercise: 2×/wk for 14 wk; warm-up, aerobics, strengthening, cool down Home program: 2×/wk for 12 wk using video exercises	Improved walking efficiency, strength, general function Group treatment more effective by measures and by satisfaction
Group aquatics aerobic exercise program[†]	Children with a variety of disabilities, >50% able to walk 2×/wk for 14 wk Recreation to achieve target heart rate; aquatic strengthening program	Improved walk/run, not strength to isometric testing Required adults monitoring to maintain target heart rates
Group training class[‡]	Children with cerebral palsy able to walk 2×/wk for 4 wk Warm-up, circuit training stations (treadmill, balance, stairs, closed-chain exercises)	Improved muscle strength, mobility, function except fine-motor test–maintained 8 wk later Therapists conducted and monitored
Strength training[§]	Children with cerebral palsy, including a majority able to walk with assistive devices 3×/wk for 6 wk Progressive strength training program, conducted in the home	Improved perceptions of strength, walking, stair management and improved psychologic benefits Clinicians to monitor, problem solve; some need for direct parental involvement
Walking–jogging program[‖]	Children with Down syndrome 3×/wk for 10 wk 30 min sessions, achieving 65-70% peak heart rate	Difficulty promoting increasing activity intensity Improved peak exercise time and grade, but not in aerobic capacity; improved walking capacity
Treadmill training program[¶]	Children with intellectual disabilities Daily for 2 mo Progressive treadmill use with goal of 20-30 min	Improved heart rate with and without activities Therapist developed and monitored, community staff implemented
Peer-guided exercise**	Adolescents with intellectual disabilities 2×/wk for 15 wk Typical adolescents and those with disabilities paired to support each other in 1 hr aerobic, weight-training, flexibility activities	Improved curl-ups, 6 min walk, and body mass index High attendance, less compliance with weight training

Recreation and organized sports are other areas where children and adolescents with disabilities can engage successfully, at times with modifications. Participation improves cardiopulmonary parameters, motor function, social competence, and general sense of well-being. Programs through Special Olympics International are an opportunity for children and adolescents to engage in supportive and monitored environments for sport and recreation.

NUTRITION AND OBESITY

Managing the combination of nutrition and physical activity is the key ingredient of weight control. Obesity is a significant problem affecting a large portion of the general population, including children with special needs. Estimates suggest that children with physical activity limitations were twice as likely as the general population to be overweight and youth with cognitive impairments are at increased risk. It is unclear if obesity is a cause for the activity limitations or is a result of the limited activity, which may be an important distinction in developing interventions. The concern with obesity contrasts with early life weight gain needs of many children with disabilities, and may pose important management confusion for parents and families with the change of focus to weight decrease. Confounding factors include (1) the propensity of some disabilities, usually those that are genetically mediated, to be associated with obesity; (2) standards of measurement may not be appropriate for certain diagnoses or disability types (e.g., expected body composition differences, short statures, contractures, or limb deficiencies or amputations); (3) obesity may be a side effect of medication and must be weighed against benefits (e.g., antidepressants, mood stabilizers, steroids); and (4) the social network of family, friends, schools, and healthcare providers may unwittingly influence healthy habits in a negative way, including use of food as reward for behavior management.

EMOTIONAL HEALTH AND LEISURE ACTIVITIES

Emotional health is often overlooked in children with disabilities, unless mental health or challenging behaviors are the cause for the disability. Youth and adolescents with disabilities appear to be at higher risk for feeling low, stressed, or anxious (especially those with higher levels of limitations), and those with mental health needs may have lower adaptive functioning, a family history of mental illness, or a diagnosis of autism spectrum disorder. Adolescents with physical disabilities participate in fewer social activities, have fewer close or intimate friends, and have few plans for ongoing education. There is a risk for continued isolation into adulthood. Medications may be considered, but effectiveness is not guaranteed and unwanted side effects may produce more health conditions. Counseling requires insurance support or discretionary funding.

Leisure and recreational activities provide social supports, additional stress-coping mechanisms, and ability to develop social skills and a stronger personal identity. Girls with disabilities tend to engage

Table 717-3 Targeting Healthy Behaviors for Children with Disabilities

HEALTH ACTIVITY TARGET	RELEVANCE TO CHILDREN WITH DISABILITIES
General prevention	• Recognize risks for less healthy behaviors and barriers and facilitators about behavior changes and participation • Cover typical topics for all children; counsel regarding disability or situation context • Specifically monitor for abuse and violence • Provide typical age-appropriate adolescent information about smoking, drinking, substance abuse, sexual contacts; refer if unable to provide • Monitor for disability-specific health conditions; may require referral
Physical activity	• Promote exercise and activity—should be an expectation for activity • Ensure that family and child/adolescent are knowledgeable about benefits and possible adaptation • Review need for possible dietary changes • Consider engaging rehabilitation professionals
Nutrition and obesity	• Recognize obesity can cause limitations, and can be the result of poor dietary habits and limited activity • Ensure that family and child/adolescent are knowledgeable about healthy nutrition • Consider referral to nutritionist or other professional to engage patient and family in modeling/direction or behavior suggestions • Review need for increased activity level with dietary changes
Emotional health	• Question for sense of anxiety/feeling low, stress management and ability to adapt, social activities • Consider medications and counseling based on expected effect, monitor effects/side effects; consider referral, making sure that insurance/payment coverage is available • Consider recreation and leisure activities to promote social support and ability to develop social skills
Recreation and leisure	• Question about social activities outside the home; promote importance for development of social skills, sense of self, support • Consider referral to community programs or rehabilitation professionals
Dental	• Discuss more than preventive dental care • Suggest behavior strategies if there are problems engaging in dental appointments and refer for this service as needed

in social or skill-based activities, and boys in physical activities, with decreasing participation with increasing age. Rehabilitation professionals can assist with problem-solving activities, such as using computerized technologies (e.g., Wii, Xbox), adaptation of equipment (e.g., modified upper-limb prosthesis to allow baseball glove use), and knowledge of adapted recreation programs in the area (e.g., horseback riding, winter/water sports) to increase participation.

DENTAL CARE

Dental care is a frequently unmet health care need for children with disabilities. The principal deficits are in receipt of further or specific dental care (not preventive services) and that condition severity and low income may be associated with unmet dental needs. Challenging behaviors often limit dental care, and the use of behavior management techniques and education programs have been effective in allowing both preventive and additional dental care.

ROLE OF HEALTHCARE PROVIDERS

Healthcare providers should have higher expectations for health and healthy behaviors for children with disabilities. Healthy behaviors do not come naturally to most people, including children with disabilities and their families, and there is a role for healthcare providers in providing a better understanding of health and behavior change concepts. Primary care and other healthcare providers should be mindful of discussing and promoting health and healthy behaviors with children and adolescents with disabilities and their families (Table 717-3).

Environmental Health Hazards

PART XXXIV

Chapter 718
Biologic Effects of Radiation on Children

Thomas L. Slovis and Donald P. Frush

BASIC PRINCIPLES

Radiation exposure occurs from both natural (50%) and manmade (50%) sources. Radon gas accounts for the majority (37%) of natural radiation. The contribution of medical radiation has dramatically increased to 50% in 2006 from 15% in the mid-1980s. CT is responsible for 24% of all radiation exposure and almost half of manmade radiation (Fig. 718-1). Medical radiation is concerning. Estimates of dose risks ranging from no risk to as much as 2% of all cancers in the United States may be attributable to radiation from CT studies. Studies implicate CT examinations in childhood with subsequent development of cancer. In addition, radiation doses from medical imaging can be poorly understood. Seventy-five percent of radiologists and emergency department physicians are reported to underestimate the radiation dose from CT. Some imaging procedures do not produce radiation (Table 718-1), and not all radiation-producing modalities expose a child to the same amount of radiation (Table 718-2).

Nuclear medicine and positron emission tomography examinations are described by the amount of radioactivity injected (millicuries or becquerels) or are converted to effective dose (milliSieverts). The units of absorbed dose, as defined by the International Commission of Radiation Units, are the **rad,** introduced in the 1960s, and the **Gray** (Gy), introduced in 1985. The metric used in denoting biologic response is the rem (older unit) and the Sievert (Sv) (Table 718-3). Equivalent dose and effective dose are measured in Sv and mSv. Not all radiation has the same effect on biologic tissue for a given dose. Beta rays are quite superficial; alpha particles and protons cause significantly more damage than gamma radiation (x-rays) for a given absorbed dose. Diagnostic imaging uses x-rays (gamma rays). Each dose has a modifier, for example, skin dose, whole-body dose, organ dose, or effective dose. **Effective dose** considers specific tissues and their radiosensitivity.

BIOLOGIC EFFECTS OF RADIATION

Biologic effects of radiation are divided into 2 types. **Tissue reactions** (previously **deterministic effects)** (determined by the dose) are characterized by a threshold dose and severity is directly related to the magnitude once the threshold is exceeded. For example, cataracts have traditionally been reported to occur with an acute exposure to >2.0 Gy or with long-term exposure to >5.0 Gy (Table 718-4), although publications indicate lower thresholds as well as debate about these thresholds. Tissue reactions never occur from the radiation organ doses generally used in single diagnostic examinations (<100 mGy), but invasive procedures (therapeutic and interventional) have on rare occasions led to these effects. **Stochastic** (random) **effects** are of concern because they can occur at any dose; that is, there is no threshold, with the probability of an effect increasing with rising dose. These effects can be caused by any radiation striking vulnerable tissue (most importantly DNA, but cytoplasm also may be at risk) and causing irreversible damage. These effects lead to the **linear no (dose) threshold** model, which states that radiation damage increases with rising dose in a linear fashion. This concept stresses that no level of radiation exposure can be considered to be absolutely safe.

Radiation can cause permanent cell injury, carcinogenesis, genetic mutations, or cell death. The biologic effects of radiation result primarily from damage to DNA directly (**direct effect**) through interaction of fast recoil electrons caused by the absorption of x-rays (one third of the damage) or secondarily by the formation of free radicals (**indirect effect**). Approximately 80% of the cell is water, so most of the energy deposited in a cell results in production of aqueous free radicals. The reactions are rapid (10^{-18} to 10^{-3} sec). A dose of 10 mGy results in approximately 10^3 ionizations per cell type. The biochemical and physiologic changes that follow take hours or days, whereas the induction of cancer may take a few years to decades.

The manifestations of DNA injury are variable. The cell containing the damaged DNA might die; cell death (apoptosis) is a mechanism for eliminating heavily damaged and potentially mutable cells. Damage to a base pair is the most prevalent and least significant effect. Breaks of a single strand of DNA usually have little biologic significance because each strand is repaired with use of the opposite strand as a template, but a mutation can result if misrepair occurs.

Breakage of both strands of DNA (the least-common event) is more problematic. The end result seems to depend on the proximity of the break in each strand. If widely separated, repairs occur as with a single-strand break. If the breaks in the 2 strands are opposite each other (or separated by only a few base pairs) repair is more difficult without a template. This type of break is the mechanism of radiation-induced cell death, chromosomal damage leading to mutations, and carcinogenesis.

When DNA damage occurs, aberrations are produced in chromosomes, resulting in an *unstable aberration* (usually lethal to dividing cells) or *stable aberration.* Stable aberrations can result in failure of chromosomes to reunite (leading to deletions) or in abnormal rearrangement of chromosomes, such as reciprocal translocation or aneuploidy. Although it is logical to think that these abnormalities in chromosomes lead to mutations that can activate oncogenes or protooncogenes or cause mutations in tumor-suppressor genes (see Chapter 492), few radiation-induced cancers show specific translocations such as would be associated with activation of specific oncogenes or known tumor-suppressor genes. An exception is the radiation induction of papillary thyroid carcinoma in children, which probably results from activation of the RET oncogene (see Chapter 506).

Radiation carcinogenesis seems to be a progressive multistep process composed of 3 independent stages: morphologic changes, cellular immortality, and tumorigenicity. Radiation exposure induces cellular genomic instability. This instability is transmitted to a cell's progeny, resulting in a continued elevation in the rate at which genetic changes arise in the subsequent generations of the irradiated cell (Fig. 718-2).

A longitudinal study of the lifetime risks of excess cancer mortality secondary to irradiation has been evaluated in *atomic bomb survivors*. More than 86,000 survivors have been followed for more than 65 yr since exposure. Individual radiation doses were estimated by considering the person's location in relation to distance from the epicenter and individual shielding situations. Most of the exposure was direct gamma irradiation, with some neutron exposure. Age at exposure and ethnic differences in cancer occurrence influence the sensitivity to radiation-induced cancers (Fig. 718-3). Compared with the middle-aged adult, children are 2-10 times more sensitive to radiation-induced carcinogenesis, and the youngest neonate is more sensitive than the older child. Because of the higher risks associated with breast and thyroid cancer, girls are more sensitive than boys. It must be understood that

cancer rates in this study are mortality figures. The incidence of cancer in this population is approximately 2 times greater than mortality incidence.

The doses used in *diagnostic radiology for multidetector CT* scans overlap with low-dose induced cancer in atomic bomb survivors (Fig. 718-4). Estimates for lifetime risk of cancer following head and abdominal CT scans in children vary widely, from as low as 1 : 500 to more than 1 : 10,000 (including the possibility that these doses do not incur a risk). Therefore, since stochastic effects are random but increase with rising dose, it is mandatory that we use the lowest dose necessary to get sufficiently diagnostic images. The advent of digital picture archiving communication systems utilizes postprocessing algorithms and can make all images diagnostic, even those with higher-than-necessary exposures. Since the elimination of film-based systems, where overexposures were evident as "dark" films, digital technology eliminates the imager's ability to know whether enough or too much radiation was given. It does not allow the imager to determine whether the patient received "as low as reasonably achievable" radiation dosing. It is for this reason that some radiation metric (and familiarity with this metric) should appear on each image.

Increased biologic vulnerability to radiation can be seen in the fetus exposed in utero through maternal radiation. In utero radiation exposure is associated with a 92% excess risk of dying from leukemia

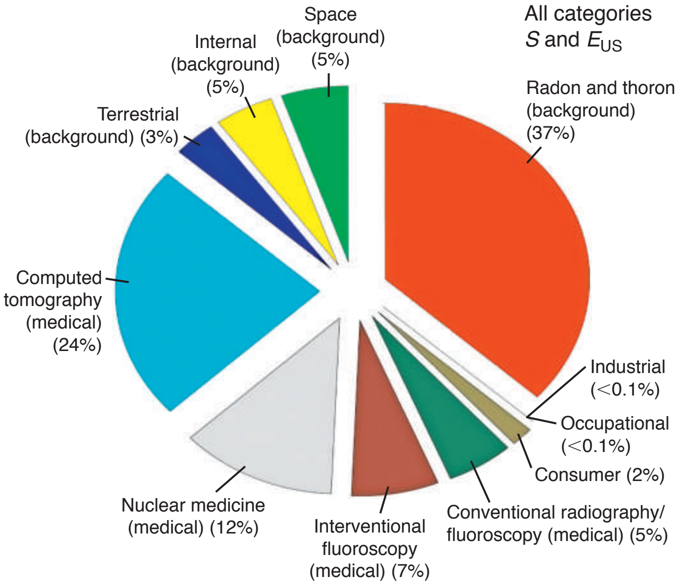

Figure 718-1 All exposure categories collective effective dose (percentage) 2006. *(From the National Council on Radiation Protection and Measurements. Ionizing Radiation Exposure of the Population of the United States (NCRP report 160), Bethesda, MD, National Council on Radiation Protection and Measurements http://pubs.rnsa.org/doi/full/10.1148/radiol.2532090494.)*

Table 718-1 Imaging Modalities

MODALITY	SOURCE
Plain film	Radiation (x-ray)
Angiography/fluoroscopy	Radiation (x-ray)
Ultrasound	Sound beams
Computed tomography	Radiation (x-ray)
Magnetic resonance imaging	Magnetic field; radiofrequency
Nuclear medicine (including positron emission tomography)	Radiation (injected isotope)

Table 718-2 Radiation Dose by Imaging Test*

EXAMINATION	DOSE	SITE MEASURED
Chest—2 views	0.1-0.2 mGy	Entrance (skin)
Abdominal—2 views	0.5-1.0 mGy	Entrance (skin)
Fluoroscopy		Entrance (skin)
Nonpulsed	3-5 mGy/min	
Pulsed	1-3 mGy/min	
Computed tomography†		
Head (2 yr old)	20-30 mGY	Middiameter of phantom of 16 cm
Abdomen (2 yr old)	2-3 mGY	Middiameter of phantom of 32 cm
Nuclear medicine‡ (technetium ^{99m}Tc mercaptoacetyltriglycine–renal)	120 mSv	Effective dose
Positron emission tomography‡ (brain fludeoxyglucose ^{18}F)	185 mSv	Effective dose, whole body

*Background radiation = 0.01 mSv/day or 3 mSv/yr.
†Scan explained as CT dose index (CTDI). First dose is with adult factors; second dose, shown in parentheses, is examination adjusted for children.
‡Expressed as effective dose. These are rough guidelines for dose given to a 5 yr old with normal renal function.

Table 718-3 Radiation Measurements

UNITS	RADIOACTIVITY	ABSORBED DOSE	DOSE EQUIVALENT	EXPOSURE
Common units	curie (Ci)	rad	rem	roentgen (R)
New units	Becquerel (Bq)	Gray (Gy)	Sievert (Sv)	coulombs/kg

CONVERSION EQUIVALENTS
1 millicurie (mCi) = 37 megabecquerels (MBq)*
100 rad = 1 Gy
1 rad = 1 cGy
100 rem = 1 Sv
1 rem = 10 mSv
Background radiation dose is approximately 1 millirad/day

*To convert mBq to mSv, use conversion table:
1 mrad = millirad = 1/1,000 of a rad.
rem = rad × radiation factor; weighting for gamma and x-ray, this factor is 1.
rem = rad × 1.

Table 718-4 Deterministic Dose Rates

INJURY	APPROXIMATE THRESHOLD
SKIN	
Transient erythema	200 rad (2 Gy)
Dry desquamation	1,000 rad (10 Gy)
Moist desquamation	1,500 rad (15 Gy)
Temporary epilation	200 rad (2 Gy)
Permanent epilation	700 rad (7 Gy)
EYES	
Cataracts (acute)	>200 rad (2.0 Gy)*

*Has been reported as occurring between 0.5 and 1.0 Gy.
Modified from Hall EJ: Radiobiology for the radiologist, *ed 5, Philadelphia, 2000, Lippincott Williams & Wilkins.*

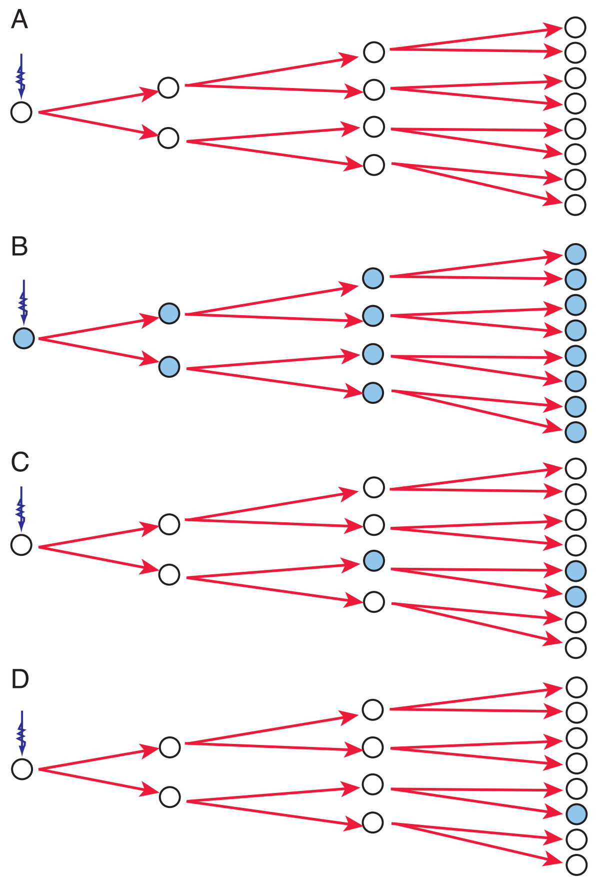

Figure 718-2 **Schematic of radiation-induced mutagenesis.** *Open circles* represent normal wild-type cells, whereas *solid blue circles* represent mutated cells. **A,** Most of the cells in an irradiated population retain the wild-type phenotype. **B,** Example of a cell directly mutated by radiation exposure; the mutation is transmitted to all of its progeny. **C** and **D** are examples of mutations arising as a result of radiation-induced genomic instability. The irradiated cell and its immediate progeny are wild type, but the frequency with which mutations arise among the more distant descendants of the irradiated cell is elevated. *(From Little JB: Ionizing radiation. In Kufe DW, Pollock RE, Weichselbaum RR, et al, editors:* Holland-Frei cancer medicine, *ed 3, Ontario, Canada, 2003, BC Decker.)*

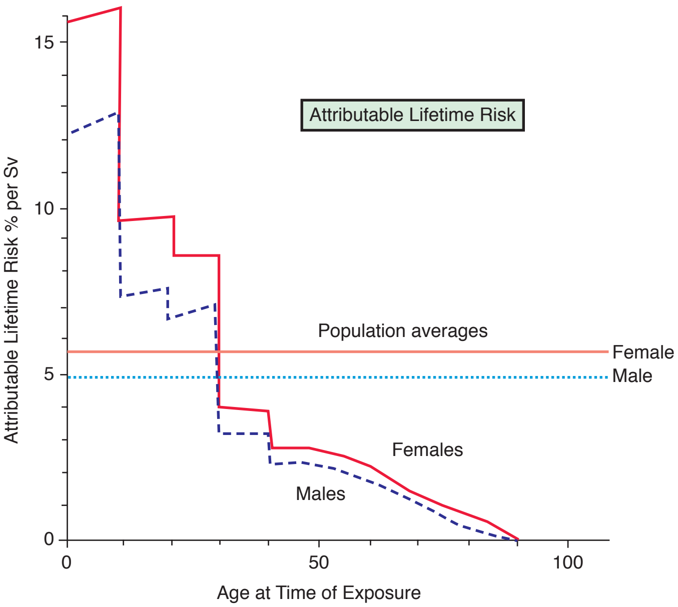

Figure 718-3 **Lifetime risk of excess cancer per Sievert (Sv) as a function of age at the time of exposure.** Data from the atomic bomb survivors. The average risk across all ages in a population is approximately 5% per Sievert, but the risk varies considerably with age: children are much more sensitive than adults. At early ages, girls are more sensitive than boys. *(From Hall EJ: Introduction to session I: Helical CT and cancer risk, Pediatr Radiol 32:225–227, 2002.)*

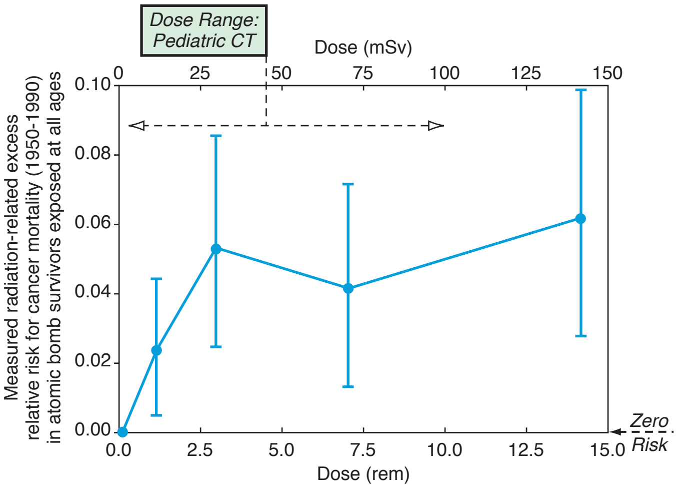

Figure 718-4 **Relevant dose range for pediatric CT: 6-100 mSv (0.006-0.1 Sv).** There is direct, statistically significant evidence for risk in the dose range from 0-0.1 Sv. *(From Brenner DJ: Estimating cancer risks from pediatric CT: going from the qualitative to the quantitative, Pediatr Radiol 32:228–231, 2002.)*

before age 10 yr and a 180% excess risk of dying from other malignant diseases. Even 40 yr later there is a 228% increased relative risk of cancer associated with radiation in utero.

The fetus and infant are most vulnerable to radiation-induced cancer because (1) they are growing rapidly, with many cells undergoing mitotic activity; (2) radiation-induced tumors (except leukemia) take a long time to develop and children have a longer lifetime; and (3) there is a greater time to have imaging studies, with accumulation of the risks related to doses.

Most childhood tumors occur sporadically, but 10-15% of cases have a strong familial association. Familial tumors have specific chromosomal deletions in common. In some of these tumors (retinoblastoma), the 2-hit hypothesis by Knudson is apparent (see Chapter 491). It is not coincidental that individuals with many of the congenital diseases are at risk for the development of tumors after irradiation.

Table 718-5 Inherited Human Syndromes Associated with Sensitivities to X-Rays

Ataxia-telangiectasia	Fanconi anemia
Basal cell nevoid syndrome	Gardner syndrome
Cockayne syndrome	Nijmegen breakage syndrome
Down syndrome	Usher syndrome

Modified from Slovis TL, Frush DP, Berdon WE, et al: Biologic effects of diagnostic radiation on children. In Slovis TL, editor: Caffey's pediatric diagnostic imaging, *ed 11, Philadelphia, 2008, Mosby, p. 5; and Hall EJ:* Radiobiology for the radiologist, *ed 6, Philadelphia, 2006, Lippincott Williams & Wilkins, p. 41.*

Table 718-5 lists diseases that are associated with sensitivity to radiation.

DECREASING UNNECESSARY DIAGNOSTIC RADIATION IN CHILDREN WHILE STILL OBTAINING DIAGNOSTIC IMAGES

Selecting the correct examination is the responsibility of the ordering physician and may involve consultation with the radiologist, preferably with pediatric expertise. Evidence-based medicine has shown little yield from an imaging work-up (including CT) of a child with a single nonfebrile seizure without other neurologic abnormalities. This is especially true if there is no antecedent history of abnormal behavior or of personality or developmental change. CT does not detect as many abnormalities as MRI, and CT involves ionizing radiation. MRI detects the subtle changes of congenital or acquired anomalies that may be responsible for seizures much more easily. Therefore, it is appropriate, **except** in an emergency situation, to obtain MRI within a reasonable time frame instead of performing 2 tests (CT followed by an MRI).

It has been estimated that perhaps up to 30% of imaging examinations, including CT examinations, are questionably indicated, and may be replaced by another, non–radiation-producing modality, or are performed without evidence-based indications.

Reducing Radiation from the CT Examination

The most common source of medical radiation is CT. We have progressed from a single-slice scanner to scanners that can obtain up to 320 slices in subsecond time. The images have excellent detail, including multiplanar and 3-dimensional reconstruction of the acquired data. It once took more than 30 min to obtain 10-12 images, but now hundreds to thousands of images are generated in seconds. When adult parameters for CT settings are used for children, the dosage for children is actually higher than the dosage for adults. This occurs because lower-energy x-rays that would have been absorbed in the near field in an adult pass into the entire child, irradiating all organs. When comparing dosages given to newborns and adults during CT scanning of the head, with the same parameters in both groups, the dosage given to newborns is 4 times that of the dosage given to adults. With abdominal imaging, the dosage is increased by 60%.

It is the role of the radiologist to tailor the examination to the pediatric patient. One can determine whether the examination is tailored to the pediatric patient by looking at the dose report or the parameters of tube current (milliamperage/second [mAs]) and peak kilovoltage (kVp). Scanning range should be limited to only the necessary area. Multiphase scanning should only be obtained when necessary. The radiologist has many ways to decrease parameters so that children receive diagnostic imaging without excessive radiation. In some instances, reducing the radiation dose by half, even in adults receiving CT, does not change the diagnostic efficacy of the study and the radiologist's ability to make the proper diagnosis.

RADIATION THERAPY—ACUTE AND LATE EFFECTS

Radiation therapy uses high doses to kill malignant cells. The sensitivity of normal cells is quite close to that of malignant cells, and to achieve significant cure rates, radiation oncologists must accept a given

Table 718-6 Late Effects of Radiation Therapy in Children Treated for Cancer

SYSTEM	LATE EFFECT	DOSE (Gy)
Musculoskeletal	Muscular hypoplasia	>20
	Scoliosis, kyphosis, lordosis	10-20
	Osteocartilaginous exostosis	?
Neuroendocrine (cranial or cranial spinal)	Impaired growth hormone	>18
	Adrenocorticotropic hormone deficiency	>40
	Thyrotropin-releasing deficiency	>40
	Precocious puberty (females mostly)	>20
	Gonadotropin deficiency	<40
Gonad failure	Ovarian failure	4-12
	Testicular failure	>3
Central nervous system dysfunction*	Structured changes	>18
	Cognitive changes	?
Other	Pulmonary fibrosis	
	Nephropathy	
	Liver failure	
	Arteritis	
	Eye impairment	
	Ear impairment	
	Bone marrow dysfunction	
	Cardiac impairment	

*With intrathecal chemotherapy (methotrexate).

percentage of serious complications (5-10%). Radiation causes tissue loss plus injury to the underlying vasculature. The vascular change may be progressive, leading to arteriocapillary fibrosis and irreparable injury, in turn leading to further tissue loss.

The acute effects of therapy (occurring less than 3 mo after therapy begins) are usually related to the area of the body being irradiated (except fatigue, which can begin during this time period). These acute effects include radiation-caused pneumonitis, dermatitis, mucositis and esophagitis, cerebral edema, and swelling of the organ irradiated. There may be changes in bowel movement patterns. Of these, one of the most severe acute reactions is pneumonitis. It can be manifest within 24 hr of irradiation when there is an exudation of proteinaceous material into the alveoli and intraalveolar edema. Most often, however, radiation pneumonitis begins 2-6 mo after the beginning of radiation with a clinical presentation of fever, cough, congestion, and pruritic pain. The late effects of therapy (beginning more than 3 mo after therapy) are numerous (Table 718-6). The most common are abnormalities of pulmonary function, hearing loss, endocrine/reproductive function, cardiac function, and neurocognitive loss.

Annually, childhood cancer affects 70-160 per million children between the ages of 0 and 14 yr. Because of earlier diagnosis and improved therapy, more than 79% of children who were diagnosed from 1995-2001 with cancer are long-term survivors. Approximately 1 in 570 young adults is a long-term survivor of cancer, and up to 25% have a complication related to their therapy. Second cancers account for 6-10% of all cancers in children or adults. Among children in the Childhood Cancer Survivor Study, there is a cumulative incidence of second neoplasms of 3.2% at 20 yr from original diagnosis. Primary malignancies with the highest cumulative incidence of a second neoplasm in the order of frequency are Hodgkin disease (7.6), soft tissue

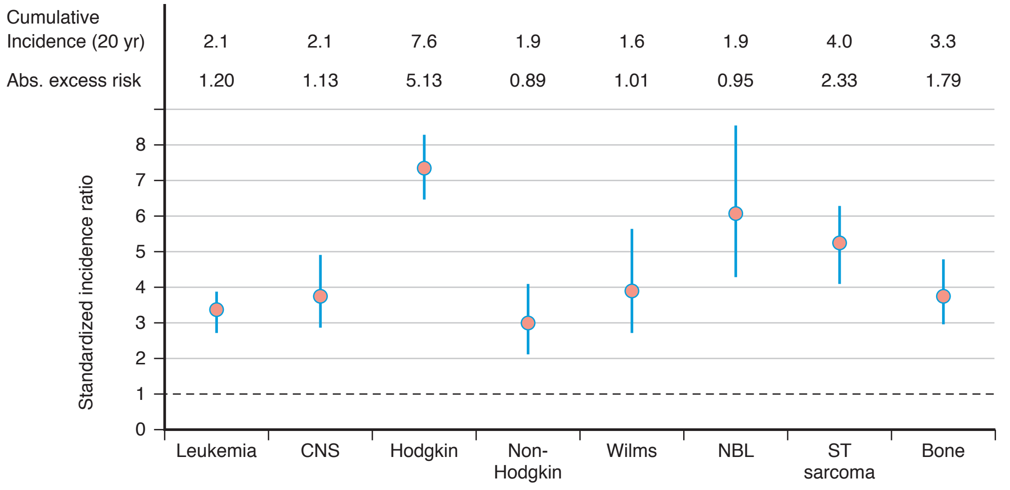

Figure 718-5 Second malignancies among the Childhood Cancer Survivor Study cohort. CNS, central nervous system; NBL, neuroblastoma; ST, soft tissue. *(From Robison LL: Treatment-associated subsequent neoplasms among long-term survivors of childhood cancer: the experience of the Childhood Cancer Survivor Study, Pediatr Radiol 39[Suppl 1]:S32–S37, 2009, Fig. 1.)*

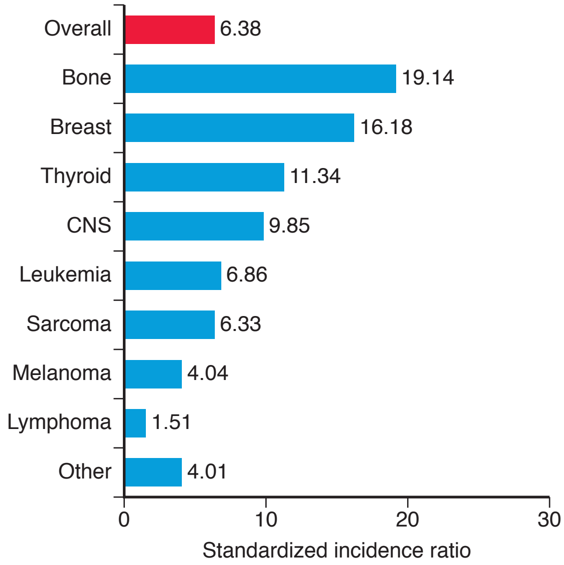

Figure 718-6 Standardized incidence ratio by type of second malignancy. CNS, central nervous system. *(Robison LL: Treatment-associated subsequent neoplasms among long-term survivors of childhood cancer: the experience of the Childhood Cancer Survivor Study, Pediatr Radiol 39[Suppl 1]:S32–S37, 2009, Fig. 2.)*

sarcoma (4.0), cancers of bone (3.3), leukemia (2.1), central nervous system (CNS) cancers (2.1), and non-Hodgkin disease lymphoma (1.9). This reflects an overall standard incidence rate of 6.38% (Fig. 718-5). The most prevalent second tumors are bone, breast, thyroid, and CNS lesions (Fig. 718-6). Table 718-7 relates second cancers to primary cancer and latency period. Almost 70% of the second neoplasms are in the field of the original irradiation. Radiation therapy increases the risk of second cancers in a dose-dependent manner for nongenetic neoplasms.

The exact complications depend on the location of the treatment field. In children, because of the location of many childhood tumors, the normal brain is commonly in the treatment field. Standard irradiation of the brain in children results in cortical atrophy in more than half of patients who receive 2,000-6,000 rads; 26% are left with white matter changes (leukoencephalopathy) and 8% with calcifications. The younger the child is at the time of irradiation, the greater is the atrophy. Some patients also demonstrate mineralizing microangiopathy. Radiation-induced changes of the brain are potentiated by methotrexate administered before, during, or after radiation therapy.

Cerebral necrosis is a serious complication of radiation-induced vascular disease. It usually is diagnosed 1-5 yr after irradiation but can occur up to a decade later. Brain necrosis may manifest as headache, increased intracranial pressure, seizures, sensory deficits, and psychotic changes.

Spinal cord irradiation may result in **radiation myelitis,** which may be either transient or permanent. Acute transient myelitis often appears 2-4 mo after irradiation. Patients with myelitis usually present with **Lhermitte sign,** a sensation of little electrical shocks in the arms and legs occurring with neck flexion or other movements that stretch the spinal cord. Reversal of transient myelopathy usually occurs between 8 and 40 wk and does not necessarily progress to delayed necrosis.

Delayed myelopathy occurs after a mean latent period of 20 mo but can occur earlier if the total dose or the dose per fraction is high. It usually manifests as discontinuous deterioration and is irreversible. In the cervical and thoracic regions, sensory dissociation develops, followed by spastic and then flaccid paresis. In the lumbar cord, flaccid paresis is dominant. The mortality for high thoracic and cervical lesions reaches 70%, death being due to pneumonia and urinary tract infections.

Central nervous system irradiation may also affect growth by compromising function of the pituitary-hypothalamic axis and leading to diminishing growth hormone production and release. Non–growth hormone trophins may also be affected by CNS irradiation, leading to gonadotrophin deficiency or precocious puberty. Central hypothyroidism can also develop. CNS irradiation also compromises bone mineral deposition both locally (in the radiation field) and systemically.

Irradiation also has other effects specific to children (see Table 718-6). Scoliosis and hypoplasia of bones may occur if fractionated treatment schemes exceed 4,000 rad. Fractionated doses higher than 2,500 rad can result in slipped capital femoral epiphyses. An increase in the incidence of benign osteochondromas also has been reported after childhood irradiation. Chest wall irradiation of girls (besides causing breast cancer) may impair breast development and/or cause fibrosis and atrophy of breast tissue.

WHOLE-BODY IRRADIATION

Uncontrolled Large- or Small-Scale Exposure to Radiation

Large-scale exposure to radiation can occur in an event of nuclear accidents, war, or terrorist attacks (see Chapters 39.2 and 723). Radiation as well as explosive and thermal injury need to be considered.

Table 718-7 Second Cancers and Their Relationship with Primary Cancers

SECOND CANCERS	PRIMARY CANCERS	LATENCY (MEDIAN IN Yr)	RISK FACTORS
Brain tumors	ALL; brain tumors; HD	9-10	Radiation; younger age
Myelodysplastic syndromes/acute myelogenous leukemia	ALL; HD; bone tumors	3-5	Topoisomerase II inhibitors; alkylating agents
Breast cancer	HD; bone tumors; soft-tissue sarcomas; ALL; brain tumors; Wilms tumors; NHL	15-20	Radiation; female gender
Thyroid cancer	ALL: HD; neuroblastoma; soft-tissue sarcomas; bone tumors; NH: L	13-15	Radiation; younger age; female gender
Bone tumors	Retinoblastoma (heritable); other bone tumors; Ewing sarcoma; soft-tissue sarcomas; ALL	9-10	Radiation; alkylating agents; removal of the spleen
Soft-tissue sarcomas	Retinoblastoma (heritable); soft-tissue sarcomas; HD; Wilms tumors; bone tumors; ALL	10-11	Radiation; younger age; anthracyclines

ALL, acute lymphocytic leukemia; HD, Hodgkin disease; NHL, non-Hodgkin lymphoma.
From Bhatia S, Sklar S: Second cancers in survivors of childhood cancer. Nat Rev Cancer *2:124–132, 2002.*

Table 718-8 Dose–Effect Relationships After Acute Whole-Body Irradiation from Gamma Rays or X-Rays

WHOLE-BODY ABSORBED DOSE, RAD (Gy)	FINDINGS
5 (0.05)	Asymptomatic
15 (0.15)	Asymptomatic (but chromosome aberrations may be present in cultured peripheral lymphocytes)
50 (0.5)	Asymptomatic (minor depression of white blood cell and platelet counts in a few persons)
100 (1.0)	Nausea and vomiting in approximately 10% of patients within 2 days of exposure
200 (2.0)	Nausea and vomiting in most persons exposed, with clear hematologic depression
400 (4.0)	Nausea, vomiting, and diarrhea within 48 hr; 50% mortality without medical treatment
600 (6.0)	100% mortality within 30 days from bone marrow failure without medical treatment
5,000 (50.0)	Cardiovascular collapse and central nervous system damage, with death in 24-72 hr

Table 718-9 Expected Outcome Based on Absolute Lymphocyte Count After Acute Penetrating Whole-Body Irradiation

MINIMAL LYMPHOCYTE COUNT WITHIN FIRST 48 HR AFTER EXPOSURE	PROGNOSIS
1,000-3,000 (normal range)	No significant injury
1,000-1,500	Significant but probably nonlethal injury, good prognosis
500-1,000	Severe injury, fair prognosis
100-500	Very severe injury, poor prognosis
<100	Lethal without compatible bone marrow donor

Clinical Manifestations

Table 718-8 presents dose–effect relationships for acute whole-body penetrating radiation. A large single exposure of penetrating radiation can result in **acute radiation syndrome.** The signs and symptoms of this syndrome result from damage to major organ systems that have different levels of radiation sensitivity, modulated by the rate at which the radiation exposure occurred. Delivery of 100 rads in 1 min would be symptomatic, but delivery of 1 rad/day for 100 days would not be symptomatic.

The **hematopoietic syndrome** results from acute whole-body doses above 200 rad. A prodromal phase consists of nausea and vomiting within the 1st 12 hr, with symptoms usually lasting up to 48 hr. A latent period of 2-3 wk, during which patients may feel quite well, follows. Although patients are asymptomatic, bone marrow impairment has occurred. The most obvious laboratory finding is lymphocyte depression (Table 718-9). Maximal bone marrow depression occurs approximately 30 days after exposure, when hemorrhage and infection can be major problems. If the bone marrow was not completely eradicated, a recovery phase then ensues. This radiation effect is similar to what occurs when whole-body irradiation (given as 1,200 rads in 2 treatments) is used to obliterate the bone marrow in children with leukemia before bone marrow transplantation.

The **gastrointestinal syndrome** occurs from acute whole-body doses above 800 rads. Prompt onset of nausea, vomiting, and diarrhea follows. There is a latent period of approximately 1 wk followed by recurrence of gastrointestinal symptoms, sepsis, and electrolyte imbalance, which may result in death.

At dose levels exceeding 3,000 rad, the **cardiovascular/CNS syndrome** predominates. Nausea, vomiting, prostration, hypotension, ataxia, and convulsions are almost immediate. Death usually occurs promptly.

Treatment

For the hematopoietic and gastrointestinal syndromes, treatment is supportive, involving transfusions, fluids, antibiotics, and antiviral agents.

Localized Irradiation

Clinical Manifestations

Because localized exposure involves a small amount of tissue, systemic manifestations may be less severe and patients may survive even if locally absorbed doses are very high. The hand is the most common

Table 718-10 Skin Changes After a Single, Acute, Localized Radiation Exposure

ABSORBED DOSE (Gy)	CHANGE
3-4	Epilation in 2-3 wk
10-15	Threshold for erythema; appears 18-20 days after exposure at lower doses; may appear within a few hours at higher doses
20	Moist desquamation, possible ulceration
25	Ulceration with slow healing
30-50	Blistering, necrosis at 3 wk
100	Blistering, necrosis at 1-2 wk

Data from Gusev I, Guskova AK, Mettler FA Jr, editors: Medical management of radiation accidents, *ed 2, Boca Raton, FL, 2001, CRC Press.*

site for accidental localized irradiation injuries, usually as a result of picking up or playing with lost radiation sources. The second most common accidental site is the thigh and buttocks, predominantly from placing unsuspected highly radioactive sources in the pockets.

Table 718-10 lists the skin changes that occur after a single acute, localized irradiation. As opposed to other forms of thermal burns, signs of irradiation appear a period of days *after* the exposure. Vascular insufficiency may appear months to years later and cause ulcerations or necrosis in formerly healed areas. The penetrability of the radiation is an important factor in the outcome of local radiation injury. Beta rays from heavy radiation fallout can cause superficial skin burns because they have low penetrability.

Some tissues that may receive localized radiation exposure are relatively radiosensitive. **Cataract formation** (see Chapter 628) may occur with single gamma ray exposures in the range of less than 1 Gy to several Gy. Such cataracts usually take from 2 mo to several years to develop. **Oligospermia** may take up to 2 mo to develop. Transient infertility in men may result from doses as low as 15 rad, and permanent sterility may occur in men at dose levels between 300 and 600 rad.

Treatment

Skin therapy is directed at prevention of infections. Treatment of localized injuries usually involves plastic surgery and grafting, if the radiation exposure was not very penetrating (see Chapter 75). The nature of the surgery depends on the dose at various depths in tissue and the location of the lesion. The full expression of radiation injury often is not apparent for 1-2 yr, owing to slow arteriolar narrowing that can cause delayed necrosis. After relatively penetrating radiation, amputation may be necessary because of obliterative changes in small vessels.

INTERNAL CONTAMINATION

Epidemiology

Accidents involving internal contamination are rare and are usually the result of misadministration in hospital settings or voluntary ingestion of unsuspected contaminated radioactive materials. Other possible causes of internal contamination of children include ingestion of breast milk from mothers who have had diagnostic nuclear medicine scans and radiation exposure when a parent or sibling receives a therapeutic dose of iodine-131.

Clinical Manifestations

The hazards from internal contamination depend on the nature of both the radionuclide (particularly in terms of its solubility in water, half-life, and radioactive emission) and the chemical compound.

Treatment

The most effective treatment requires knowledge of both the radionuclide and the chemical form. Treatment must be instituted quickly to be effective (Table 718-11). **Removal treatment** involves cleaning a contaminated wound and performing stomach lavage or administration of cathartics in the case of ingestion. Administration of alginate-containing antacids (e.g., Gaviscon) also usually helps in removal by decreasing absorption in the gastrointestinal tract. An example of **blocking therapy** is the administration of potassium iodine or other stable iodine-containing compounds to patients with known internal contamination with radioactive iodine. The stable iodine effectively blocks the thyroid, although its effectiveness decreases rapidly as time elapses after the contamination. The recommended dose of potassium iodine is 16 mg for neonates; 32 mg for children ages 3 yr or younger; and 65 mg for children ages 3-18 yr. Each dose protects for only 1 day. **Dilution therapy** is used in cases of tritium (radioactive hydrogen as water) contamination. Forcing fluids promotes excretion. Cases of internal contamination with transuranic elements (americium and plutonium) may require **chelation therapy** with calcium diethylene triamine pentaacetic acid.

Table 718-11 Specific Therapy for Internal Radiation Contamination

RADIONUCLIDE	THERAPEUTIC APPROACH
Tritium	Dilution (force fluids)
Iodine-125 or iodine-131	Blockage (saturated solution of potassium iodide or potassium iodide), mobilization (antithyroid drugs)
Cesium-134 or cesium-137	Reduction of gastrointestinal absorption (Prussian blue)
Strontium-89 or strontium-90	Reduction of absorption (aluminum phosphate gel antacids), blockage (strontium lactate), displacement (oral phosphate), mobilization (ammonium chloride or parathyroid extract)
Plutonium and other transuranic elements	Chelation with zinc or calcium diethylenetriamine pentaacetic acid (investigational agents)
Unknown	Reduction of absorption (emetics, lavage, charcoal, or laxatives) in cases of ingestion

From Mettler FA, Voelz GL: Major radiation exposure—what to expect and how to respond. N Engl J Med *346:1554, 2002.*

Prussian blue is a drug approved by the FDA for patients with internal contamination with cesium or thallium. It can speed fecal elimination of radioactive cesium from the body. It acts by intercepting the cesium coming into the gut from the bile. Prussian blue prevents the cesium from being absorbed again from the gut. Prussian blue can be given days after ingestion, unlike potassium iodine, which must be given initially in the 1st 12-24 hr after exposure.

EXTERNAL CONTAMINATION

The presence of external radioactive contamination on a patient's skin is not an immediate medical emergency. Management involves removing and controlling the spread of radioactive materials. If a patient has suspected surface contamination and no physical injuries, decontamination can be performed relatively easily. If substantial physical trauma or other life-threatening injuries are combined with external contamination, surface decontamination should proceed only after the patient has been stabilized physiologically. In many accident situations, essential medical care is delayed inappropriately by hospital emergency staff because of fear of radiation or spread of contamination in the hospital. After a radiation accident, triaging of patients is critical and is based on exposure and symptoms (Fig. 718-7).

Chapter 719
Chemical Pollutants

Philip J. Landrigan and Joel A. Forman

More than 85,000 new synthetic chemicals have been developed in the past 75 yr. Most did not previously exist in nature. These chemicals are used today in millions of products ranging from food packaging to clothing, building materials, motor fuels, cleaning products, cosmetics, medical products, toys, and baby bottles.

Synthetic chemicals are widely disseminated in the environment. The Toxic Release Inventory of the U.S. Environmental Protection Agency (EPA) reports that in 2011 more than 4 billion pounds of toxic chemicals were discharged to air, water, and land in the United States.

Human exposure to toxic synthetic chemicals is widespread. Children are especially likely to be exposed to the nearly 3,000 chemicals that are produced in amounts of 1 million pounds or more per yr. These are designated by the EPA as high-production-volume chemicals. Biomonitoring data on blood and urine levels of more than 200 high-production-volume chemicals are obtained annually by the Centers for Disease Control and Prevention in a sample of the U.S. population through the National Health and Nutrition Examination Survey. These data document that American children are exposed to a broad array of synthetic chemicals.

Toxic chemicals are being exported in ever-increasing quantities to the world's poorer countries as these countries pass through industrial development. Environmental safeguards in those countries are typically not as stringent as in the industrially developed nations, and the potential for serious exposure to children there is therefore high.

SYNTHETIC CHEMICALS AND HUMAN HEALTH

Some synthetic chemicals have greatly benefitted human health. Antibiotics have helped control the major communicable diseases. Chemical disinfectants have reduced deaths from dysentery. Chemotherapeutic agents have made possible the cure of many childhood cancers.

But new chemicals have also been responsible for tragic episodes of disease, death, and environmental degradation. Many of these episodes have resulted in severe injury to children. A recurrent pattern has been that new chemicals were brought to market with great enthusiasm, were presumed harmless, and underwent little or no premarket safety testing. Then yr or decades later, after they had come into wide use, established markets, and become widely disseminated in the environment, the chemicals were found to have harmful effects.

Historical examples of synthetic chemicals that were initially hailed as beneficial but later found to cause great harm include *thalidomide*, a mild sedative that proved very effective at suppressing "morning sickness" in the 1st trimester of pregnancy, but later was found to have caused an epidemic of phocomelia in infants exposed in utero; *tetraethyl lead*, which was added to gasoline in the United States from the early 1930s until 1980 and was responsible for widespread lead poisoning with subclinical neurotoxicity and reduction in IQ across 2 generations of U.S. children (see Chapter 721); the pesticide *dichlorodiphenyltrichloroethane (DDT)*, the environmental toxicity of which very nearly led to extinction of the osprey and the American bald eagle and that more recently was linked to increased risk for human breast cancer; the *polychlorinated biphenyls (PCBs)*, highly persistent pollutants of which production was banned in 1977 but which continue today to contaminate major lakes and rivers and which have been found also to be responsible for loss of IQ and disruption of behavior in U.S. children; *diethylstilbestrol (DES)*, which was administered to pregnant women to prevent miscarriage and later found to cause adenocarcinoma of the vagina in girls and young women who had been exposed in utero; and the ozone-destroying *chlorofluorocarbons*.

Other examples of synthetic chemicals that came into wide use with little assessment of their potential hazards include the *phthalates*, plasticizers widely used in plastics, cosmetics, and common household products, which are linked to increased risk for reproductive abnormalities in baby boys and to heightened risk of behavioral abnormalities that resemble attention-deficit/hyperactivity disorder (see Chapter 33); *polybrominated diphenyl ethers*, a class of chemicals widely used as flame retardants in carpets, furniture, and electronic equipment that are linked to persistent loss of intelligence and disruption of behavior; and *bisphenol A*, a plastics chemical that has been linked to neurodevelopmental disorders. These chemicals are all produced in volumes of millions of tons per yr, are widely disseminated in the environment, and are detectable in the bodies of nearly all Americans. Only now, decades after their introduction, are their possible hazards to children's health beginning to be assessed.

CHILDREN'S UNIQUE SUSCEPTIBILITY TO SYNTHETIC CHEMICALS

The health effects of synthetic chemicals are especially serious when exposure occurs in early life—during pregnancy, in infancy, or in early childhood. Children are uniquely vulnerable to chemical pollutants for several reasons:

1. Children have proportionally greater exposures to many environmental pollutants than adults. Because they drink more water, eat more food, and breathe more air per kilogram of body weight, children are more heavily exposed to pollutants in water, food, and air. Children's hand-to-mouth behavior and their play close to the ground further magnify their exposures.
2. Children's metabolic pathways, especially in the 1st few mo after birth, are immature. Although in some instances children are better able than adults to cope with environmental toxicants because they are unable to metabolize them to their active form, children are frequently less able to detoxify and excrete chemical pollutants.
3. Infants and children are growing and developing, and their complex, fast-moving, and highly choreographed developmental processes are uniquely sensitive to disruption by chemical pollutants. Exposures to even minute doses of toxic chemicals during windows of exquisite vulnerability in early development have been shown to cause a wide array of diseases in childhood and also to increase risk for chronic disease and disability lifelong (Table 719-1).
4. Because children have many future years of life, they have time for the development of multistage chronic diseases that may be triggered by early exposures.

Table 719-1 Effects of Selected Chemical Pollutants on Infants and Children

CHEMICAL POLLUTANT	EFFECT(S)
Air pollution	Asthma, other respiratory diseases, sudden infant death syndrome
Asbestos	Mesothelioma and lung cancer
Benzene, nitrosamine, vinyl chloride, ionizing radiation	Cancer
Diethylstilbestrol	Adenocarcinoma of the vagina after intrauterine exposure
Environmental tobacco smoke	Increased risk of sudden infant death syndrome and asthma
Ethyl alcohol	Fetal alcohol syndrome after intrauterine exposure
Lead	Neurobehavioral toxicity from low-dose exposure
Methyl mercury	Developmental neurotoxicity
Organophosphate insecticides	Developmental neurotoxicity
Polychlorinated biphenyls	Developmental neurotoxicity
Polybrominated diphenyl ethers	Developmental neurotoxicity
Phthalates	Developmental neurotoxicity and reproductive impairment
Thalidomide	Phocomelia after intrauterine exposure
Trichloroethylene	Elevated risk of leukemia after intrauterine exposure

The unique susceptibility of infants and children to toxic chemicals—susceptibility that is both quantitatively and qualitatively different from that of adults—is summarized in the phrase “children are not little adults.”

SAFETY TESTING OF SYNTHETIC CHEMICALS

A fundamental problem in environmental pediatrics is that only approximately 65% of high-production-volume chemicals have been tested for their potential hazards to human health, and fewer than 30% have been assessed for their pediatric or developmental toxicity. In the United States, chemicals are regulated under the 1976 Toxic Substances Control Act. Unfortunately, this law is obsolete, broken, and fails to protect children’s health against toxic synthetic chemicals.

At the time of its passage, the Toxic Substances Control Act was intended to be pioneering legislation that would require chemicals already in commerce to be tested for potential toxicity and that would also require premarket safety testing of all new chemicals. The Toxic Substances Control Act never fulfilled these noble intentions. A particularly egregious lapse was a decision by the Congress to “grandfather in” 62,000 chemicals already on the market without any toxicity testing. These chemicals were simply presumed to be safe and allowed to remain in commerce unless the EPA made a finding that they posed an “unreasonable risk.” Under the Toxic Substances Control Act, only 5 chemicals have been banned in the United States in the past 35 yr: PCBs, the ozone-destroying chlorofluorocarbons, dioxin, asbestos, and hexavalent chromium.

In consequence of the failure of current chemical safety legislation in the United States, chemicals are de facto presumed to be safe until they are proven beyond any shadow of doubt to cause harm. New chemicals are brought to the market with little or no safety testing. By contrast, the Registration, Evaluation, Authorization, and Restriction of Chemicals legislation, passed by the European Union in 2006, requires chemicals to be proven safe before they come to market and places the burden on industry to document chemical safety; there is no equivalent in the United States.

The EPA requires the manufacturers of 67 pesticide chemicals to determine whether these chemicals have the potential to disrupt the endocrine system. The results of this request for data led the EPA to develop a new Endocrine Disruptor Screening Program Comprehensive Management Plan that is analyzing the endocrine disrupting properties of chemical pesticides.

The United Nations Environment Programme (UNEP) is the agency within the United Nations that is responsible for the global management of chemicals. UNEP promotes chemical safety by providing information, policy advice, and technical guidance on toxic chemicals to developing and transitional countries. UNEP advocates for the establishment of international treaties to ban and control chemical substances. UNEP coordinates with other international organizations such as the Food and Agriculture Organization of the United Nations. UNEP has been centrally involved in partnership with the World Health Organization in coordinating the global effort to remove lead from gasoline in countries around the world.

SYNTHETIC CHEMICALS AND DISEASE IN CHILDREN

A large and growing body of evidence accumulated over the past 5 decades documents that chemical pollutants in the environment can cause disease and dysfunction in children. High-dose exposures can cause acute, clinically evident disease. Lower-dose exposures can cause subclinical injury—injury that is very real but detectable only through special testing—such as decreases in intelligence, shortening of attention span, and disruption of behavior. When exposure to a chemical pollutant is widespread, subclinical toxicity can reduce intelligence and cause other adverse effects across entire societies (Fig. 719-1).

CHEMICAL POLLUTANTS OF MAJOR CONCERN

Air Pollutants

The outdoor air pollutants of greatest concern are photochemical oxidants (especially ozone), oxides of nitrogen, fine particulates, sulfur oxides, and carbon monoxide. These pollutants result principally from the combustion of fossil fuels. Automotive emissions are the major source of air pollution worldwide, followed by stationary sources such as coal-fired power plants and other industrial sources.

Elevated values of air pollutants, especially fine particulates, ozone, and oxides of nitrogen, are associated with respiratory problems in children, including decreased pulmonary expiratory flow, wheezing, and exacerbations of asthma. Fine particulate air pollution, even at low levels, is associated with slight increases in cardiopulmonary mortality and with an increased death rate from sudden infant death syndrome (see Chapter 375). A prospective cohort study of air pollution and lung development in California found an association between pollution and reduced lung growth from ages 10-18 yr, which leads to clinically significant decreases in lung function that persist into adulthood. It is notable that these effects were seen at air toxic levels below the National Ambient Air Quality Standards set by the EPA under the Clean Air Act.

Indoor air also can be an important source of respiratory irritation, because many children spend 80-90% of their time indoors. Globally, indoor air pollution is largely caused by household use of solid fuel, such as wood, charcoal, or dung. According to the World Health Organization, globally more than 2 million children < age 5 yr die each year from acute respiratory infections of which 50% are attributable to the indoor burning of biomass fuels. Indoor air pollution has become especially important in the United States since the energy crises of the 1970s, which led to the construction of tighter, more energy-efficient homes. Second-hand cigarette smoke is an especially hazardous constituent of indoor air and a powerful asthma trigger. Allergens in indoor air can contribute to respiratory problems and include cockroach, mite, mold, and cat and dog allergens.

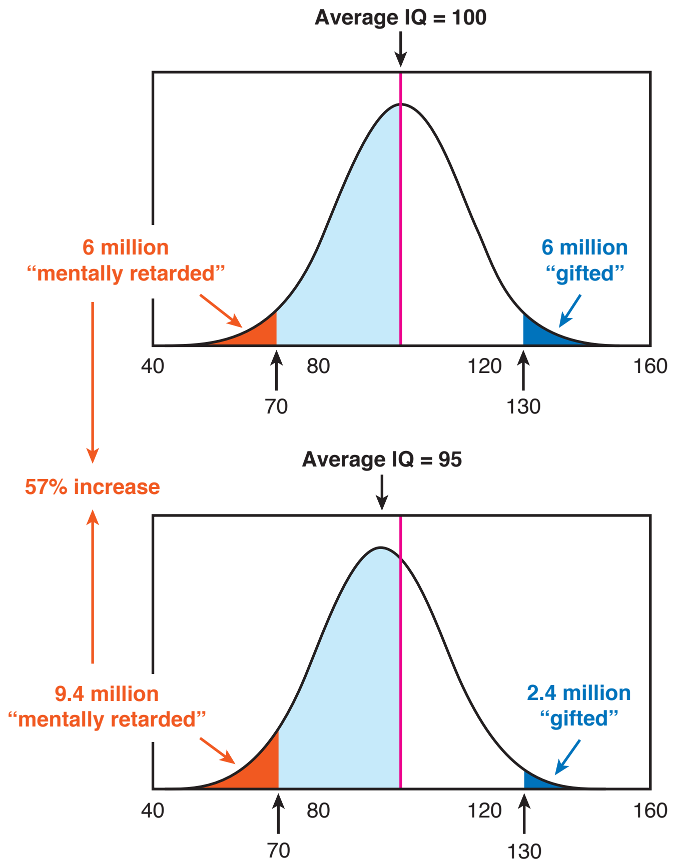

Figure 719-1 **Societal impact of subclinical neurotoxicity.** Widespread exposure to a neurotoxic chemical pollutant that reduces average IQ by 5 points can reduce the number of children in a society with truly superior intelligence (IQ scores above 130 points) by more than 50% and likewise cause a more than 50% increase in the number with IQ scores below 70, thus increasing the number of children who do poorly in school, require special education and other remedial programs, and cannot contribute fully to society when they become adults. Although subclinical effects may be small at the individual level, the aggregate effects at a population level can have far-reaching consequences. And until the toxicity is recognized, the damage can proceed unchecked for many years. *(From Schettler, T Stein J, Reich F, Valenti M.* In harm's way: toxic threats to child development. A report by Greater Boston Physicians for Social Responsibility, *2000, p 25. Available at: http://www.psr.org/chapters/boston/resources/in-harms-way.html.)*

Oil Spill Hazards

Through 2014, there have been at least 36 crude oil spills worldwide. Ten of these spills have occurred since 1980, the largest in 2010. Although specific composition and concentrations vary, crude oil contains many toxic chemicals that are of concern to human health, including metals (e.g., zinc, cadmium, and lead) (see Chapters 720 and 721), volatile organic compounds (including benzene, toluene, ethyl benzene, and styrene), and semivolatile organics (such as polycyclic aromatic compounds). Several of these compounds are classified as possible or potential carcinogens, endocrine disruptors, and neurotoxins. Chemical dispersants—mixtures of detergents and organic solvents—are often used to break up spilled oil and may also have potential adverse effects on health. Toxic effects may occur from exposure during contact with the skin, eyes, or respiratory tract or in a person's diet (e.g., drinking of contaminated water or eating of contaminated seafood).

Commonly reported symptoms from direct exposure to crude oil include eye redness and burning, rashes, sore throat, respiratory difficulty, and acute neurologic symptoms such as headache and nausea. Children with asthma may be particularly vulnerable to respiratory toxicity. The amount and duration of exposure along with individual genetic variability influence the degree of symptoms.

Most information on health effects of oil spills comes from studies of exposed adult workers; there are few studies of health effects, acute or long term, in children. Studies of workers exposed to spilled oil have noted elevated blood concentrations of heavy metals such as lead and cadmium, evidence of genotoxic effects, and endocrine disruption (as manifested by changes in prolactin and cortisol levels). Children and teens are at risk for exposure in a variety of settings, including recreational activities like swimming and boating as well as clean-up efforts. Children should not be allowed to play in or around areas where the water or beach contains oil or sludge. In light of teenagers' propensity to not adhere as well as adults to workplace safety regulations, teens should not be directly involved in spill clean-up efforts.

Lead

See Chapter 721.

Mercury

See Chapter 720.

Asbestos

Between 1947 and 1973, asbestos was sprayed as insulation on classroom walls and ceilings in approximately 10,000 schools in the United States. Subsequent deterioration of this asbestos has released asbestos fibers into the air. Asbestos is not a health hazard so long as it is intact, but once it becomes airborne, it can be inhaled by children to produce adverse health effects. Asbestos is a human carcinogen, and the 2 principal cancers caused by asbestos are lung cancer and mesothelioma. U.S. federal law requires that all schools be inspected periodically for asbestos and that the results be made public. Removal is required only when asbestos is visibly deteriorating or is within the reach of children. In most cases, placement of barriers (drywall walls or drop ceilings) provides appropriate protection.

Second-Hand Tobacco Smoke

Smoking during pregnancy poses a hazard to the fetus (see Chapter 96). Infants born to women who smoke are, on average, 10% smaller than infants born to nonsmoking women. Infants of parents who smoke have a higher risk of sudden infant death syndrome. Nicotine from tobacco smoke appears to be a developmental neurotoxin.

Second-hand smoke exposure is also a hazard to children. The United States has made substantial progress in reducing exposure to second-hand smoke over the last 15 yr and serum cotinine levels have declined by 70% in U.S. nonsmokers of all ages. Children <12 yr old continue to have mean cotinine levels twice those of adults, highlighting their unique vulnerability. Children exposed to second-hand tobacco smoke have increased frequency of lower respiratory illness, more middle-ear effusions, and more viral respiratory illnesses than unexposed children.

Pesticides

Pesticides are a diverse group of chemicals used to control insects, weeds, fungi, and rodents. Approximately 600 pesticides are registered with the EPA for use in the United States.

Diet is a major route of children's exposure to pesticides, because children are exposed to residues of multiple pesticides on fruit and vegetables, especially fruits and vegetables imported from countries where pesticide use is heavier than in the United States. Children also may be exposed in homes or schools, on lawns, and in gardens. They may be exposed to pesticide drift from agricultural areas that have been sprayed. Children employed in agriculture or living in migrant farm camps are at risk of direct exposure to many pesticides.

Children can be acutely overexposed to pesticides. High-dose exposure to both organophosphates and carbamate pesticides can cause acute neurotoxicity. Both of these classes of pesticides act through inhibition of acetylcholinesterase and are responsible for the largest number of acute poisoning cases. Symptoms include meiosis (although not in all cases), excess salivation, abdominal cramping, vomiting,

diarrhea, and muscle fasciculation. In severe cases, the child may experience loss of consciousness, cardiac arrhythmias, and death by respiratory arrest. The war gas sarin is an organophosphate. See Chapter 63 for treatment of poisoning from drugs, chemicals, and plants.

Pesticides can also cause a range of chronic toxic effects: polyneuropathy and central nervous system dysfunction (organophosphates); hormonal disruption and reproductive impairment (DDT, kepone, dibromochloropropane); cancer (aldrin, dieldrin, chlorophenoxy herbicides [2,4,5-T]); and pulmonary fibrosis (paraquat). Prenatal exposure to organophosphate pesticides at levels that produce no evident toxicity in pregnant women has been associated with neurodevelopmental disability in children, with reduction in IQ and disordered executive function.

Children's exposures to pesticides can be reduced by minimizing applications to lawns, gardens, schools, and playgrounds; adapting techniques of integrated pest management; and reducing pesticide applications to food crops. Consumption of organic produce dramatically reduces organophosphate pesticide exposure in school-age children. Exposure to herbicides may increase due to an EPA decision to expand their use in agriculture.

Polychlorinated Biphenyls, DDT, Dioxins, Brominated Flame Retardants, and Other Halogenated Hydrocarbons

Chlorinated hydrocarbons are used as insecticides (DDT), plastics (polyvinyl chloride), electrical insulators (PCBs), and solvents (trichloroethylene). Highly toxic dioxins and furans are formed during synthesis of chlorinated herbicides or as by-products of plastic combustion. All of these materials are widely dispersed in the environment. Brominated flame retardants are used in carpets, furniture, and computers. DDT, PCBs, and dioxins are highly persistent.

The embryo, fetus, and young child are at particularly high risk of injury from halogenated hydrocarbons. All of these compounds are lipid-soluble. They readily cross the placenta, and they accumulate in breast milk. Intrauterine exposure to PCBs and brominated flame retardants has been linked to persistent neurobehavioral dysfunction in children.

Fish from contaminated waters are a major source of children's exposure to PCBs. Children can be exposed in utero or through breast milk. To protect children and pregnant women in the United States against PCBs in fish, government agencies have issued advisories concerning fish consumption for certain lakes and rivers. Combustion of medical wastes containing polyvinyl chloride and the use of chlorine to bleach paper products are major preventable sources of environmental dioxin and should be discouraged. Older fluorescent light ballasts that were installed decades ago in schools in the United States are another source of PCB exposure. PCB-containing ballasts should be removed from schools as soon as possible to prevent environmental contamination. Removal must be performed by trained workers.

Endocrine Disruptors

A number of chemicals have been shown to adversely affect the endocrine systems of animals and humans, including DES, DDT, PCBs, and dioxins. Other chemicals, such as other pesticides and phthalates (plasticizers), are also suspected of possessing endocrine disruptor effects. Phthalates have been associated with obesity in animal experiments. Higher urinary levels of bisphenol A are associated with obesity-related outcomes, such as cardiovascular disease, in a cross-sectional analysis of National Health and Nutrition Examination Survey 2003-2004 data in adults. The many effects of endocrine disruptors on wildlife include eggshell thinning in birds, sterility in seals, feminization and cryptorchidism in panthers, and low hatching rates in alligators. In humans, endocrine disruption is implicated in the epidemiologic observations of a trend toward earlier thelarche and menarche in girls (see Chapter 14), the rising rates of testicular cancer and hypospadias, and diminishing sperm counts. The most clearly observed effects include adenocarcinoma of the vagina in women and cryptorchidism in men whose mothers took DES and shortening of the anogenital distance, a measure of in utero feminization, in baby boys whose mothers had elevated exposures to phthalates during pregnancy. The presence of elevated concentrations of plasma phthalate esters is associated with early thelarche in Puerto Rican girls. Some endocrine disruptors may also have adverse effects on brain development. Prenatal exposure to low-molecular-weight phthalates is associated with shortening of attention span in children 4-9 yr old.

Environmental Carcinogens

Children may be exposed to carcinogenic pollutants in utero or after birth. Children appear more sensitive than adults to certain chemical carcinogens and also to ionizing radiation (see Chapter 718). The potential for in utero carcinogenesis was first recognized with the discovery that clear cell adenocarcinoma of the vagina could develop in women after intrauterine exposure to DES.

Carcinogenesis also may be associated with exposures in the home and community. Children of asbestos workers and children who have grown up near asbestos plants have been found to have a higher incidence of mesothelioma than unexposed populations. Children who grow up on farms have elevated rates of leukemia; pesticides are suspected of playing an etiologic role. Intrauterine exposure to trichloroethylene via contaminated drinking water has been associated with an increased incidence of leukemia among girls living near an industrial facility and industrial waste site.

Routes of Exposure

Transplacental. Heavy metals such as lead and mercury, fat-soluble compounds such as PCBs and DDT, and endocrine disruptors such as phthalates readily cross the placenta. They may have serious and irreversible toxic effects on the developing nervous, endocrine, and reproductive organs, even at very low levels.

Water. Approximately 200 chemicals have been found in various amounts in water supplies. Lead is especially common. In some older neighborhoods, lead in water derives from lead pipes. More commonly, it is dissolved (leached) by soft, acidic water from lead-containing solder. The highest levels of lead occur in water that has been standing in pipes overnight. It is wise therefore to run water for 2-3 min each morning before making up infant formula. Solvents and components of gasoline such as methyl tertiary-butyl ether and benzene are commonly encountered in groundwater. Herbicides, like atrazine, are commonly found contaminants in drinking water in agricultural areas.

Air. Vehicular emissions are the major source of urban air pollution. Diesel exhaust is a human carcinogen. In rural areas, wood smoke can contribute to air pollution. Children living in the vicinity of smelters and chemical production plants can be exposed to toxic industrial emissions such as lead, benzene, and 1,3-butadiene.

Food. Many chemicals are intentionally added to food to improve appearance, taste, texture, or preservation, but many such chemicals have been poorly tested for potential toxicity. Residues of many pesticides are found in both raw and processed foods. Levels of pesticides are lower in organic produce than in conventionally grown fruits and vegetables. Children who consume organic produce have substantially lower urinary pesticide levels than children who eat conventional produce.

Work Clothes. Illnesses in children sometimes may be traced to contaminated dust from parents' work clothes; toxicity from lead, beryllium, dioxin, organophosphate pesticides, and asbestos has occurred. Such exposure (termed "fouling the nest") can be prevented by providing facilities at work for changing and showering.

Schools. Children may be exposed in schools, kindergartens, and nurseries to lead paint, molds, asbestos, environmental tobacco smoke, pesticides, and hazardous arts and crafts materials. Substantial opportunities for prevention exist in the school environment, and pediatricians are often consulted for advice.

Child Labor. Four to 5 million children and adolescents in the United States work for pay, and child labor is widespread around the world. Working children are at high risk of physical trauma and injury. They also may be exposed to a wide range of toxic chemicals, including

pesticides in agriculture and lawn work, asbestos in construction and building demolition, and benzene in pumping gasoline.

THE PHYSICIAN'S ROLE

Pediatricians have time and again played key roles in the initial recognition of diseases caused by toxic chemicals. Every pediatrician needs to be an "alert clinician" ever open to the possibility of discovering new diseases in children caused by exposures in the environment. In considering the origins of noninfectious disease, pediatricians should ask about the home environment, parental occupation, unusual exposures, and neighborhood factories. An environmental cause is particularly likely when several unusual cases of disease or constellations of findings occur together. Any adolescent with a traumatic injury may have been injured at work.

The history is the single most important instrument for obtaining information on environmental exposures. Information about current and past exposures (including questions about work and travel to or residence in developing countries) should be sought routinely on every new patient and on every patient with illness of unclear causation through a few brief screening questions. Changes in patterns of exposure or new exposures may be especially important. If suspicious information is elicited, more detailed follow-up should be pursued. Referral to a pediatric environmental health specialty unit may be indicated (http://aoec.org/PEHSU/index.html). Accurate diagnosis of an environmental cause of disease can lead to better care of sick children and prevention of disease in other children.

Chapter 720

Heavy Metal Intoxication

Prashant V. Mahajan

Lead, mercury, arsenic, and cadmium, 4 of the World Health Organization's (WHO) "10 chemicals of greatest public health concern," are the heavy metals posing the greatest threats to humans. The most prevalent of these exposures is lead (see Chapter 721). This chapter discusses mercury and arsenic.

Heavy metal intoxication results in diverse multiorgan toxicity through widespread disruption of vital cellular functions. A meticulous history of environmental exposure may be necessary to correctly identify heavy metals as the source of the protean manifestations associated with such exposure. Arsenic exposure can occur from contaminated food or water; globally, more than 100 million people are estimated to be chronically exposed to drinking water containing high arsenic levels. Mercury exposure occurs primarily through food; fish is a major source of methyl mercury exposure.

ARSENIC

Epidemiology

Arsenic is a metalloid that exists in 4 forms: elemental arsenic, arsine gas, inorganic arsenic salts (pentavalent arsenate form or trivalent arsenite form), and organic arsenic compounds. Toxic manifestations are higher in the more soluble and higher-valence compounds. **Arsine gas** is the most toxic form of arsenic. Mass poisonings from exposure to arsenic have occurred throughout history, including one in 1998 in Wakayama, Japan, in which 70 people were poisoned. Children may be poisoned after exposure to inorganic arsenic found in pesticides, herbicides, dyes, homeopathic medicines, and certain contaminated folk remedies from China, India, and Southeast Asia (see Chapter 64). Soil deposits contaminate artesian well water. Groundwater contamination with arsenic is a common problem in developing countries and has been reported to be a common well contaminant in Alaska, Maine, North Carolina, and areas in western United States. Food products (e.g., rice, organic brown rice syrup, fruit juices) cooked in contaminated water may actually absorb arsenic, thus concentrating it in the food. The WHO has set 10 µg/L as the upper limit of safety. In many parts of Asia and South America, this limit is frequently exceeded. Arsenic concentrations in one quarter of the wells in Bangladesh exceed 50 µg/L and 35-77 million of the 125 million inhabitants of Bangladesh regularly consume arsenic-contaminated water. Occupational exposure may occur in industries involved in the manufacturing, mining, smelting, or refining of glass, pottery, electronic and semiconductor components, and lasers. Although arsenic is no longer produced in the United States, it is produced in many countries and is imported into the United States for industrial use. Organic arsenic compounds may be found in seafood, pesticides, and some veterinary pharmaceuticals. In contrast to mercury, the organic forms of arsenic found in seafood are nontoxic.

Pharmacokinetics

Elemental arsenic is insoluble in water and bodily fluids and, therefore, is insignificantly absorbed and nontoxic. Inhaled arsine gas is rapidly absorbed through the lungs. The inorganic arsenic salts are well absorbed through the gastrointestinal tract, lungs, and skin. The organic arsenic compounds are well absorbed through the gastrointestinal tract. After acute exposure, arsenic initially is bound to the protein portion of hemoglobin in the red blood cells (RBCs) and rapidly distributed to all tissues. Inorganic arsenic is methylated and is eliminated predominantly by the kidneys, with approximately 95% excreted in the urine and 5% excreted in the bile. Most of the arsenic is eliminated in the 1st few days, with the remainder slowly excreted over a period of several weeks. Arsenic concentrates in hair, nails, and skin. Measurement of the distance of **Mees lines** (transverse white striae on the nail) from the nail bed can provide an estimate of time of exposure (nails grow at the rate of 0.4 mm/day).

Pathophysiology

After exposure to arsine gas, absorbed arsine enters RBCs and is oxidized to arsenic dihydride and elemental arsenic. Complexing of these derivatives with red cell sulfhydryl groups results in cell membrane instability and massive hemolysis. The inorganic arsenic salts poison enzymatic processes vital to cellular metabolism. Trivalent arsenic binds to sulfhydryl groups, resulting in decreased production of adenosine triphosphate through the inhibition of enzyme systems such as the pyruvate dehydrogenase and α-ketoglutarate complexes. Pentavalent arsenic may be biotransformed to trivalent arsenic or substituted for phosphate in the glycolytic pathway, resulting in uncoupling of oxidative phosphorylation.

Clinical Manifestations

Arsine gas is colorless, odorless, nonirritating, and highly toxic. Inhalation causes no immediate symptoms. After a latent period of 2-24 hr, exposed individuals experience massive hemolysis, malaise, headache, weakness, dyspnea, nausea, vomiting, abdominal pain, hepatomegaly, pallor, jaundice, hemoglobinuria, and renal failure (Table 720-1). Acute ingestion of arsenic produces gastrointestinal toxicity within minutes to hours and is manifested as nausea, vomiting, abdominal pain, and diarrhea. Hemorrhagic gastroenteritis with extensive fluid loss and third spacing may result in hypovolemic shock. Cardiovascular toxicity includes QT interval prolongation, polymorphous ventricular tachycardia, congestive cardiomyopathy, pulmonary edema, and cardiogenic shock. Acute neurologic toxicity includes delirium, seizures, cerebral edema, encephalopathy, and coma. Lethal doses of arsenates are 5-50 mg/kg; lethal doses of arsenites are <5 mg/kg.

Late sequelae include hematuria, proteinuria, and acute tubular necrosis. A delayed sensorimotor peripheral neuropathy may appear days to weeks after acute exposure, secondary to axonal degeneration. Neuropathy manifests as painful dysesthesias followed by diminished vibratory, pain, touch, and temperature sensation; decreased deep tendon reflexes; and, in the most severe cases, an ascending paralysis with respiratory failure mimicking Guillain-Barré syndrome (see

Chapter 616). Adult survivors of infant arsenic poisoning experience higher mortality from disorders of the nervous system compared to adults without such exposure.

Subacute toxicity is characterized by prolonged fatigue, malaise, weight loss, headache, chronic encephalopathy, peripheral sensorimotor neuropathy, leukopenia, anemia, thrombocytopenia, chronic cough, and gastroenteritis. Mees lines in the nails become apparent 1-2 mo after exposure in approximately 5% of patients. Dermatologic findings include alopecia, oral ulceration, peripheral edema, a pruritic macular rash, and desquamation.

Chronic arsenic toxicity causes significant morbidity in children resulting in skin lesions, lung disease, and defect in intellectual function. **Chronic exposure** to low levels of arsenic is usually from environmental or occupational sources. Over the course of years, dermatologic lesions develop, including hyperpigmentation, hypopigmentation, hyperkeratoses (especially on the palms and soles), squamous and basal cell carcinomas, and **Bowen disease** (cutaneous squamous cell carcinoma in situ). Encephalopathy and peripheral neuropathy may be present. Hepatomegaly, hypersplenism, noncirrhotic portal fibrosis, and portal hypertension occur. **Blackfoot disease** is an obliterative arterial disease of the lower extremities associated with chronic arsenic exposure that has been described in Taiwan. Carcinogenicity of chronic arsenic exposure is reflected in increased rates of cancers of the skin, lung, liver, bladder, and kidney as well as of angiosarcomas. The effects of prenatal exposure to arsenic are uncertain but may include low birthweight.

Table 720-1 Effects of Arsenic on Organ Systems

ORGAN SYSTEM	EFFECTS OF ARSENIC
Gastrointestinal system	Submucosal vesicles, watery or bloody diarrhea, severe hematemesis
Cardiovascular system	Reduced myocardial contractility, prolonged QT intervals, tachyarrhythmias
	Vasodilation, hypotension
Kidneys	Hematuria, proteinuria, acute tubular necrosis
Nervous system	Toxic encephalopathy with seizures, cerebral edema, and coma
	Chronic exposure: peripheral painful sensorimotor neuropathy
Hematologic and lymphatic system	Anemia and thrombocytopenia; acute hemolysis with arsine gas
Liver	Fatty degeneration with central necrosis
Skin	Desquamation, alopecia, hyperkeratosis, nail changes
	Chronic exposure: hyperkeratosis, hyperpigmentation
Teratogenic	Neural tube defects in the fetus
Oncologic	Urologic cancer, other malignancies

Laboratory Findings

The diagnosis of arsenic intoxication is based on characteristic clinical findings, a history of exposure, and elevated urinary arsenic values, the last of which confirm the exposure. A spot urine arsenic level should be determined for symptomatic patients before chelation, although initially the result may be negative. Because urinary excretion of arsenic is intermittent, definitive diagnosis depends on a 24 hr urine collection. Concentrations greater than 50 μg/L in a 24 hr urine specimen are consistent with arsenic intoxication (Table 720-2). Urine specimens must be collected in metal-free containers. Ingestion of seafood containing nontoxic arsenobetaine and arsenocholine can cause elevations of urinary arsenic. Blood arsenic levels rarely are helpful because of their high variability and the rapid clearance of arsenic from the blood in acute poisonings. Elevated arsenic values in the hair or nails must be interpreted cautiously because of the possibility of external contamination. Abdominal radiographs may demonstrate ingested radiopaque arsenic.

Later in the course of illness, a complete blood cell count may show anemia, thrombocytopenia, and leukocytosis, followed by leukopenia, karyorrhexis, and basophilic stippling of RBCs. The serum concentrations of creatinine, bilirubin, and transaminases may be elevated; urinalysis may show proteinuria, pyuria, and hematuria; and examination of the cerebrospinal fluid may show protein elevations.

MERCURY

Epidemiology

Mercury exists in 3 forms: elemental mercury, inorganic mercury salts, and organic mercury (Table 720-3). **Elemental mercury** is present in thermometers, sphygmomanometers, barometers, batteries, and some latex paints produced before 1991. Workers in industries producing these products may expose their children to the toxin when mercury is brought home on contaminated clothing. Vacuuming of carpets contaminated with mercury and breaking of mercury fluorescent light bulbs may result in elemental mercury vapor exposure. Severe inhalation poisonings have resulted from attempts to separate gold from gold ore by heating mercury and forming a gold-mercury amalgam. Elemental mercury has been used in folk remedies by Asian and Mexican populations for chronic stomach pain, by Latin Americans and Caribbean natives in occult practices, and as a skin-lightening agent. Dental amalgams containing elemental mercury release trace amounts of mercury. An expert panel for the National Institutes of Health concluded that existing scientific evidence does not indicate that dental amalgams pose a health risk and should not be replaced merely to decrease mercury exposure. A 2009 WHO expert panel concluded that a global near-term ban on amalgam would be problematic for public and dental health. However, this committee recommended that alternatives to amalgam should be sought as part of a phase-out of the use of mercury-containing amalgams.

Inorganic mercury salts are found in pesticides, disinfectants, antiseptics, pigments, dry batteries, and explosives and as preservatives in some medicinal preparations. **Organic mercury** in the diet, especially fish containing methyl mercury, is a major source of mercury exposure among the general population. Industries that may produce mercury-containing effluents include chlorine and caustic soda production, mining and metallurgy, electroplating, chemical and textile manufacturing, paper and pharmaceutical manufacturing, and leather tanning. Mercury compounds in the environment are methylated to methyl

Table 720-2 Acceptable and Toxic Levels of Arsenic and Mercury

	ARSENIC	MERCURY
Molecular weight	74.9 Da	200.59 Da
Acceptable blood level	<5 μg/L (<0.665 nmol/L)	<10 μg/L (<50 nmol/L)
Acceptable urine level	<50 μg/L (<6.65 nmol/L) 24 hr urine sample	<20 μg/L (<100 nmol/L)
Intervene at blood level		>35 μg/L (>175 nmol/L)
Intervene at urine level	>100 μg/L (>13.3 nmol/L) 24 hr urine sample	>150 μg/L (>750 nmol/L)

Table 720-3 Differential Characteristics of Mercury Exposure

	ELEMENTAL	INORGANIC (SALT)	ORGANIC (ALKYL)
Primary route of exposure	Inhalation	Oral	Oral
Primary tissue distribution	CNS, kidney	Kidney	CNS, kidney, liver
Clearance	Renal, GI	Renal, GI	Methyl: GI Aryl: renal, GI
Clinical effects:			
CNS	Tremor	Tremor, erethism (irritability)	Paresthesias, ataxia, tremor, tunnel vision, dysarthria
Pulmonary	+++	—	—
Gastrointestinal	+	+++ (caustic)	+
Renal	+	+++ (acute tubular necrosis)	+
Acrodynia	+	++	—
Therapy	BAL, DMSA	BAL, DMSA	DMSA (early)

BAL, British antilewisite; CNS, central nervous system; DMSA, 2,3-dimercaptosuccinic acid; GI, gastrointestinal; +, mild; ++, moderate; +++, severe.

From Sue YJ: Mercury (heavy metals). In Nelson LS, Lewin NA, Howland MA, et al, editors: Goldfrank's toxicologic emergencies, *ed 9, New York, 2011, McGraw-Hill, Tab 96-4, p. 1330.*

mercury by soil and water microorganisms. Methyl mercury in the water rapidly accumulates in fish (swordfish, king mackerel, fresh tuna, tile fish, shark) and other aquatic organisms, which are in turn consumed by humans. To address concerns that maternal consumption of large quantities of fish during pregnancy may expose the fetus to concentrations of mercury with adverse consequences, the longitudinal Seychelles Child Development Study has been ongoing since the late 1980s. The first cohort of the study involved nearly 800 mother–child pairs, with subsequent cohorts enrolled. Despite a high maternal fish intake (mean of 12 fish meals per wk), follow-up of children at least through 9 yr of age has revealed no consistent adverse developmental effects. Well-known large outbreaks of methyl mercury intoxication include the incidents in Japan in the 1950s (**Minamata disease,** from consumption of contaminated seafood) and in Iraq in 1971 (from consumption of grain treated with a methyl mercury fungicide).

Thimerosal is a mercury-containing preservative used in some vaccines. Thimerosal contains 49.6% mercury by weight and is metabolized to ethyl mercury and thiosalicylate. During an ongoing review of biologic products in response to the U.S. Food and Drug Administration (FDA) Modernization Act of 1997, the FDA determined that infants who received thimerosal-containing vaccines at multiple visits might have been exposed to more mercury than recommended by federal guidelines. As a precautionary measure, the American Academy of Pediatrics, American Academy of Family Physicians, Advisory Committee on Immunization Practices, and U.S. Public Health Service issued a joint recommendation in 1999 that thimerosal be removed from vaccines as quickly as possible. *In the United States, thimerosal has been removed from all vaccines in the recommended childhood immunization schedule.* Infants and children who have received thimerosal-containing vaccines do not need to undergo blood, urine, or hair testing for mercury because the concentrations of mercury would be quite low and would not require treatment. The benefits and risks of vaccines containing thimerosal should be discussed with parents (as with all vaccines). The larger risks of not vaccinating children far outweigh any known risk of exposure to thimerosal-containing vaccines. Studies do *not* demonstrate a link between thimerosal-containing vaccines and autistic spectrum disorders (see Chapter 30.1), and no evidence supports a change in the standard of practice with regard to administration of thimerosal-containing vaccines in areas of the world where they are used. A rise in blood mercury levels following a single dose of hepatitis vaccine was seen in preterm infants, but the clinical significance is unknown.

Pharmacokinetics

Inhaled elemental mercury vapor is 80% absorbed by the lungs and is distributed rapidly to the central nervous system because of its high lipid solubility. The elemental mercury is oxidized by catalase to the mercuric ion, which is the reactive form that causes cellular toxicity. Elemental mercury liquid is poorly absorbed from the gastrointestinal tract, with less than 0.1% being absorbed. The half-life of elemental mercury in the tissues is approximately 60 days, most of the excretion occurring in the urine.

Inorganic mercury salts are approximately 10% absorbed from the gastrointestinal tract and cross the blood–brain barrier to a lesser extent than elemental mercury. Mercuric salts are more soluble than mercurous salts and, therefore, produce greater toxicity. Elimination occurs primarily in the urine, with a half-life of approximately 40 days.

Methyl mercury is the most avidly absorbed of the organic mercury compounds, with approximately 90% absorbed from the gastrointestinal tract. The lipophilic, short-chain alkyl structure of methyl mercury allows it to distribute rapidly across the blood–brain barrier and placenta. Methyl mercury is approximately 90% excreted in the bile, with the remainder being excreted in the urine. The half-life is 70 days.

Pathophysiology

After absorption, mercury is distributed to all tissues, particularly the central nervous system and kidneys. Mercury reacts with sulfhydryl, phosphoryl, carboxyl, and amide groups, resulting in disruption of enzymes, transport mechanisms, membranes, and structural proteins. Widespread cellular dysfunction or necrosis results in the multiorgan toxicity characteristic of mercury poisoning.

Clinical Manifestations

Five syndromes describe the clinical presentation of mercury poisoning. **Acute inhalation of elemental mercury vapor** results in rapid onset of cough, dyspnea, chest pain, fever, chills, headaches, and visual disturbances. Gastrointestinal findings include metallic taste, salivation, nausea, vomiting, and diarrhea. Depending on the severity of the exposure, the illness may be self-limited or may progress to necrotizing bronchiolitis, interstitial pneumonitis, pulmonary edema, and death from respiratory failure. Younger children are more susceptible to pulmonary toxicity. Survivors may demonstrate restrictive lung disease. Renal dysfunction and neurologic disturbances (ataxia, persistent weakness, emotional lability) may develop subacutely. Chronic exposure to volatilized elemental mercury in dental amalgams has not been found to be of any clinical significance.

Acute ingestion of inorganic mercury salts (typically secondary to ingestion of a button battery) can manifest in a few hours as corrosive gastroenteritis, signified by metallic taste, oropharyngeal burns, nausea, hematemesis, severe abdominal pain, hematochezia, acute tubular necrosis, cardiovascular collapse, and death.

Chronic inorganic mercury intoxication produces the **classic triad** consisting of tremor, neuropsychiatric disturbances, and

gingivostomatitis. The syndrome may result from long-term exposure to elemental mercury, inorganic mercury salts, or certain organic mercury compounds, all of which may be metabolized to mercuric ions. The tremor starts as a fine intention tremor of the fingers that is abolished during sleep but that may later involve the face and progress to choreoathetosis and spasmodic ballismus. Mixed sensorimotor neuropathy and visual disturbances may also be present. The neuropsychiatric disturbances include emotional lability, delirium, headaches, memory loss, insomnia, anorexia, and fatigue. Renal dysfunction ranges from asymptomatic proteinuria to nephrotic syndrome.

Acrodynia, or **pink disease,** is a rare idiosyncratic hypersensitivity reaction to mercury that occurs predominantly in children exposed to mercurous powders. The symptom complex includes generalized pain, paresthesias, and an acral (hands, feet) rash that may spread to involve the face. The rash typically is red-pink, papular, pruritic, and painful; it may progress to desquamation and ulceration. Morbilliform, vesicular, and hemorrhagic variants have been described. Other important features include anorexia, apathy, photophobia, and hypotonia, especially of the pectoral and pelvic girdles. Irritability, tremors, diaphoresis, insomnia, hypertension, and tachycardia may be present. Some cases initially were diagnosed as pheochromocytoma. The outcome is good after removal of the source of mercury exposure.

Methyl mercury intoxication (also known as **Minamata disease** after the widespread mercury poisoning that occurred at Minamata Bay in Japan in people who had ingested contaminated fish) manifests as delayed neurotoxicity that appears after a latent period of weeks to mo. It is characterized by ataxia; dysarthria; paresthesias; tremors; movement disorders; impairment of vision, hearing, smell, and taste; memory loss; progressive dementia; and death. Infants exposed in utero are the most severely affected, with low birthweight, microcephaly, profound developmental delay, cerebral palsy, deafness, blindness, and seizures. Although there is significant residual morbidity from methyl mercury neurotoxicity, observations on long-term follow-up of children exposed in Iraq reveal complete or partial resolution in most cases.

Laboratory Findings

The diagnosis of mercury intoxication is based on characteristic clinical findings, a history of exposure, and elevation of whole blood or urine mercury values, the last of which confirms the exposure. Thin-layer and gas chromatographic techniques can be used to distinguish organic from inorganic mercury. Blood should be collected in special tubes for trace elements from laboratories that are capable of performing those tests. Levels <10 μg/L in whole blood and <20 μg/L in a 24 hr urine specimen are considered normal (see Table 720-2). Although blood mercury levels may reflect acute exposure, they decrease as mercury redistributes into the tissues. Urine mercury levels are most useful for identifying long-term exposures, except in the case of methyl mercury, which undergoes minimal urinary excretion. Urinary mercury levels are used in monitoring efficacy of chelation therapy, whereas blood levels are used primarily in monitoring organic mercury poisonings. Hair analysis for mercury is not reliable because hair reflects both endogenous and exogenous mercury exposure (hair avidly binds mercury from the environment). Abdominal radiographs may demonstrate ingested radiopaque mercury.

Urinary markers of early nephrotoxicity include microalbuminuria, retinol-binding protein, β_2-microglobulin, and *N*-acetyl-β-D-glucosaminidase. Early neurotoxicity may be detected with neuropsychiatric testing and nerve conduction studies, whereas severe central nervous system toxicity is apparent on CT or MRI.

TREATMENT OF ARSENIC AND MERCURY INTOXICATION

The principles of management for arsenic and mercury intoxication include prompt removal from the source of poisoning, aggressive stabilization and supportive care, decontamination, and chelation therapy when appropriate. Once the diagnosis is suspected, the local poison control facility should be contacted, and care coordinated with physicians who are familiar with the management of heavy metal poisoning.

Supportive care for patients exposed to arsine gas requires close monitoring for signs of hemolysis, including evaluation of the peripheral blood smear and urinalysis. Transfusion of packed RBCs may be necessary, as may administration of intravenous fluids, sodium bicarbonate, and mannitol to prevent renal failure secondary to the deposition of hemoglobin in the kidneys. After inhalation of elemental mercury vapor, patients require careful monitoring of respiratory status, which may include pulse oximetry, arterial blood gas analysis, and chest radiography. Supportive care involves administration of supplemental oxygen and, in severe cases, intubation and mechanical ventilation.

Acute ingestion of inorganic arsenic and mercury salts results in hemorrhagic gastroenteritis, cardiovascular collapse, and multiorgan dysfunction. Fluid resuscitation, pressor agents, and transfusion of blood products may be required for management of cardiovascular instability. Severe respiratory distress, coma with loss of airway reflexes, intractable seizures, and respiratory paralysis are indications for intubation and mechanical ventilation. Renal function must be monitored carefully for signs of renal failure and the need for hemodialysis.

Gastrointestinal decontamination after ingestion of the inorganic arsenic and mercury salts has not been well studied. Because of the corrosive effects of these compounds, induced emesis is not recommended, and endoscopy may be considered before gastric lavage. Arsenic and mercury are not well adsorbed to activated charcoal, but its use may be helpful if coingestants are suspected. Whole-bowel irrigation is used to remove any radiopaque material remaining in the gastrointestinal tract.

Chelation for acute arsenic and mercury poisoning is most effective when administered as soon as possible after the exposure. Chelation should be continued until 24 hr urinary arsenic or mercury levels return to normal (<50 μg/L for arsenic and <20 μg/L for mercury), the patient is symptom-free, or the remaining toxic effects are believed to be irreversible. The efficacy of chelation in long-term exposures is reduced because heavy metal in the tissue compartment is relatively unexchangeable and some degree of irreversible toxicity has already occurred.

Dimercaprol, also known as *2,3-dimercaptopropanol* or *British antilewisite (BAL)*, is the chelator of choice for a patient who cannot tolerate oral therapy, as often is true for critically ill patients and after ingestion of the corrosive inorganic arsenic and mercury salts. BAL is available suspended in peanut oil and benzyl benzoate in 3 mL ampules at a concentration of 100 mg/mL for deep intramuscular (IM) injection. For **arsenic poisoning,** the recommended regimen of BAL is 2.5 mg/kg IM q6h for the 1st 2 days, 2.5 mg/kg IM q12h on the 3rd day, and then 2.5 mg/kg/day IM for 10 days. For severe arsenic poisoning, the dose of BAL is increased to 3 mg/kg IM q4h for 2 days, 3 mg/kg IM q6h on day 3, and then 3 mg/kg IM q12h for 10 days. The dose of BAL for **inorganic mercury poisoning** is 5 mg/kg IM on the 1st day, and then 2.5 mg/kg IM q12-24h for 10 days. The BAL–heavy metal complex is excreted in the urine and bile. A period of 5 days between courses of chelation is recommended. Adverse effects of BAL include pain at the injection site, hypertension, tachycardia, diaphoresis, nausea, vomiting, abdominal pain, a burning sensation in the oropharynx, and a feeling of constriction in the chest. BAL may cause hemolysis in glucose-6-phosphate dehydrogenase–deficient individuals. It is important to note that BAL is contraindicated for chelation of methyl mercury because BAL redistributes methyl mercury to the brain from other tissue sites, resulting in increased neurotoxicity.

D-Penicillamine is an orally administered chelator that can be considered for less-severe mercury poisoning or as an adjunct to BAL therapy in arsenic poisoning, but its use is largely restricted because of the potential for significant leukopenia, thrombocytopenia, and proteinuria. A newer investigational analog, *N*-acetyl-D,L-penicillamine, is used with variable success in mercury poisoning.

Oral chelating agents are used to replace the painful BAL injections when the patient is stable enough to tolerate oral therapy and prolonged chelation is necessary. **Succimer,** also known as *2,3-dimercaptosuccinic acid* (DMSA), is an orally administered water-soluble derivative of BAL. DMSA is available in 100 mg capsules. The

recommended regimen of DMSA is 10 mg/kg orally every 8 hr for 5 days. The DMSA–heavy metal complex is excreted in the urine and bile. A period of 2 wk between courses of chelation is recommended. Mild adverse effects include nausea, vomiting, diarrhea, loss of appetite, and transient elevations in liver enzyme levels. DMSA also may cause hemolysis in glucose-6-phosphate dehydrogenase–deficient patients. Patients with ingestion of elemental mercury require no follow-up unless there is an underlying disease that decreases the gastrointestinal transit time. Serial abdominal radiographs to document the progression of the metal are recommended. Acute inhalation of mercury fumes and ingestion of inorganic mercury require hospitalization to monitor the respiratory and gastrointestinal status, respectively. Therapeutic abortion may be considered in pregnant patients, because of the teratogenic effect of mercury.

Chapter 721

Lead Poisoning

Morri Markowitz

Lead is a metal that exists in 4 isotopic forms. Clinically, it is purely a toxicant; no organism has an essential function that is lead dependent. Chemically, its low melting point and ability to form stable compounds have made it useful in the manufacture of hundreds of products; this commercial attractiveness has resulted in the processing of millions of tons of lead ore, leading to widespread dissemination of lead in the human environment.

The blood lead level (BLL) is the gold standard for determining health effects. However, the threshold level at which lead begins to cause biochemical, subclinical, or clinical disturbance remains to be determined. The Centers for Disease Control and Prevention (CDC), recognizing that a BLL of 10 µg/dL qualifies neither as a threshold of toxicity nor as a protective parameter of children with lead exposure, changed its standard. It no longer refers to a level of concern or toxicity but has designated 5 µg/dL as the *"reference value based on the 97.5th percentile of the population BLL in children aged 1-5 years to identify children living or staying for long periods in environments that expose them to lead hazards."* As a measure of the distribution of BLLs in young children, this number will change in a manner dependent on the epidemiology of BLLs rather than on identification of the starting point for toxicity.

Although stated as a reference value, it is likely that clinicians and departments of health will consider this a threshold for action. It is important to recognize that lead toxicity occurs at levels below 5 µg/dL; no safe level has been identified. In part, this reflects the accuracy limitations of available clinical laboratory methodologies.

PUBLIC HEALTH HISTORY

In the late 1970s, nearly all preschool-age children in the United States had BLLs above the current reference value of 5 µg/dL. Around that time government regulations were issued that resulted in the significant reduction of 3 main contributors to lead exposure by means of (1) the elimination of the use of tetraethyl lead as a gasoline additive, (2) the banning of lead-containing solder to seal cans of food and beverages, and (3) the application of a federal rule that limited the amount of lead allowed in paint intended for household use to less than 0.06% by weight (further reduced by the Consumer Product Safety Commission to 0.009% in 2008). Surveillance by many of the states in the United States and by national health surveys conducted by the CDC has shown that the prevalence of elevated BLLs has declined markedly. Approximately 535,000 young children currently have BLLs ≥5 µg/dL. Including all children <18 yr of age yields an estimated 705,000 with levels above the reference value (National Health and Nutritional Examination Surveys show that for 2007-2010, 0.95% of children < age 18 yr have BLL ≥5 µg/dL). Several subgroups remain at higher risk for lead poisoning. The mean BLL of non-Hispanic black children (1.8 µg/dL) is greater than that of either non-Hispanic white children (1.3 µg/dL) or Mexican American children (1.3 µg/dL); the mean BLL among poor children (1.6 µg/dL) is higher than among more well-to-do children (1.2 µg/dL). Another high-risk group that has been identified consists of recent immigrants from less-wealthy countries, including adoptees. Fortunately, children with levels high enough to be life-threatening (>100 µg/dL) are rarely seen in the United States.

As of 2014 only 6 countries continue to use leaded gasoline (Afghanistan, Algeria, Iraq, North Korea, Myanmar, and Yemen) and these are expected to phase out its use. In all countries examined, the end of this source of exposure was associated with a marked decrease in average BLLs at all ages. In Malta, after the import of red lead paint was banned and the use of lead-treated wood for fuel in bakeries was prohibited, mean BLLs of pregnant women and newborns decreased by 45%. After it was documented that children living in the neighborhood of a battery factory in Nicaragua had a mean BLL of 17.2 µg/dL whereas children in the control community had a mean BLL of 7.4 µg/dL, the factory was closed. Despite these advances, the World Health Organization estimates that nearly a quarter billion people have BLLs above 5 µg/dL; of those who are children, 90% live in developing countries, where, in some regions, BLLs may be 10-20–fold higher than in developed countries.

In 2010, the CDC and World Health Organization, after being alerted by Doctors Without Borders, identified numerous lead-contaminated villages in northern Nigeria. The grinding of ore to extract gold caused widespread leaded dust dissemination. It is likely that hundreds of children died as a consequence of this activity, and all remaining children in the villages assessed to date were lead poisoned, with 97% having a BLL ≥45 µg/dL.

SOURCES OF EXPOSURE

Lead poisoning may occur in utero, because lead readily crosses the placenta from maternal blood. The spectrum of toxicity is similar to that experienced by children after birth. The source of maternal blood lead content is either redistribution from endogenous stores (i.e., the mother's skeleton) or lead newly acquired from ongoing environmental exposure.

Several hundred products contain lead, including batteries, cable sheathing, cosmetics, mineral supplements, plastics, toys (Table 721-1),

Table 721-1 Sources of Lead
Paint chips
Dust
Soil
Parent's or older child's occupational exposure (auto repair, battery manufacturing or recycling, smelting, construction, mining, remodeling, plumbing, gun/bullet exposure, indoor firing ranges, painting)
Glazed ceramics
Herbal remedies (e.g., Ayurvedic medications)
Home remedies, including antiperspirants, deodorants (e.g., litargirio)
Jewelry (as toys or belonging to parents)
Stored battery casings (or living near a battery smelter)
Lead-based gasoline
Moonshine alcohol
Contaminated foods (e.g., Mexican candies; Ecuadorian chocolates, imported rice)
Indoor firing ranges
Imported spices (svanuri marili, saffron, kuzhambu)
Cosmetics (kohl, surma, kajal, tiro, lipstick)
Lead plumbing (water)
Imported foods in lead-containing cans
Imported toys
Home renovations
Antique toys or furniture

Table 721-2 Cases of Lead Encephalopathy Associated with Traditional Medicines by Type of Medication

and traditional medicines (Table 721-2). Major sources of exposure vary among and within countries; the major source of exposure in the United States remains old lead-based paint. Approximately 38 million homes, mainly built before 1950, have lead-based paint (2000 estimate). As paint deteriorates, it chalks, flakes, and turns to dust. Improper rehabilitation work of painted surfaces (e.g., sanding) can result in dissemination of lead-containing dust throughout a home. The dust can coat all surfaces, including children's hands. All of these forms of lead can be ingested. If heat is used to strip paint, then lead vapor concentrations in the room can reach levels sufficient to cause lead poisoning via inhalation.

METABOLISM

The nonnutritive hand-to-mouth activity of young children is the most common pathway for lead to enter the body. In nearly all cases, lead is ingested as a component of solids or dissolved in liquids. Cutaneous contamination with inorganic lead compounds, such as those found in pigments, does not result in a substantial amount of absorption. Organic lead compounds, such as tetraethyl lead, may penetrate through skin, however. This is rarely encountered in the United States.

The percentage of lead absorbed from the gut depends on several factors: particle size, pH, other material in the gut, and nutritional status of essential elements. Large paint chips are difficult to digest and are mainly excreted; this is fortunate as a single chip may contain a lethal dose of lead. Fine dust can be dissolved more readily, especially in an acid medium. Lead eaten on an empty stomach is better absorbed than that taken with a meal. The presence of calcium and iron may decrease lead absorption by direct competition for binding sites; iron (and probably calcium) deficiency results in enhanced lead absorption, retention, and toxicity.

After absorption, lead is disseminated throughout the body. Most retained lead accumulates in bone, where it may reside for years. It circulates bound to erythrocytes; approximately 97% in blood is bound on or in the red blood cells. The plasma fraction is too small to be measured by conventional techniques employing atomic absorption spectroscopy or anodic stripping voltammetry; it is presumably the plasma portion that may enter cells and induce toxicity. Thus, clinical laboratories report the BLL, not the serum or plasma lead level. It is possible, but not yet sufficiently shown by testing, that some of the variance in the relationship between BLLs and outcome measures of toxicity is a result of the limitations of using BLLs to assess risk. Studies that examine plasma lead concentrations in relation to its toxicity are needed.

Lead has multiple effects in cells. It binds to enzymes, particularly those with available sulfhydryl groups, changing the contour and diminishing function. For example, the heme pathway, present in all cells, consists of 8 enzymes, 3 of which are susceptible to lead inhibitory effects. The accumulation of excess amounts of heme precursors also is toxic (see Chapter 91). The last enzyme in this pathway, ferrochelatase, enables protoporphyrin to chelate iron, thus forming heme. Heme is essential for multiple metabolic pathways and not merely as a component of hemoglobin. Erythrocyte protoporphyrin levels higher than 35 µg/dL are abnormal and are consistent with lead poisoning, iron deficiency, or recent inflammatory disease.

Erythrocyte protoporphyrin levels begin to rise several weeks after BLLs have reached 20 µg/dL in a susceptible portion of the population, and are elevated in nearly all children with BLLs higher than 50 µg/dL. A drop in erythrocyte protoporphyrin levels also lags behind a decline in BLLs by several weeks, because it depends on both cell turnover and cessation of further overproduction by marrow red blood cell precursors. Measurement of the erythrocyte protoporphyrin level is, therefore, a useful tool for monitoring more severe biochemical lead toxicity.

A second mechanism of lead toxicity works via its competition with calcium. Many calcium-binding proteins have a higher affinity for lead than for calcium. Lead bound to these proteins may alter function, resulting in abnormal intracellular and intercellular signaling. Neurotransmitter release is, in part, a calcium-dependent process that is adversely affected by lead.

Although these 2 mechanisms of toxicity may be reversible, a third mechanism prevents the development of the normal tertiary brain structure. In immature mammals the normal neuronal pruning process that results in elimination of multiple intercellular brain connections is inhibited by lead. Failure to construct the appropriate tertiary brain structure during infancy and childhood may result in a permanent abnormality. A longitudinal study of childhood lead poisoning that followed a cohort from birth and into their 20s performed MRI and functional MRI–phosphorus magnetic resonance spectroscopy assessments confirmed the association of early childhood lead exposure and subsequent decreased gray and white matter volume and neuronal function. The investigators concluded that early lead exposure in life causes a persistent reorganization of brain architecture and diminished function.

CLINICAL EFFECTS

The BLL is the best-studied measure of the lead burden in children. Although subclinical and clinical findings correlate with BLLs in populations, there is considerable interindividual variability in this relationship. Lead encephalopathy is more likely to be observed in children with BLLs higher than 100 µg/dL; however, 1 child with a BLL of 300 µg/dL may have no symptoms, whereas another with the same level may be comatose. Susceptibility may be associated with polymorphisms in genes coding for lead-binding proteins, such as Δ-aminolevulinic acid dehydratase, an enzyme in the heme pathway.

Several subclinical effects of lead have been demonstrated in cross-sectional epidemiologic studies. Hearing and height are inversely related to BLLs in children. As BLLs increased in the study population, more sound (at all frequencies) was needed to reach the hearing threshold. Children with higher BLLs are shorter than those with lower levels; for every 10 µg increase in the BLL, the children are 1 cm shorter. Chronic lead exposure also may delay puberty. However, these associations with rising BLLs do not reach a point that would bring an individual child to medical attention.

Several longitudinal studies have followed cohorts of children from birth for as long as 20 yr and examined the relationship between BLLs and cognitive test scores over time. In general, there is agreement that BLLs, expressed either as levels obtained at around 2 yr of age or as a measure that integrates multiple BLLs drawn from subjects over time, are inversely related to cognitive test scores. On average, for each 1 µg/dL elevation in BLL the cognitive score is approximately 0.25-0.50 points lower. Because the BLLs from early childhood are predictors of the cognitive test results performed years later, this finding implies that the effects of lead can be permanent. Concurrent testing of lead levels and cognition sometimes also shows an inverse association.

The effect of in utero lead exposure is less clear. Scores on the Bayley Scale of Mental Development were obtained repeatedly every 6 mo for the 1st 2 yr of life in a cohort of infants born to middle-class families. Results correlated inversely with cord BLLs, a measure of in utero exposure, but not with BLLs obtained concurrently at the time of developmental testing. After 2 yr of age, all other cognitive tests performed on the cohort over the next 10 yr correlated with the BLLs at age 2 yr but not with cord BLLs, indicating that the effects of prenatal lead exposure on brain function were superseded by early childhood events and later BLLs. Later studies, performed in cohorts of Mexican children monitored from the prenatal period, confirm the association between in utero lead exposure and later cognitive outcomes. No threshold for BLL was identified in these studies; maternal BLLs between 0 and 10 µg/dL, even as early as the 1st trimester, were associated with about a 6-point drop in cognitive test score results when the children were tested up to age 10 yr.

Behavior also is adversely affected by lead exposure. Hyperactivity is noted in young school-age children with histories of lead poisoning or with concurrent elevations in BLL. Older children with higher bone lead content are more likely to be aggressive and to have behaviors that are predictive of later juvenile delinquency. Multiple reports support the concept of long-term effects of early lead exposure. In 1 longitudinal study, the mothers of a cohort were enrolled during their pregnancies. BLLs were obtained early in pregnancy, at birth, and then multiple times in the offspring during the 1st 6 yr. The investigators report that the relative rate of arrests, especially for violent crimes, increased significantly in relationship to the presence of these BLLs early in life. For every 5 µg/dL increase in BLL the adjusted arrest rate was 1.40 for prenatal BLLs and 1.27 for 6 yr BLLs. Epidemiologic data support the findings in this observational study. In an analysis that combined 2 national data sets, total annual leaded gasoline use (U.S. Geological Survey) and total reported violent criminal acts (U.S. Department of Justice), the amount of leaded gasoline used yearly was found to be strongly associated with violent criminal behavior with a lag time of 23 yr; that is, early exposure was followed 2 decades later by violent behavior rising and falling in close tandem. A similar association was found, this time between urban air lead levels and later violent crime, with a similar best-fit model employing a lag of approximately 22 yr.

An intervention study, in which children with moderate lead poisoning and initial BLLs of 20-55 µg/dL were aggressively managed over 6 mo, addressed the issue of the effects of treatment on cognitive development. Components of treatment included education regarding sources of lead and its abatement, nutritional guidance, multiple home and clinic visits, and, for a subset, chelation therapy. Average BLLs declined and cognitive scores were inversely related to the change in BLLs. For every 1 µg/dL fall in BLLs, cognitive scores were 0.25 point higher. A randomized placebo-controlled treatment study of 2 yr old children with initial BLLs of 20-44 µg/dL that employed the chelating agent succimer administered over 6 mo found no difference in *mean* cognitive scores at age 4 yr. However, as in the earlier treatment study, regression analysis did find an inverse relation between *change* scores; that is, a change in BLLs was associated with a change in cognitive scores.

Whether the behavioral effects of lead are reversible is unclear. In one small, short-term study, 7 yr old hyperactive children with BLLs in the 20s were randomly allocated to receive a chelating agent (penicillamine), methylphenidate, or placebo. Teacher and parent ratings of behavior improved for the first 2 groups but not the placebo group. BLLs declined only in the chelated group. Lead-poisoned children age 2 yr old who were enrolled in a placebo-controlled trial of the chelating agent succimer showed no mean difference in behavior at 4 or 7 yr of age. However, mean BLLs were also not different in the 2 groups at those ages.

CLINICAL SYMPTOMS

Gastrointestinal Tract and Central Nervous System

Gastrointestinal symptoms of lead poisoning include anorexia, abdominal pain, vomiting, and constipation, often occurring and recurring over a period of weeks. Children with BLLs higher than 20 µg/dL are twice as likely to have gastrointestinal complaints as those with lower BLLs. **Central nervous system symptoms** are related to worsening cerebral edema and increased intracranial pressure. Headaches, change in mentation, lethargy, papilledema, seizures, and coma leading to death are rarely seen at levels lower than 100 µg/dL but have been reported in children with a BLL as low as 70 µg/dL. The last-reported death directly attributable to lead toxicity in the United States was in 2006 in a child with a BLL of 180 µg/dL. There is no clear cutoff BLL value for the appearance of hyperactivity, but it is more likely to be observed in children who have levels higher than 20 µg/dL.

Other organs also may be affected by lead toxicity, but symptoms usually are not apparent in children. At high levels (>100 µg/dL), **renal tubular dysfunction** is observed. Lead may induce a reversible Fanconi syndrome (see Chapter 529). In addition, at high BLLs, **red blood cell survival** is shortened, possibly contributing to a hemolytic anemia, although most cases of anemia in lead-poisoned children are a result of other factors, such as iron deficiency and hemoglobinopathies. Older patients may develop a peripheral neuropathy leading to wrist drop and footdrop.

DIAGNOSIS

Screening

It is estimated that 99% of lead-poisoned children are identified by screening procedures rather than through clinical recognition of lead-related symptoms. Until 1997 universal screening by blood lead testing of all children at ages 12 mo and 24 mo was the standard in the United States. Given the national decline in the prevalence of lead poisoning, the recommendations have been revised to target blood lead testing of high-risk populations. High risk is based on an evaluation of the likelihood of lead exposure. Departments of health are responsible for determining the local prevalence of lead poisoning, as well as the percentage of housing built before 1950, the period of peak leaded paint use. When this information is available, informed screening guidelines for practitioners can be issued. For instance, in the state of New York, where a large percentage of housing was built before 1950, the Department of Health mandates that all children be tested for lead poisoning via blood analyses. *In the absence of such data the practitioner should continue to test all children at both 12 mo and 24 mo.* In areas where the prevalence of lead poisoning and old housing is low, targeted screening may be performed on the basis of a risk assessment. Three questions form the basis of most published questionnaires (Table 721-3), and items that are pertinent to the locale or individual may be added. If there is a lead-based industry in the child's neighborhood, the child is a recent immigrant from a country that still permits use of leaded

Table 721-3	Minimum Personal Risk Questionnaire
1. Does the child live in or visit regularly a house that was built before 1950? (Include settings such as daycare, babysitter's or relative's home.)	
2. Does the child live in or regularly visit a house built before 1978 with recent (past 6 mo) or ongoing renovations or remodeling?	
3. Does the child have a sibling or playmate that has or did have lead poisoning?	

From Screening young children for lead poisoning: guidance for state and local public health officials, *Atlanta, 1997, Centers for Disease Control and Prevention.*

gasoline, or the child has pica or developmental delay, blood lead testing would be appropriate. All Medicaid-eligible children should be screened by blood lead testing. Unfortunately, answers on questionnaires are not more successful at identifying children with lead poisoning than is chance. Venous sampling is preferred to capillary sampling because the chances of false-positive and false-negative results are less with the former.

TREATMENT

Once lead is in bone, it is released slowly and is difficult to remove even with chelating agents. Because the cognitive/behavioral effects of lead may be irreversible, the main effort in treating lead poisoning is to **prevent** it from occurring and to **prevent** further ingestion by already-poisoned children. The main components in the effort to eliminate lead poisoning are universally applicable to all children (and adults) and are as follows: (1) identification and elimination of environmental sources of lead exposure, (2) behavioral modification to reduce nonnutritive hand-to-mouth activity, and (3) dietary counseling to ensure sufficient intake of the essential elements calcium and iron. For the small minority of children with more-severe lead poisoning, drug treatment is available that enhances lead excretion.

During health maintenance visits a limited risk assessment is warranted, which includes questions pertaining to the most common sources of lead exposure: the condition of old paint, secondary occupational exposure via an adult living in the home, and/or proximity to an industrial source of pollution. If such a source is identified, its elimination usually requires the assistance of public health and housing agencies as well as education for the parents. The family should move out of a lead-contaminated apartment until repairs are completed. During repairs, repeated washes of surfaces and the use of high-efficiency particle accumulator vacuum cleaners help reduce exposure to lead-containing dust. Careful selection of a contractor who is certified to perform lead abatement work is necessary. Sloppy work can cause dissemination of lead-containing dust and chips throughout a home or building and result in further elevation of a child's BLL. After the work is completed, dust wipe samples should be collected from floors and windowsills or wells to verify that the risk from lead has abated.

A single case of lead poisoning is often discovered in a household with multiple affected family members, including other young children, even in a household with a common source of exposure such as peeling lead-based paint. The mere presence of lead in an environment does not produce lead poisoning. Parental efforts at **reducing the hand-to-mouth activity** of the affected child are necessary to reduce the risk of lead ingestion. Handwashing effectively removes lead, but in a home with lead-containing dust, lead rapidly begins to reaccumulate on the child's hands after washing. Therefore, handwashing is best limited to the period immediately before nutritive hand-to-mouth activity occurs.

Because there is competition between lead and essential minerals, it is reasonable to promote a healthy diet that is sufficient in calcium and iron. The recommended daily intakes of these metals vary somewhat with age. In general, for children 1 yr of age and up a calcium intake of about 1 g/day is sufficient and convenient to remember (roughly the calcium content of a quart of milk [≈1,200 mg/qt] or calcium-fortified orange juice). Calcium absorption is vitamin D dependent; milk is fortified with vitamin D, but other nutritional sources of calcium often are not. A multivitamin containing vitamin D may be prescribed for children who do not drink sufficient milk or who have inadequate sunlight exposure. Iron requirements also vary with age, ranging from 6 mg/day for infants to 12 mg/day for adolescents. For children identified biochemically as being iron deficient, therapeutic iron at a daily dose of 5-6 mg/kg for 3 mo is appropriate. Iron absorption is enhanced when iron is ingested with ascorbic acid (citrus juices). Giving additional calcium or iron above the recommended daily intakes to mineral-sufficient children has not been shown to be of therapeutic benefit in the treatment of lead poisoning.

Drug treatment to remove lead is lifesaving for children with lead encephalopathy. In nonencephalopathic children, it prevents symptom progression and further toxicity. Guidelines for chelation are based on the BLL. *A child with a venous BLL of 45 µg/dL or higher should be treated.* Four drugs are available in the United States: 2,3-dimercaptosuccinic acid (DMSA [succimer]), $CaNa_2EDTA$ (versenate), British antilewisite (BAL [dimercaprol]), and penicillamine. DMSA and penicillamine can be given orally, whereas $CaNa_2EDTA$ and BAL can be administered only parenterally. The choice of agent is guided by the severity of the lead poisoning, the effectiveness of the drug, and the ease of administration (Table 721-4). Children with BLLs of 44-70 µg/dL may be treated with a single drug, preferably DMSA. Those with BLLs of 70 µg/dL or greater require 2-drug treatment: $CaNa_2EDTA$ in combination with either DMSA or BAL for those without evidence of encephalopathy, or $CaNa_2EDTA$ and BAL for those with encephalopathy. Published data on the combined treatment with $CaNa_2EDTA$ and DMSA for children with BLLs higher than 100 µg/dL are very limited. However, anecdotal information derived from the treatment of hundreds of severely lead poisoned children in northern Nigeria indicates that single-drug treatment with DMSA is lifesaving, although the degree of residual damage in survivors has not been reported.

Acute drug-related toxicities are minor and reversible. These include gastrointestinal distress, transient elevations in transaminases, active urinary sediment, and neutropenia. These types of events are least common for $CaNa_2EDTA$ and DMSA and more common for BAL and

Table 721-4 Chelation Therapy

NAME	SYNONYM	DOSE	TOXICITY
Succimer	Chemet, 2,3-dimercaptosuccinic acid (DMSA)	350 mg/m^2 body surface area/dose ***(not 10 mg/kg)*** q8h, PO for 5 days, then q12h for 14 days	Gastrointestinal distress, rashes; elevated LFTs, depressed white blood cell count
Edetate*	$CaNa_2EDTA$ (calcium disodium edetate), versenate	1,000-1,500 mg/m^2 body surface area/day; IV infusion—continuous or intermittent; IM divided q6h or q12h for 5 days	Proteinuria, pyuria, rising blood urea nitrogen/creatinine—all rare Hypercalcemia if too rapid an infusion Tissue inflammation if infusion infiltrates
British antilewisite (BAL)	Dimercaprol	300-500 mg/m^2 body surface area/day; **IM only** divided q4h for 3-5 days. Only for BLL ≥70 µg/dL	Gastrointestinal distress, altered mentation; elevated LFTs, hemolysis if glucose-6-phosphate dehydrogenase deficiency; no concomitant iron treatment
D-Pen	Penicillamine	10 mg/kg/day for 2 wk increasing to 25-40 mg/kg/day; oral, divided q12h. For 12-20 wk	Rashes, fever; blood dyscrasias, elevated LFTs, proteinuria Allergic cross reactivity with penicillin

*Always given as the calcium salt; never as the sodium salt without calcium.
BLL, blood lead level; IM, intramuscularly; IV, intravenously; LFT, liver function test; PO, by mouth.
From Markowitz ME: Lead poisoning, Pediatr Rev *21:327–335, 2000.*

penicillamine. All of the drugs are effective in reducing BLLs when given in sufficient doses and for the prescribed time. These drugs also may increase lead absorption from the gut and should be administered to children in lead-free environments. *Some authorities also recommend the administration of a cathartic immediately prior to or concomitant with the initiation of chelation to eliminate any lead already in the gut.*

None of these agents removes all lead from the body. Within days to weeks after completion of a course of therapy the BLL rises, even in the absence of new lead ingestion. The source of this rebound in the BLL is believed to be bone. Serial examinations of bone lead content have shown that chelation with $CaNa_2EDTA$ is associated with a decline in bone lead levels but that residual bone lead remains detectable even after multiple courses of treatment.

Repeat chelation is indicated if the BLL rebounds to 45 μg/dL or higher. Children with initial BLLs higher than 70 μg/dL are likely to require more than 1 course. A minimum of 3 days between courses is recommended to prevent treatment-related toxicities, especially in the kidney.

The indication for chelation therapy for children with BLLs <45 μg/dL is less clear. Although use of these drugs in children with BLLs from 20-44 μg/dL will result in transiently lowered BLLs, and in some cases reversal of lead-induced enzyme inhibition, few such children increase their excretion of lead significantly during chelation, raising the question of whether any long-term benefit is achieved. A study of 2 yr old children with BLLs of 20-44 μg/dL who were randomized to receive either DMSA or placebo found that the drop in BLLs was greater in the 1st 6 mo after enrollment in the DMSA-treated group, but the levels converged by 1 yr of follow-up. Mean cognitive test scores obtained at 4 and 7 yr of age were not statistically different between the groups. Chelation with DMSA (and $CaNa_2EDTA$) is not recommended for all children with BLLs <45 μg/dL. It remains to be demonstrated whether other chelating agents available in the United States or elsewhere are effective at either substantially reducing body stores (bone) of lead or at reversing the cognitive deficits attributable to lead at these BLLs.

With successful intervention (with or without chelation), BLLs decline, with the greatest fall in BLL occurring in the 1st 2 mo after therapy is initiated. Subsequently, the rate of change in BLL declines slowly so that by 6-12 mo after identification, the BLL of the average child with moderate lead poisoning (BLL >20 μg/dL) will be 50% lower. Children with more markedly elevated BLLs may take years to reach the CDC reference level, 5 μg/dL, even if all sources of lead exposure have been eliminated, behavior has been modified, and nutrition has been maximized. Early screening remains the best way of avoiding and therefore obviating the need for the treatment of lead poisoning.

Chapter 722
Nonbacterial Food Poisoning

722.1 Mushroom Poisoning

Denise A. Salerno and Stephen C. Aronoff

Mushrooms are an ideal food. They are low in calories, fat free, and high in protein, making them a great source of nutrition. Unfortunately, some are highly toxic if ingested. Picking and consumption of wild mushrooms are increasingly popular in the United States. This rise in popularity has led to increased reports of severe and fatal mushroom poisonings.

The clinical syndromes produced by mushroom poisoning are divided according to the rapidity of onset of symptoms and the predominant system involved (Table 722-1). The symptoms are caused by the principal toxin present in the ingested mushrooms. The 8 major toxins produced by mushrooms are categorized as cyclopeptides, monomethylhydrazine, muscarine, hallucinogenic indoles, isoxazole, coprine (disulfiram-like reaction), orellanine, and gastrointestinal tract–specific irritants. The edible wild mushroom *Tricholoma equestre* is associated with delayed rhabdomyolysis, and *Clitocybe amoenolens* and *Clitocybe acromelalga* have been reported to cause erythromelalgia. The toxins responsible for these effects are unknown. An enzyme-linked immunosorbent assay immunoassay is available to detect amanitotoxin; additional rapid tests are becoming available to identify other specific toxins.

Symptoms after eating mushrooms may not be the direct effect of a toxin but may be an allergic reaction or a toxic effect of pesticides or other contaminants. In addition, all who ate the same mushroom may not become sick or if they do they may become sick at different intervals. Table 722-2 lists general principles of management.

GASTROINTESTINAL: DELAYED ONSET

Amanita Poisoning

Poisonings by species of *Amanita* and *Galerina* account for 95% of the fatalities from mushroom intoxication; the mortality rate for this group is 5-10%. Most species produce 2 classes of cyclopeptide toxins: (1) phallotoxins, which are heptapeptides believed to be responsible for the early symptoms of *Amanita* poisoning, and (2) amanitotoxin, an octapeptide that inhibits nuclear RNA polymerase II and subsequent production of messenger RNA leading to impaired protein synthesis and cell death. Cells with high turnover rates, such as those in the gastrointestinal mucosa, kidneys, and liver, are the most severely affected. Other suggested toxin effects are induction of apoptosis, glutathione depletion in the liver, and oxygen free radical formation. Acute yellow atrophy of the liver and necrosis of the proximal renal tubules are found in lethal cases.

The **clinical course** of poisoning with *Amanita* or *Galerina* species is biphasic. Nausea, vomiting, and severe abdominal pain ensue 6-24 hr after ingestion. Profuse watery diarrhea follows shortly thereafter and may last for 12-24 hr or longer. During this time, patients become severely dehydrated. From 24-48 hr after poisoning, jaundice, hypertransaminasemia (peaking at 72-96 hr), renal failure, and coma occur. Death occurs 4-7 days after the ingestion. A prothrombin time less than 10% of control is a poor prognostic factor.

Treatment

Treatment for *Amanita* poisoning is both supportive and specific. Fluid loss from severe diarrhea during the early course of the illness is profound, requiring aggressive correction of fluid loss, electrolytes, and acid–base disturbances. In the late phase of the disease, management of renal and hepatic failure is also necessary.

Specific therapy for *Amanita* poisoning is designed to remove the toxin rapidly and to block binding at its target site. Oral activated charcoal is recommended as part of the initial treatment for children with *Amanita* poisoning. Forced diuresis should be avoided, as this increases renal exposure. For significant ingestions, consider silibinin (5 mg/kg IV over 1 hr followed by a continuous intravenous infusion of 20 mg/kg/24 hr) for 3 days postingestion. If silibinin is not available, intravenous penicillin G (400,000 units/kg/24 hr) may be used. Silibinin and penicillin G inhibit binding of both toxins, interrupt enterohepatic recirculation of amanitotoxin, and protect the liver from further injury. Acetylcysteine has shown promise in some studies. Hemodialysis and hemoperfusion are also recommended as part of the initial treatment for intoxicated children. Orthotopic liver transplantation is recommended for children with severe hepatic failure.

Monomethylhydrazine Intoxication

Species of *Gyromitra* contain gyromitrin which decomposes in the stomach to form monomethylhydrazine (CH_3NHNH_2) and inhibits

Table 722-1 Summary of Common Mushroom-Associated Syndromes

SYNDROME	CLINICAL COURSE	TOXIN(S)	TYPICAL CAUSATIVE MUSHROOM(S)
Delayed gastroenteritis followed by hepatorenal syndrome	Stage 1: 24 hr after ingestion: onset of nausea, vomiting, profuse cholera-like diarrhea, abdominal pain, hematuria Stage 2: 12-48 hr after ingestion: apparent recovery; levels of hepatic enzymes are rising during this stage Stage 3: 24-72 hr after ingestion: progressive hepatic and renal failure, coagulopathy, cardiomyopathy, encephalopathy, convulsions, coma, death	Cyclopeptides, principally amatoxins	"Deadly *Amanitas*," *Galerina* species
Hyperactivity, delirium, coma	30 min to 2 hr after ingestion: delirium, hallucinations, and coma	Muscimol, ibotenic acid	*Amanita muscaria, Amanita pantherina*
Delayed gastroenteritis with central nervous system abnormalities	6-24 hr after ingestion: nausea, vomiting, diarrhea, abdominal pain, muscle cramps, delirium, convulsions, coma; hemolysis and methemoglobinemia may occur	Gyromitrin	*Gyromitra esculenta* ("false morel")
Cholinergic syndrome	30 min to 2 hr after ingestion: bradycardia, bronchorrhea, bronchospasm, salivation, perspiration, lacrimation, convulsions, coma	Muscarine	*Boletus* species, *Clitocybe* species, *Inocybe* species, *Amanita* species
Disulfiram-like reaction with ethanol	30 min after drinking ethanol (may occur up to 1 wk after eating coprine-containing mushrooms): flushing of skin of face and trunk, hypotension, tachycardia, chest pain, dyspnea, nausea, vomiting, extreme apprehension	Coprine	*Coprinus atramentarius*
Hallucinations	30 min to 3 hr after ingestion: hallucinations, euphoria, drowsiness, compulsive behavior, agitation	Psilocybin and psilocin	*Psilocybe* species
Delayed gastritis and renal failure	Abdominal pain, anorexia, vomiting starting over 30 hr after ingestion, followed by progressive renal failure 3-14 days later	Orelline, orellanine	*Cortinarius* species
Immune-mediated hemolytic anemia	Syncope, gastroenteritis, oliguria, hemoglobinuria, back pain, hemolysis	Immunoglobulin mediated	*Paxillus involutus*
General gastrointestinal irritants	30 min to 2 hr after ingestion: nausea, vomiting, abdominal cramping, diarrhea; may recover without treatment	Unidentified, probably multiple	*Chlorophyllum molybdites*, backyard mushrooms ("little brown mushrooms"), many others

From Brent J, Palmer RB: Mushrooms. In Shannon MW, Borron SW, Burns MJ, editors: Haddad and Winchester's clinical management of poisoning and drug overdose, *ed 4, Philadelphia, 2007, WB Saunders, Table 23-1.*

Table 722-2 General Management of Mushroom Ingestion

1. Determine history of ingestion: how many types of mushrooms ingested, what time, if anyone else ate them, and what symptoms are present.
2. Attempt to determine which of the possible syndromes (see Table 722-1) the patient may have. For example, gastrointestinal symptoms occurring more than 6 hr after ingestion strongly suggest cyclopeptide, gyromitrin, or *Cortinarius* poisoning.
3. Administer activated charcoal. If the patient has diarrhea, do not give a cathartic. If a cathartic is used, give it only with the first dose of activated charcoal. Use repeated doses of activated charcoal for suspected amatoxin poisonings.
4. If feasible and when indicated, send gastric aspirate or emesis, along with any remaining mushrooms, to a mycologist for identification.
5. Try to perform a preliminary identification of mushroom and spores. Start to develop a spore print as soon as possible.
6. Maintain supportive measures, including airway support, intravenous fluids, and vasopressors (if needed). Monitor volume status.
7. Avoid antispasmodics for gastrointestinal symptoms.
8. Anticipate the clinical course.

From Brent J, Palmer RB: Mushrooms. In Shannon MW, Borron SW, Burns MJ, editors: Haddad and Winchester's clinical management of poisoning and drug overdose, *ed 4, Philadelphia, 2007, WB Saunders, Box 23-1.*

central nervous system (CNS) enzymatic production of γ-aminobutyric acid. Monomethylhydrazine also oxidizes iron in hemoglobin, resulting in methemoglobinemia. Children with *Gyromitra* poisoning experience vomiting, diarrhea, hematochezia, and abdominal pain within 6-24 hr of ingestion of the toxin. CNS symptoms such as vertigo, diplopia, headache, ataxia, and seizures develop later in the clinical course. Hemolysis and methemoglobinemia (see Chapter 462.6) are rare but potential life-threatening complications of gyromitrin poisoning.

Treatment

Hypovolemia from gastrointestinal fluid losses and seizures require supportive intervention. Pyridoxal phosphate, the coenzyme that catalyzes the production of γ-aminobutyric acid, can reverse the effects of monomethylhydrazine when administered in high doses. **Pyridoxine hydrochloride (25 mg/kg infused over 30 min)** is given at a frequency that is dependent on clinical improvement. Diazepam is given for persistent seizures. Parenteral administration of methylene blue is indicated if the methemoglobin concentration exceeds 30%; severe methemoglobinemia may require dialysis. Blood transfusions may be required for significant hemolysis.

RENAL: DELAYED ONSET

Orellanine Poisoning

Species of *Cortinarius* contain the heat-stable toxin bipyridyl orellanine, which causes severe nonglomerular renal injury characterized by

interstitial fibrosis and acute tubular necrosis. Although the exact mechanism of injury is not fully understood, a metabolite of orellanine is thought to inhibit renal protein synthesis. *Cortinarius* poisoning is characterized by nausea, vomiting, and diarrhea that manifest 36-48 hr after ingestion. Although the initial symptoms may be trivial, more serious renal toxicity occurs in several days. Acute renal failure occurs in 30-50% of those affected, beginning with polyuria and progressing to renal failure (see Chapter 535).

Treatment

Treatment for orellanine poisoning is supportive. Early presentation, within 4-6 hr after ingestion, can be treated with activated charcoal and gastric lavage. Hemodialysis may be needed in patients suffering from renal failure. Most patients recover within 1 mo but chronic renal insufficiency develops in one third to one half of patients who subsequently require renal transplantation.

AUTONOMIC NERVOUS SYSTEM: RAPID ONSET

Muscarine Poisoning

Mushrooms of the genera *Inocybe* and, to a lesser degree, *Clitocybe* contain muscarine or muscarine-related compounds. These quaternary ammonium derivatives bind to postsynaptic receptors, producing an exaggerated cholinergic response.

The onset of symptoms is rapid (30 min to 2 hr after consumption) and intoxication is characterized by a hypercholinergic response: diaphoresis, excessive lacrimation, salivation, miosis, bradycardia, hypotension, urinary and fecal incontinence, and vomiting. Respiratory distress caused by bronchospasm and increased bronchopulmonary secretions is the most serious complication. The symptoms subside spontaneously within 6-24 hr.

Treatment

Atropine sulfate, the specific antidote, is administered intravenously (0.01 mg/kg; maximum: 2 mg). This is repeated until the pulmonary symptoms resolve or the patient becomes overtly tachycardic.

Coprine Ingestion

Coprinus atramentarius and *Clitocybe clavipes* contain coprine. Like disulfiram (Antabuse; Odyssey Pharmaceuticals, Inc.), coprine inhibits the metabolism of acetaldehyde after ethanol ingestion. The clinical manifestations result from accumulation of acetaldehyde.

Coprine intoxication becomes apparent after ethanol ingestion and may occur up to 5 days after consumption of the mushroom. Hyperemia of the face and trunk, tingling of the hands, metallic taste, tachycardia, and vomiting occur acutely. Hypotension may result from intense peripheral vasodilation.

The syndrome typically is self-limited and lasts only several hours. No specific antidote is available. If hypotension is severe, vascular reexpansion with isotonic parenteral solutions may be required. Small oral doses of propranolol have also been suggested.

CENTRAL NERVOUS SYSTEM: RAPID ONSET

Isoxazole Intoxication

Although *Amanita muscaria* and *Amanita pantherina* may contain muscarine, the toxins responsible for the CNS symptoms after ingestion of these mushrooms are muscimol and ibotenic acid, the heat-stable derivatives of the isoxazoles. Muscimol, a hallucinogen, and ibotenic acid, an insecticide, act as γ-aminobutyric acid agonists. From 30 min to 3 hr after ingestion, CNS symptoms appear: obtundation, alternating lethargy and agitation, and, occasionally, seizures. Nausea and vomiting are uncommon. If large amounts of muscarine are contained in the mushroom, symptoms of cholinergic crisis also may occur.

Specific therapy must be carefully selected. If an exaggerated cholinergic response is observed, atropine should be administered. Because ingestions of *A. muscaria* often are associated with anticholinergic findings, the acetylcholinesterase inhibitor physostigmine is often used to reverse the delirium and coma. Benzodiazepines also are used for the agitation and delirium. Seizures can be controlled with diazepam. In most cases, however, early treatment with ipecac (if the patient is conscious) and close observation are all that is required.

Indole Intoxication

Mushrooms belonging to the genus *Psilocybe* ("magic mushrooms") contain psilocybin and psilocin, 2 psychotropic compounds. Within 30 min after ingestion, patients experience euphoria and hallucinations, often accompanied by tachycardia and mydriasis. Fever and seizures have also been observed in children with psilocybin poisoning. These symptoms are short lived, usually lasting for 6 hr after consumption of the mushroom. Treatment consists of rest and observation in a quiet environment. Severely agitated patients may show response to diazepam.

GASTROINTESTINAL: RAPID ONSET

Many mushrooms from various genera produce local gastrointestinal manifestations. The causative toxins are diverse and largely unknown. Within 1 hr of ingestion, patients experience acute abdominal pain, nausea, vomiting, and diarrhea. Symptoms may last from hours to days, depending on the species of mushroom.

Treatment is mainly supportive. Children with large fluid losses may require parenteral fluid therapy. It is imperative to differentiate ingestion of mushrooms of this class from ingestion of *Amanita* and *Galerina* species containing cyclopeptide toxins.

Bibliography is available at Expert Consult.

722.2 Solanine Poisoning

Denise A. Salerno and Stephen C. Aronoff

Potatoes exposed to light and allowed to turn green and/or sprout produce a number of alkaloid glycosides containing the cholesterol derivative solanidine. Two of these glycosides, α-solanine and α-chaconine, are found in highest concentration in the peels of greened potatoes and in the sprouts. Some solanine can be removed by boiling but not by baking. The major effect of α-solanine and α-chaconine is the reversible inhibition of cholinesterase. Cardiotoxic and teratogenic effects have also been reported.

Clinical manifestations of solanine and chaconine poisoning intoxication occur within 7-19 hr after ingestion. The most common symptoms are vomiting, abdominal pain, and diarrhea; in more severe instances of poisoning, neurologic symptoms, including drowsiness, apathy, confusion, weakness, and vision disturbances, are rarely followed by coma or death.

Treatment of solanine poisoning is largely supportive. In the most severe cases, symptoms resolve within 11 days.

Bibliography is available at Expert Consult.

722.3 Seafood Poisoning

Denise A. Salerno and Stephen C. Aronoff

CIGUATERA FISH POISONING

The most frequently reported seafood-toxin illness in the world, ciguatera fish poisoning, has been reported in Florida, Hawaii, French Polynesia, the Marshall Islands, Caribbean and South Pacific islands, and the Virgin Islands. With modern methods of transportation, the illness now occurs worldwide. Grouper is the most commonly identified source of the toxin, followed by snapper, kingfish, amberjack, dolphin, eel, and barracuda. Poisoning has also been associated with farm-raised salmon.

The dinoflagellate *Gambierdiscus toxicus,* a microscopic unicellular organism found along coral reefs, produces high concentrations of ciguatoxin and maitotoxin. The toxins are passed along the food chain

from small herbivorous fish that consume the dinoflagellate to larger predatory fish and then to humans. These toxins are harmless in fish but produce distinct clinical symptoms in humans.

The lipid ciguatoxin-1 is odorless, colorless, and tasteless and is not destroyed by cooking or freezing. Ciguatoxin-1 increases the sodium ion permeability of excitable membranes and depolarizes nerve cells, actions that are inhibited by calcium and tetrodotoxin.

Between 2 and 30 hr after ingestion, ciguatoxin poisoning typically produces a biphasic illness. The initial symptoms are not specific and are of gastrointestinal origin (diarrhea, vomiting, nausea, and abdominal pain). The second phase occurs within a few days of ingestion and consists of intense itching, anxiety, myalgias, painful intercourse, and rash on palms and soles; the neurologic symptoms of circumoral or extremity dysesthesias (characterized by reversal of hot and cold sensation) are characteristic of this disease and may last for months. Tachycardia, bradycardia, hypotension, and death occur infrequently. Eating fish organs, roe, or viscera is associated with greater symptom severity. The diagnosis of ciguatera fish poisoning is based on clinical presentation and a compatible epidemiologic history; the diagnosis is confirmed by testing the ingested fish for toxin. There is no human biomarker to confirm ciguatera fish poisoning.

Treatment

Treatment of ciguatera fish poisoning is supportive. Gastric lavage is recommended to remove any remaining toxin. Intravenous fluids may be required for severe diarrhea, and parenteral administration of calcium can be used to treat hypotension. Once adequate hydration is established, mannitol (0.5-1.0 g/kg, IV over 30-45 min) given within 48-72 hr of the toxic fish ingestion is recommended for reduction of acute symptoms (especially neurologic symptoms) and possible prevention of chronic neurologic symptoms. Various other medications and herbal remedies have been tried, with variable results. Most cases are self-limited, and death occurs in less than 0.1% of cases.

SCOMBROID (PSEUDOALLERGIC) FISH POISONING

Ingestion of members of the Scomberesocidae and Scombridae families, including albacore, mackerel, tuna, bonita, and kingfish, have been linked to major outbreaks of pseudoallergy fish poisoning. Nonscombroid fish and marine mammals, such as mahi-mahi (dolphin fish), swordfish, and bluefish, also are associated with poisoning.

Scombrotoxin, either histamine or the product of the action of the toxin on fish flesh, is responsible for the clinical syndrome. Histidine is found in high concentrations in the flesh of scombroid fish; the action of bacterial decarboxylases during putrification converts the histidine to histamine. Fish containing more than 20 mg of histamine per 100 g of flesh are toxic. In patients receiving isoniazid, a potent histaminase blocker, ingestion of fish flesh containing a lower concentration of histamine may be toxic.

The onset of **clinical manifestations** is acute and occurs within 10 min to 2 hr of ingestion. The most common symptoms and signs are diarrhea, erythema, sweating, flushing, diaphoresis, urticaria, nausea, and headache (Fig. 722-1). Abdominal pain, tachycardia, oral burning or numbness, dizziness, respiratory distress, hives, and facial swelling also occur. The illness is usually self-limited, terminating within 8-24 hr.

Treatment

Treatment is mainly supportive. Gastric lavage decreases continued absorption of histamine. With severe diarrhea, fluid replacement may be necessary. Antihistamines have been variably successful. Four patients with severe toxicity treated with cimetidine (a histamine blocker) showed rapid response. Because data on these possible treatments are limited, cimetidine or ranitidine should be reserved for severe cases.

PARALYTIC SHELLFISH POISONING

Mussels, clams, oysters, scallops, and other filter-feeding mollusks may become contaminated during dinoflagellate blooms or “red tides.” During periods of contamination, water in coastal areas can be colored red by the algae; this sign is the origin of the term *red tide*. (Such discoloration does not necessarily indicate the presence of toxin, and toxin may be present in high quantities without discoloration. Nonetheless, discolored water should be regarded with suspicion.) The dinoflagellates *Alexandrium* spp. and *Gymnodinium catenatum* often are responsible for these red tides and contain several potent neurotoxins. Paralytic shellfish poisoning is a distinctive neurologic illness caused by 20 closely related heat-stable paralytic shellfish toxins. Saxitoxin is the most potent of the neurotoxins responsible for paralytic shellfish poisoning. This toxin prevents nerve conduction by inhibiting the sodium–potassium pump. Other toxins may be bioconverted to less toxic compounds. Consumption of bivalves, such as mussels, scallops, and clams, is the usual pathway of intoxication, although crustaceans and fish have been implicated as well.

The onset of **clinical manifestations** of paralytic shellfish poisoning occurs rapidly, 30 min to 2 hr after ingestion. Abdominal pain and

nausea are common. Paresthesias are common and occur circumorally or in a stocking–glove distribution, or both. Perioral numbness or tingling, diplopia, ataxia, dysarthria, and the sensation of floating are seen less commonly. Hot-cold reversal in temperature sensation is not unusual. In severe cases, respiratory failure from diaphragmatic paralysis may result. Swimming in the water during a red tide episode does not appear to have neurologic sequalae, although skin or mucosal irritation may result.

Treatment

No antidote for paralytic shellfish poisoning is known. Supportive care, including mechanical ventilation, may be needed. Although the symptoms are usually self-limited and short-lived, weakness and malaise may persist for weeks after ingestion.

NEUROTOXIC SHELLFISH POISONING

Neurotoxic shellfish poisoning is a rare disease caused by molluscan shellfish contaminated with brevetoxins. Shellfish harvested along the Gulf of Mexico during or right after a red tide are at risk of contamination with brevetoxins produced by the dinoflagellate *Karenia brevis*. There has also been recent evidence of brevetoxin production by raphidophytes (*Chattonella* spp.). Brevetoxins are a group of more than 10 lipid-soluble neurotoxins that activate sodium ion channels, causing nerve membrane depolarization. Shellfish are not affected by the brevetoxins. Rinsing, cleaning, cooking, and freezing do not destroy the toxins. Consumption of contaminated shellfish goes unnoticed because the brevetoxins cannot be detected by taste or smell.

The onset of **clinical manifestations** of neurotoxic shellfish poisoning occurs from within a few min up to 18 hr after consumption. The majority of symptoms are gastrointestinal (nausea, vomiting, and diarrhea) or neurologic (numbness and tingling of the lips, mouth, face, and extremities, ataxia, partial limb paralysis, reversal of hot and cold sensation, slurred speech, headache, and fatigue). Neurotoxic shellfish poisoning is similar to a mild case of paralytic shellfish poisoning.

Treatment

There are no specific antidotes for brevetoxins. Treatment involves mostly supportive care. Brevenal, a natural antagonist of brevetoxin produced by *K. brevis*, may be used as a form of treatment in the future.

DIARRHETIC SHELLFISH POISONING

Several outbreaks of diarrhetic shellfish poisoning have been reported in Europe after consumption of mussels, cockles, and other shellfish. The dinoflagellates *Dinophysis* and *Prorocentrum* produce okadaic acid and its derivatives, the dinophysistoxins. These compounds inhibit protein phosphatases. The intracellular accumulation of phosphorylated proteins causes increased fluid secretion by gut cells via calcium influx, which is mediated by cyclic adenosine monophosphate and prostaglandins.

Patients have severe diarrhea. Care is supportive and directed at rehydration. The illness is self-limited, and recovery occurs in 3-4 days; few patients require hospitalization.

AMNESIC SHELLFISH POISONING

Amnesic shellfish poisoning was first reported in 1987 in Canada when a group of people demonstrated severe gastroenteritis as well as neurologic symptoms, including memory loss, after eating mussels from Prince Edward Island. Subsequent cases have been identified after consumption of shellfish from the United States, Spain, and the United Kingdom. The responsible toxin, domoic acid, comes from a diatom, *Pseudonitzschia multiseries,* and is a potent glutamate agonist, disrupting neurochemical transmission in the brain. It also binds to glutamate receptors, which increase calcium influx, producing neuronal swelling in the hippocampal area of the brain and death.

The initial **clinical manifestations** are gastrointestinal. Memory loss is closely related to advanced age. Those patients <40 yr are more likely to suffer only from diarrhea, whereas those >50 yr suffer from short-term memory loss lasting months to years.

AZASPIRACID POISONING

The azaspiracids are a class of algal toxins. Azaspiracid poisoning results from ingestion of contaminated bivalve shellfish, especially mussels. Azaspiracid toxins are distributed throughout the muscle tissue in the shellfish. Azaspiracid is cytotoxic to cells and an inhibitor of Ca^{++} channels in plasma membranes. Symptoms start 6-18 hr after ingestion and include nausea, vomiting, severe stomach cramps, and diarrhea, which often persist up to 5 days.

Bibliography is available at Expert Consult.

722.4 Melamine Poisoning

Denise A. Salerno and Stephen C. Aronoff

Melamine (1,3,5-triazine-2,4,6-triamine, or $C_3H_6N_6$), a compound developed in the 1830s, is found in many plastics, adhesives, laminated products, cement, cleansers, fire retardant paint, and more. Melamine poisoning from food products was unheard of until 2007, when melamine-tainted pet food caused the death of many dogs and cats in the United States. In 2008, feeding of melamine-tainted infant formula to more than 300,000 children resulted in kidney injuries, 50,000 hospitalizations, and 6 deaths in China. This was the first reported epidemic of melamine-tainted milk products.

Melamine contains 66% nitrogen by mass. The illegal addition of melamine to infant formula can give the formula a milky appearance and falsely raise the protein content as measured by nitrogen testing.

Melamine, combined with cyanuric acid, forms cyanurate crystals in the kidneys. Along with protein, uric acid, and phosphate, melamine forms renal calculi.

Clinical manifestations are initially subtle and nonspecific. The severity is dose related. The first symptoms in affected infants are unexplained crying (especially when urinating), vomiting, and discolored urine caused by the formation of stones and gravel in the urinary tract. Urinary obstruction and acute renal failure follow. In the absence of a specific diagnosis, death from renal failure occurs. Whether children with melamine-induced renal failure will have chronic sequelae is currently unknown. Animal studies have shown that melamine may cause cognitive impairment but further investigation is needed.

The melamine stones and gravel can be treated with hydration, alkalinization, or lithotripsy. Acute renal failure requires supportive care and dialysis if needed.

Chapter 723

Biologic and Chemical Terrorism

Theodore J. Cieslak and Frederick M. Henretig

Tragically, increasing numbers of children are being victimized by terrorist actions. Brought to the forefront of American consciousness by Timothy McVeigh's references to child fatalities as "collateral damage" during the Oklahoma City bombing in April 1995, the intentional targeting of children became firmly ensconced as a global reality with the attack upon a school in Beslan, Russia, in September 2004. The attack, which left 334 (Including 186 children) dead, presaged additional attacks specifically directed against children at an Amish School in Pennsylvania in 2006, at a camp for teenagers in Utoya, Norway, in

2011, and at Sandy Hook Elementary School in Connecticut in 2012, among others.

Paralleling the targeting of children is an apparent trend toward the use of "unconventional" weapons of terror. In 1984, members of the Rajneeshee cult employed *Salmonella typhi* in a wave of intentional poisonings that affected 751 persons, including 142 teenage patrons of a popular pizza parlor. In 1995, the Aum Shinrikyo cult killed 12 and sickened thousands by intentionally releasing sarin nerve agent in the Tokyo subway system. A disgruntled scientist deployed anthrax spores via the U.S. mail in October 2001, killing 5 and injuring 17 in an attack upon a nation already reeling in the wake of the 9/11 attacks.

These developments remind us that terrorists can strike at any time utilizing any number of unconventional weapons, including biologic and chemical agents. Children will not be spared in these attacks on civilians, and, indeed, schools and daycare sites may be the targets of these actions.

ETIOLOGY

Terrorists may choose to use **weapons of opportunity,** agents that for some reason are readily available to some member of the terrorist group. The motives of terrorists often are obscure and difficult to predict. Prevention and response strategies should thus concentrate not on those agents most likely to be used but, rather, on those agents that, if used, would constitute the gravest potential threats to public health and security.

Biologic threat agents, including pathogens and toxins, have been divided by the Centers for Disease Control and Prevention into 3 categories, with **category A** including diseases caused by those 6 agents posing the greatest threat: anthrax, plague (see Chapter 203.3), tularemia (see Chapter 206), smallpox, botulism (see Chapter 210), and the viral hemorrhagic fevers (see Chapter 271).

Terrorists could also procure and release a vast array of potentially harmful chemicals. Tank cars full of flammable industrial gases and liquids, corrosive industrial acids and bases, poisonous compounds such as cyanides and nitrites, pesticides, dioxins, and explosives traverse our railways and roads daily. Four classes of "military-grade" chemicals with a history of use in warfare or manufactured specifically for use as weapons include the organophosphate-based nerve agents, vesicants, "blood agents" (cyanides), and certain pulmonary irritants or "choking agents."

EPIDEMIOLOGY AND PEDIATRIC-SPECIFIC CONCERNS

Large-scale attacks on civilian targets will likely involve pediatric victims, and children may be more susceptible than adults to the effects of certain biologic and chemical agents (see Chapter 719). A thinner and less-keratinized epidermis makes dermally active chemical agents, such as mustard, a greater risk to children than adults. A larger surface area per unit volume further increases the problem. A small relative blood volume makes children more susceptible to the volume losses associated with enteric infections such as cholera and to gastrointestinal intoxications such as might be seen with exposure to the staphylococcal enterotoxins. Children's high minute ventilation, compared with that of adults, increases the threat of agents delivered via the inhalational route. The fact that children live "closer to the ground" compounds this effect when heavier-than-air chemicals are involved. An immature blood–brain barrier may heighten the risk of central nervous system toxicity from nerve agents. Developmental considerations make it less likely that a child would readily flee an area of danger, thereby increasing exposure to these various adverse effects.

Children appear to have a unique susceptibility to certain potential agents that might be used by terrorists. Although adults generally suffer only a brief, self-limited incapacitating illness after infection with Venezuelan equine encephalitis virus, young children are more likely to experience seizures, permanent neurologic sequelae, and death. In the case of smallpox, waning herd immunity may disproportionately affect children. Vaccine-induced immunity to smallpox probably diminishes significantly after ages 3-10 yr. Although most adults are considered susceptible to smallpox, given that routine civilian immunization ceased in the early 1970s, older adults may have some residual protection from death, if not from the development of disease. Today's children are among the first to grow up in a world without any individual or herd immunity to smallpox.

Children also may experience unique disease manifestations not seen in adults; suppurative parotitis is a common characteristic ring among children with melioidosis but is not generally seen in adults with *Burkholderia pseudomallei* infection (see Chapter 205.2).

Pediatricians are likely to experience unique problems in managing childhood victims of biologic or chemical attack. Many of the drugs useful in treating such casualties are unfamiliar to pediatricians or have relative contraindications in childhood. The fluoroquinolones and tetracyclines are commonly cited as agents of choice in the treatment and prophylaxis of anthrax, plague, tularemia, brucellosis, and Q fever. Both drug classes are often avoided in children, although the risk of morbidity and mortality from diseases induced by agents of bioterrorism far outweighs the minor risks associated with short-term use of these agents. Ciprofloxacin received, as its first licensed pediatric indication, FDA approval for use in the prophylaxis of anthrax after inhalational exposure during a terrorist attack. Doxycycline and levofloxacin are licensed specifically in children for the same indication and levofloxacin is also licensed for postexposure prophylaxis of children against plague. Immunizations potentially useful in preventing biologic agent–induced diseases are often not approved for use in pediatric patients. The available anthrax vaccine is licensed only for those between 18 and 65 yr of age. The plague vaccine, currently out of production and probably ineffective against inhalational exposures, was approved only for individuals ages 18-61 yr. The smallpox vaccine, a live vaccine employing vaccinia virus, can cause fetal vaccinia and demise when given to pregnant women.

Many otherwise useful pharmaceutical agents are not available in pediatric dosing regimens. The military distributes nerve agent antidote kits consisting of prefilled autoinjectors designed for the rapid administration of atropine and pralidoxime. Many emergency departments and some ambulances stock these kits. The doses of agents contained in the nerve agent antidote kit are calculated for soldiers and thus are far in excess of those appropriate for young children, and pediatric pralidoxime autoinjectors are not yet available. Atropine autoinjectors specifically formulated for children are approved by the FDA and are available.

Although physical protective measures and devices (e.g., "gas masks") are likely to be of little utility in a civilian terrorism setting, such commercially available devices are not often available in pediatric sizes. The Israeli experience during the first Gulf War suggests that frightened parents may improperly use such masks on their children, resulting in inadvertent suffocation.

In the event of a large-scale terrorist attack, there may be an insufficient number of pediatric hospital beds. In any large disaster, excess bed capacity might potentially be provided at civilian and veterans hospitals under the auspices of the National Disaster Medical System, but that system makes no specific provision for pediatric beds.

CLINICAL MANIFESTATIONS

Should a terrorist attack occur, clinicians may be called on to make prompt diagnoses and render rapid lifesaving treatments before the results of confirmatory diagnostic tests are available. Although each potential agent of terrorism produces its own unique clinical manifestations, it is useful to consider their effects in terms of a limited number of distinct clinical syndromes. This approach helps clinicians make prompt, rational decisions regarding empirical therapy. Casualties resulting from a terrorist attack would either experience symptoms immediately upon exposure to an agent (or within the 1st several hr after exposure) or, alternatively, would see their symptoms develop slowly over a period of days to weeks. In the former case, the sinister nature of the event is often obvious and the etiology more likely to be conventional or chemical in nature. Biologic agents differ from conventional, chemical (see Chapter 719), and nuclear (see Chapter 718) weapons in that they have inherent incubation periods. Consequently, patients are likely to present removed in time and place from the point

Table 723-1 Diseases Caused By Agents of Chemical and Biologic Terrorism, Classified By Syndrome

	NEUROMUSCULAR SYMPTOMS PROMINENT	RESPIRATORY SYMPTOMS PROMINENT	DERMATOLOGIC FINDINGS PROMINENT
Sudden-onset	Nerve agents	Chlorine Phosgene Cyanide	Mustard Lewisite
Delayed-onset	Botulism	Anthrax Plague Tularemia Ricin	Smallpox

of an unannounced and unnoticed exposure to a biologic agent. Whereas traditional first responders, such as firefighters and paramedics, may be at the forefront of a conventional or chemical terrorism response, the primary care physician is likely to constitute the first line of defense against the effects of a biologic agent.

Casualties can thus be categorized as either immediate or delayed in presentation. Within each of these categories, patients can be further classified as having primarily respiratory, neuromuscular, or dermatologic manifestations (Table 723-1). A limited number of agents may cause each particular syndrome, permitting institution of empiric therapy targeted at a short list of potential etiologies. The viral hemorrhagic fevers might manifest as fever and a bleeding diathesis; these agents are considered separately in Chapter 271. In most cases, supportive care is the mainstay of hemorrhagic fever treatment.

Sudden-Onset Neuromuscular Syndrome: Nerve Agents

The very rapid onset of neuromuscular symptoms after an exposure should lead the clinician to consider nerve agent intoxication. The nerve agents (*tabun, sarin, soman,* and *VX*) are **organophosphate** analogs of common pesticides that act as potent inhibitors of the enzyme acetylcholinesterase. They are hazardous via ingestion, inhalation, or cutaneous absorption (see Chapter 63).

The inhibition of cholinesterase by these compounds results in the accumulation of acetylcholine at neural and neuromuscular junctions, causing excess stimulation. The resultant **cholinergic syndrome** involves central, nicotinic, and muscarinic effects. Central effects include altered mental status progressing rapidly to lethargy and coma, as well as ataxia, convulsions, and respiratory depression. Studies on pesticide exposure suggest that children may be more prone to central neurologic dysfunction with organophosphate toxicity than adults. Nicotinic effects include muscle fasciculations and twitching, followed by weakness, which can progress to flaccid paralysis as muscles fatigue. Muscarinic effects include miosis, visual blurring, profuse lacrimation, and watery rhinorrhea. Bronchospasm and increased bronchial secretions lead to cough, wheezing, dyspnea, and cyanosis. Cardiovascular manifestations include bradycardia, hypotension, and atrioventricular block. Flushing, sweating, salivation, nausea, vomiting, diarrhea, abdominal cramps, and urinary incontinence are also seen. In the absence of prompt intervention, death can quickly result from a combination of central effects and respiratory muscle paralysis.

Delayed-Onset Neuromuscular Syndrome: Botulism

The delayed onset (hours to days after exposure) of neuromuscular symptoms is characteristic of botulism. Botulism occurs after exposure to 1 of 7 related neurotoxins produced by certain strains of *Clostridium botulinum,* a strictly anaerobic, spore-forming, Gram-positive bacillus commonly found in soil. Naturally occurring botulism (see Chapter 210) usually follows ingestion of preformed toxin (food poisoning) or results from intestinal toxin production (infantile botulism). An aerosol exposure would likely result in a case of clinical botulism indistinguishable from that caused by natural exposures.

Following exposure to botulinum toxin, clinical manifestations typically begin with bulbar palsies, causing patients to complain of ptosis, photophobia, and blurred vision resulting from difficulty in accommodation. Symptoms can progress to include dysarthria, dysphonia, and dysphagia and, finally, a descending symmetric paralysis. Sensation and sensorium are typically not affected. In the absence of intervention, death often results from respiratory muscle failure.

Sudden-Onset Respiratory Syndrome: Chlorine, Phosgene, and Cyanide

The acute onset of respiratory symptoms shortly after exposure should prompt the clinician to consider a range of potential chemical agents. Of note, nerve agents, discussed previously, may affect respiration via massive bronchial hypersecretion, bronchospasm, and respiratory muscle paresis. However, the nerve agent casualty will likely have generalized muscle involvement and central nervous system manifestations. In contrast, the toxic inhalants chlorine and phosgene produce respiratory distress without neuromuscular involvement.

Chlorine is a dense, acrid, yellow-green gas that is heavier than air. After mild to moderate exposure, ocular and nasal irritation occurs, followed by cough, a choking sensation, bronchospasm, and substernal chest tightness. Pulmonary edema, mediated by hydrochloric acid and free oxygen radical generation, follows moderate to severe exposures within 30 min to several hours. Hypoxemia and hypovolemia secondary to pulmonary edema are the factors responsible for death when it occurs.

Phosgene, like chlorine, is a common industrial compound that was used as a weapon on the battlefields of World War I. Its odor has been described as similar to "new-mown hay." Like chlorine, phosgene also is thought to result in the generation of hydrochloric acid, contributing particularly to upper airway, nasal, and conjunctival irritation. Acylation reactions caused by the effects of phosgene on the pulmonary alveolar-capillary membrane lead to pulmonary edema. Phosgene lung injury also may be mediated, in part, by an inflammatory reaction associated with leukotriene production. Patients with mild to moderate exposures to phosgene may be asymptomatic, a fact that may cause victims to remain in a contaminated area. Pulmonary edema occurs 4-24 hr after exposure and is dose dependent, with heavier exposures causing earlier symptoms. Dyspnea may precede radiologic findings. In severe exposures, pulmonary edema may be so marked as to result in hypovolemia and hypotension. As in the case of chlorine, death results from hypoxemia and asphyxia.

Cyanide is a cellular poison, with protean clinical manifestations. Initially, cyanide toxicity is most likely to manifest as tachypnea and hyperpnea, progressing rapidly to apnea in cases with significant exposure (see Chapter 63). The efficacy of cyanide as a chemical terrorism agent is limited by its volatility in open air and relatively low lethality in comparison with nerve agents. Released in a closed room, however, cyanide could have devastating effects, as evidenced by its use in the Nazi gas chambers during World War II. Cyanide inhibits cytochrome a_3, interfering with normal mitochondrial oxidative metabolism and leading to cellular anoxia and lactic acidosis. In addition to respiratory distress, early findings among cyanide victims include tachycardia, flushing, dizziness, headache, diaphoresis, nausea, and vomiting. With greater exposure, seizures, coma, apnea, and cardiac arrest may follow within min. An elevated anion gap metabolic acidosis is typically

present, and decreased peripheral oxygen utilization leads to an elevated mixed venous oxygen saturation value.

Delayed-Onset Respiratory Syndrome: Anthrax, Plague, Tularemia, and Ricin

A delayed onset of respiratory symptoms (days after exposure) is characteristic of several infectious diseases and 1 toxin that might be adapted for sinister purposes by terrorists. Among the most threatening and problematic of these are anthrax, plague, tularemia, and ricin, the latter having garnered considerable media attention in recent years.

Anthrax is caused by infection with the Gram-positive spore-forming rod *Bacillus anthracis.* Its ability to form a spore enables the anthrax bacillus to survive for long periods in the environment and enhances its potential as a weapon.

The vast majority of naturally occurring anthrax cases are cutaneous, acquired by close contact with the hides, wool, bone, and other by-products of infected ruminants (principally cattle, sheep, and goats). Cutaneous anthrax is amenable to therapy with a variety of antibiotics and is readily recognizable to experienced clinicians in endemic areas; consequently, it is rarely fatal. Although it is common in parts of Asia and sub-Saharan Africa, only 2 cases of cutaneous anthrax had occurred in the United States in the 9 yr that preceded the attacks of 2001 (when 11 cutaneous cases were seen). Gastrointestinal anthrax, which has never been described in the United States, can occur after the ingestion of contaminated meat. In the past, inhalational anthrax, or **woolsorters' disease**, was an occupational hazard of abattoir and textile workers. Now eliminated as a naturally occurring disease in the United States, it is this inhalational form of anthrax that poses the greatest terror threat. Following an inadvertent release in 1979 from a bioweapons facility at Sverdlovsk in the former Soviet Union, 66 of 77 (86%) known adult victims of inhalational anthrax died. In the 2001 attacks involving contaminated mail in the United States, 5 of 11 (46%) patients with inhalational anthrax died. Whether better intensive care modalities, changes in antibiotic therapy, or earlier recognition accounted for this improved mortality rate remains unknown.

Symptomatic inhalational anthrax typically begins 1-6 days after exposure, although incubation periods of up to several weeks have been reported. The disease begins as a flu-like illness, characterized by fever, myalgia, headache, and cough. A brief intervening period of improvement sometimes follows, but rapid deterioration then ensues; high fever, dyspnea, cyanosis, and shock mark this second phase. Hemorrhagic meningitis occurs in up to 50% of cases. Chest radiographs obtained late in the course of illness may reveal a widened mediastinum or prominent mediastinal lymphadenopathy; pleural effusions also may be seen. Bacteremia is often so profound that Gram stains of peripheral blood may demonstrate the organism at this stage. Prompt treatment is imperative; death occurs in as many as 95% of inhalational anthrax cases if such treatment is begun more than 48 hr after the onset of symptoms.

Whereas inhalational anthrax is a disease primarily of mediastinal lymphatic tissue, exposure to aerosolized plague bacilli typically leads to a primary pneumonia. Endemic **plague** is usually transmitted via the bites of fleas and is discussed in Chapter 203.3. The causative organism of all forms of human plague, *Yersinia pestis,* is a bipolar-staining, Gram-negative facultative intracellular bacillus. An ability to survive within the macrophage aids its dissemination to distant sites following inoculation or inhalation. "Buboes," markedly swollen, tender regional lymph nodes in the distribution of a bite, are the hallmark feature of bubonic plague. Fever and malaise are typically present, and septicemia often develops as bacteria gain access to the circulation. Petechiae, purpura, and overwhelming disseminated intravascular coagulopathy commonly occur, and 80% of bubonic plague victims ultimately have positive blood culture results. Plague is extremely infective and lethal, as illustrated by the fact that the "Black Death" eliminated one third of the population of Europe during the Middle Ages.

Intentional aerosol dissemination of *Y. pestis* would likely result in a preponderance of pneumonic plague cases. Pneumonic plague may also arise secondarily after seeding of the lungs of septicemic patients. Symptoms include fever, chills, malaise, headache, and cough. Chest radiographs may reveal a patchy consolidation, and the classic clinical finding is blood-streaked sputum. Disseminated intravascular coagulation and overwhelming sepsis typically develop as the disease progresses. Untreated pneumonic plague has a fatality rate approaching 100%.

Tularemia is a highly infectious disease caused by the Gram-negative coccobacillus *Francisella tularensis.* Naturally occurring tularemia is discussed in Chapter 206. The high degree of infectivity of *F. tularensis* (<10 organisms are thought to be necessary to produce infection via inhalation), as well as its survivability in the environment, contributes to its inclusion on the list of agents of concern. Several clinical forms of endemic tularemia are known, but inhalational exposure resulting from a terrorist attack would likely lead to a plague-like primary pneumonia or to typhoidal tularemia, manifesting as a variety of nonspecific symptoms including fever, malaise, and abdominal pain.

Ricin is a protein toxin derived from the castor bean plant (*Ricinus communis*) that inhibits ribosomal protein synthesis. It is highly toxic in animal studies when inhaled and may result in the delayed onset of respiratory distress, pulmonary edema, and acute respiratory failure. One case series of 8 persons from the 1940s described a febrile respiratory illness after inhalational exposure. If injected it may cause a sepsis-like syndrome that may progress to multiorgan system failure; ingestion can lead to severe gastroenteritis. Ricin-containing letters were mailed to a U.S. Senate office building in 2004, and again to President Obama and New York City Mayor Bloomberg in 2013, although no persons were sickened in either attack.

Sudden-Onset Dermatologic Syndrome: Mustard and Lewisite

The development of skin lesions shortly after exposure is characteristic of the chemical vesicants. These compounds, often referred to as *blistering agents*, are cellular poisons and include the alkylating agent mustard and the organic arsenical agent lewisite. Tissue injury to rapidly reproducing cells begins within minutes of contact with these agents. Clinical effects typically become evident several hours after exposure to mustard, whereas patients exposed to lewisite feel immediate pain. Both mustard and lewisite affect the eyes and respiratory tract and their inadvertent ingestion may produce significant gastrointestinal symptoms. Mustard exposure may lead to bone marrow suppression.

Delayed-Onset Dermatologic Syndrome: Smallpox

The appearance of an exanthem days to weeks after exposure is likely to be a presenting feature of smallpox. Caused by infection with variola virus, a member of the orthopoxvirus family, smallpox has an incubation period of 7-17 days. This would likely permit the wide dispersal of asymptomatic exposed persons, thus contributing to the spread of an outbreak. During the incubation period, virus replicates in the upper respiratory tract. A primary viremia ensues, during which time seeding of the liver and spleen occurs. A secondary viremia then develops, the skin is seeded, and the classic exanthem of smallpox appears.

Symptoms of smallpox begin abruptly during the phase of secondary viremia and include fever, rigors, vomiting, headache, backache, and extreme malaise. Within 2-4 days, macules appear on the face and extremities and then progress in synchronous fashion to papules, pustules, and finally scabs. As the scabs separate, survivors often are left with disfiguring, depigmented scars. The synchronous nature of the rash and its centrifugal distribution distinguish smallpox from chickenpox, which has a centripetal distribution. Historically, smallpox had a 30% mortality rate, with death typically resulting from visceral organ involvement.

DIAGNOSIS

In some cases, the terrorist nature of a chemical or biologic attack may be obvious, for example, a chemical attack in which victims succumb in close temporal and geographic proximity to a dispersal device or terrorists announce their attack. In other instances, the clinician may

need to rely on epidemiologic clues to suspect an intentional release of chemical or biologic agents. The presence of large numbers of victims clustered in time and space should raise the index of suspicion, as should cases of unexpected death or unexpectedly severe disease. Diseases unusual in a given locale, in a given age group, or during a certain season likewise may warrant further investigation. Simultaneous outbreaks of a disease in noncontiguous areas should cause one to consider an intentional release, as should outbreaks of multiple diseases in the same area. Even a single case of a rare disorder such as anthrax or certain viral hemorrhagic fevers would be suspicious, and a single case of smallpox would almost certainly be the result of an intentional dissemination. Large numbers of dying animals might provide evidence of an unnatural aerosol release, as would evidence of disparate attack rates between those known to be indoors and outdoors at a given time.

In a mass casualty setting, diagnoses may be made largely on clinical grounds. The diagnosis of nerve agent intoxication is based primarily on clinical recognition and patient response to antidotal therapy. Several simple rapid detection devices developed for military use can detect the presence of nerve agents. Some of these are now commercially available and are stocked in certain emergency departments and public safety vehicles. Measurements of acetylcholinesterase in plasma or erythrocytes of nerve agent victims may be helpful in long-term prognostication, but correlation between cholinesterase levels and clinical effects is often poor, and the test rarely is available on an emergency basis.

Botulism should be suspected clinically among patients presenting with a symmetric, descending, flaccid paralysis. Although the differential diagnosis of botulism includes other uncommon neurologic disorders, such as myasthenia gravis and the Guillain-Barré syndrome, the presence of multiple casualties with similar symptoms should aid in the determination of a botulism outbreak.

Initially, the diagnosis of **cyanide poisoning** also will likely be made on clinical grounds in the presence of the appropriate toxidrome. An unusually high anion gap metabolic acidosis with elevated serum lactate and an oxygen concentration greater than expected in mixed venous blood lend support to the clinical diagnosis. Elevated blood cyanide concentrations can confirm the clinical suspicion.

Anthrax should be suspected upon finding Gram-positive bacilli in skin biopsy material (in the case of cutaneous disease), blood smears, pleural fluid, or spinal fluid. Chest radiographs demonstrating a widened mediastinum in the context of fever and constitutional signs, and in the absence of another obvious explanation (e.g., blunt trauma or postsurgical infection), should also lead one to consider the diagnosis. Confirmation can be obtained by blood culture. State health laboratories and federal facilities at the U.S. Centers for Disease Control and Prevention and at the U.S. Army Medical Research Institute of Infectious Diseases can confirm a diagnosis of anthrax by polymerase chain reaction and immunohistochemical assay.

A diagnosis of **plague** can be suspected on finding bipolar "safety-pin"–staining bacilli in Gram or Wayson stains of sputum or aspirated lymph node material; confirmation is obtained by culturing *Y. pestis* from blood, sputum, or lymph node aspirate. The organism grows on standard blood or MacConkey TRA agars but it is often misidentified by automated systems. *F. tularensis* grows poorly on standard media; its growth is enhanced on media containing cysteine. Because of its extreme infectivity, however, many laboratories prefer to make a diagnosis via polymerase chain reaction or serologically using an enzyme-linked immunosorbent assay or serum agglutination assay.

Smallpox should be suspected on clinical grounds and can be confirmed by culture or electron microscopy of scabs or vesicular fluid, although the manipulation of clinical material from suspected smallpox victims should be attempted only at public health laboratories able to employ maximum biocontainment (Biosafety Level 4) precautions. Similar caution should be exercised with specimens from patients with various viral hemorrhagic fevers.

PREVENTION

Preventive measures can be considered in both a preexposure and a postexposure context. **Preexposure protection** against a chemical or biologic attack may consist of physical, chemical, or immunologic measures. **Physical protection** against primary attack often involves gas masks and protective suits; such equipment is used by the military and by certain hazardous materials response teams but it is unlikely to be available to civilians at the precise moment that a release occurs. Medical personnel need to understand the principles of physical protection as they apply to infection control and the spread of contamination.

Pneumonic plague is spread through respiratory droplets. Droplet precautions, including the use of simple surgical masks, are thus warranted for providers caring for patients with plague. Smallpox is transmitted by droplet nuclei. Airborne precautions, including (ideally) a high-efficiency particulate air filter mask, are thus warranted with smallpox victims. Similarly, patients with viral hemorrhagic fever should, in general, be managed with use of contact precautions. Most other biologic agent victims can be safely cared for with use of standard precautions. In the case of chemical agents, residual mustard or nerve agent on the skin or clothing of victims might potentially pose a hazard to medical personnel. For such victims, whenever possible, clothing should be removed and the patients decontaminated using copious amounts of water before extensive medical care is rendered. Most other chemical agents are volatile enough that spread of an agent among patients or from patient to caregiver is unlikely.

Preexposure chemical prophylaxis might be used on the basis of credible intelligence reports. Should officials deem that the threatened release of a specific biologic agent appears imminent, antibiotics might be distributed to a population preemptively. Opportunities to employ such a strategy are likely to be limited, although federal and state officials are examining various mechanisms for such employment.

Although licensed vaccines **(preexposure immunologic measures)** against anthrax and smallpox have been developed, widespread use of either vaccine is likely to be problematic, especially in children. The anthrax vaccine is licensed only for those persons age 18 yr and older, is given as a 5 dose series over 18 mo, and requires annual booster doses. These considerations make civilian employment of the current anthrax vaccine on a large scale unlikely, although a new recombinant anthrax vaccine is in development and being studied as a 3 dose series.

Significant obstacles to the widespread employment of smallpox vaccine also exist, although public health officials have contemplated the resumption of a smallpox vaccination campaign. Whereas in the past smallpox vaccine (prepared from vaccinia virus, an orthopoxvirus related to variola) was used safely and successfully in young infants, it has a relatively high rate of serious complications in certain patients. *Fetal vaccinia* and demise can occur when pregnant women are vaccinated. *Vaccinia gangrenosa,* an often fatal complication, can occur when immunocompromised persons are vaccinated. *Eczema vaccinatum* occurs in those with preexisting dermatoses (atopic dermatitis). Severe vaccine-related encephalitis was well known during the era of widespread vaccination; because it occurs only in primary vaccinees, it would disproportionately affect pediatric patients. Autoinoculation can occur when virus present at the site of vaccination is manually transferred to other areas of skin or to the eye. Young children would presumably be at greater risk for such inadvertent transmission. Myocarditis has been reported following vaccinations of military recruits.

To manage these complications, vaccinia immune globulin should be available when one is undertaking a vaccination campaign. Vaccinia immune globulin (0.6 mg/kg IM) may be given to vaccine recipients who experience severe complications or to significantly immunocompromised individuals exposed to smallpox and in whom vaccination would be unsafe. A compound, ST-246, has been used successfully under an Investigational New Drug permit to treat persons (including children) experiencing severe complications from vaccine. The current cell-culture–derived vaccine (ACAM2000), as well as vaccinia immune globulin and ST-246, can be obtained as needed upon consultation with officials at the Centers for Disease Control and Prevention. In addition to a potential role in preexposure prophylaxis, vaccination may be effective in postexposure prophylaxis if given within the 1st 4 days or so after exposure.

Table 723-2 Critical Biologic Agents of Terrorism

DISEASE	CLINICAL FINDINGS	INCUBATION PERIOD (DAYS)	ISOLATION PRECAUTIONS	INITIAL TREATMENT	PROPHYLAXIS
Anthrax (inhalational)* Patients who are clinically stable after 14 days can be switched to a single oral agent (ciprofloxacin or doxycycline) to complete a 60-days course†	Febrile prodrome with rapid progression to mediastinal lymphadenitis and mediastinitis, sepsis, shock, and meningitis	1-5	Standard	Ciprofloxacin‡ 10-15 mg/kg IV q12h *or* doxycycline 2.2 mg/kg IV q12h *and* clindamycin§ 10-15 mg/kg IV q8h *and* penicillin G‖ 400-600 kU/kg/day IV q4h plus raxibacumab	Ciprofloxacin 10-15 mg/kg PO q12h *or* doxycycline 2.2 mg/kg PO q12h
Plague (pneumonic)	Febrile prodrome with rapid progression to fulminant pneumonia, hemoptysis, sepsis, disseminated intravascular coagulation	2-3	Droplet (for 1st 3 days of therapy)	Gentamicin 2.5 mg/kg IV q8h *or* doxycycline 2.2 mg/kg IV q12h *or* ciprofloxacin 15 mg/kg IV q12h	Doxycycline 2.2 mg/kg PO q12h *or* ciprofloxacin 20 mg/kg PO q12h
Tularemia	Pneumonic: abrupt onset of fever with fulminant pneumonia Typhoidal: fever, malaise, abdominal pain	2-10	Standard	Same as for plague	Same as for plague
Smallpox	Febrile prodrome with synchronous, centrifugal, vesiculopustular exanthema	7-17	Airborne (+ contact)	Supportive care	Vaccination may be effective if given within the 1st several days after exposure
Botulism	Afebrile descending symmetric flaccid paralysis with cranial nerve palsies	1-5	Standard	Supportive care; antitoxin (see text) may halt the progression of symptoms but is unlikely to reverse them	None
Viral hemorrhagic fevers	Febrile prodrome with rapid progression to shock, purpura, and bleeding diatheses	4-21	Contact (consider airborne in cases of massive hemorrhage)	Supportive care; ribavirin may be beneficial in select cases	None

*In a mass casualty setting, in which resources are severely constrained, it may be necessary to substitute oral therapy for the preferred parenteral option.
†Assuming the organism is sensitive, children may be switched to oral amoxicillin (80 mg/kg/day ÷ q8h) to complete a 60-day course. We recommend that the 1st 14 days of therapy or postexposure prophylaxis, however, include ciprofloxacin and/or doxycycline regardless of age.
‡Levofloxacin or ofloxacin may be an acceptable alternative to ciprofloxacin.
§Rifampin or clarithromycin may be an acceptable alternative to clindamycin as a drug that targets bacterial protein synthesis. If ciprofloxacin or another quinolone is employed, doxycycline may be used as a second agent because it also targets protein synthesis.
‖Ampicillin, imipenem, meropenem, or chloramphenicol may be an acceptable alternative to penicillin as a drug with good central nervous system penetration.

Anthrax vaccine might similarly be employed in a postexposure setting. Some authorities recommend 3 doses of this vaccine as an adjunct to postexposure chemoprophylaxis after documented exposure to aerosolized anthrax spores. Nonetheless, postexposure administration of oral antibiotics constitutes the mainstay of management for asymptomatic victims believed to have been exposed to anthrax as well as to other bacterial agents such as plague and tularemia. Table 723-2 lists appropriate prophylactic regimens for various biologic exposures.

TREATMENT

Tables 723-2 and 723-3 provide recommended therapies for overt diseases caused by various chemical and biologic agents. It is likely that the clinician attending to victims will need to make therapeutic decisions before the results of confirmatory diagnostic tests are available and in situations in which the diagnosis is not known with certainty. In particular, decontamination by hospital personnel in appropriate personal protective equipment is required for patients exposed to chemical agents who have not been adequately decontaminated in the prehospital setting (see Table 723-3). In such cases, it is useful to note that many diseases and symptoms caused by chemical and biologic agents will resolve spontaneously, with only supportive care required. Most cases of chlorine or phosgene exposure can be successfully managed by providing meticulous attention to oxygenation and fluid balance. Mustard victims may require intensive multisystem support, but no specific antidote or therapy is available. Many viral diseases, such as smallpox, most viral hemorrhagic fevers, and the equine encephalitides, are also managed supportively.

In addition to ensuring adequate oxygenation, ventilation, and hydration, the clinician may need to provide specific empiric therapies on an urgent basis. Patients suffering from the sudden onset of severe neuromuscular symptoms may have nerve agent intoxication and should be given atropine (0.05 mg/kg) promptly for its antimuscarinic effects. Although atropine relieves bronchospasm and bradycardia, reduces bronchial secretions, and ameliorates the gastrointestinal effects of nausea, vomiting, and diarrhea, it does not improve skeletal muscle paralysis. Pralidoxime (also known as *2-PAM*) cleaves the organophosphate moiety from cholinesterase and regenerates intact enzyme if "aging" has not occurred. The effect is most prominent at the neuromuscular junction and leads to improved muscle strength. Its prompt use (at a dose of 25 mg/kg) as an adjunct to atropine is recommended in all serious cases.

Ideally, both atropine and pralidoxime should be administered intravenously in severe cases, although the intraosseous route may be acceptable. Some experts recommend that atropine be given intramuscularly in the presence of hypoxia to avoid arrhythmias associated with

Table 723-3 Critical Chemical Agents of Terrorism

AGENT	TOXICITY	CLINICAL FINDINGS	ONSET	DECONTAMINATION*	MANAGEMENT
NERVE AGENTS					
Tabun, sarin, soman, VX	Anticholinesterase: muscarinic, nicotinic, central nervous system effects	Vapor: miosis, rhinorrhea, dyspnea Liquid: diaphoresis, vomiting Both: coma, paralysis, seizures, apnea	Seconds: vapor Minutes to hours: liquid	Vapor: fresh air, remove clothes, wash hair Liquid: remove clothes, wash skin, hair with copious soap and water, ocular irrigation	ABCs. Atropine: 0.05 mg/kg IV†, IM‡ (min: 0.1 mg, max: 5 mg), repeat q2-5 min prn for marked secretions, bronchospasm Pralidoxime: 25 mg/kg IV, IM§ (max: 1 g IV; 2 g IM), may repeat within 30-60 min prn, then again q1h for 1 or 2 doses prn for persistent weakness, high atropine requirement Diazepam: 0.3 mg/kg (max: 10 mg) IV; lorazepam: 0.1 mg/kg IV, IM (max: 4 mg); midazolam: 0.2 mg/kg (max: 10 mg) IM prn for seizures or severe exposure
VESICANTS					
Mustard	Alkylation	Skin: erythema, vesicles Eye: inflammation Respiratory tract: inflammation	Hours	Skin: soap and water Eyes: water (effective only if done within minutes of exposure)	Symptomatic care
Lewisite	Arsenical		Immediate pain		Possibly British antilewisite (BAL) 3 mg/kg IM q4-6h for systemic effects of lewisite in severe cases
PULMONARY AGENTS					
Chlorine, phosgene	Liberate hydrochloric acid, alkylation	Eye, nose, and throat irritation (especially chlorine) Respiratory: bronchospasm, pulmonary edema (especially phosgene)	Minutes: eye, nose, and throat irritation, bronchospasm Hours: pulmonary edema	Fresh air Skin: water	Symptomatic care (see text)
CYANIDE					
	Cytochrome oxidase Inhibition: cellular anoxia, lactic acidosis	Tachypnea, coma, seizures, apnea	Seconds	Fresh air Skin: soap and water	ABCs, 100% oxygen Na bicarbonate prn metabolic acidosis; hydroxycobalamin 70 mg/kg IV (max: 5 g) *or* nitrite/thiosulfate, given as follows (see text): *Na nitrite (3%): dose (mL/kg) (max: 10 mL)* — *Estimated hemoglobin concentration (g/dL)* 0.27 — 10 0.33 — 12 (estimated for average child) 0.39 — 14 followed by Na thiosulfate (25%): 1.65 mL/kg (max: 50 mL)

*Decontamination, especially for patients with significant nerve agent or vesicant exposure, should be performed by healthcare providers garbed in adequate personal protective equipment. For emergency department staff, this equipment consists of a nonencapsulated, chemically resistant body suit, boots, and gloves with a full-face air-purifier mask/hood.

†Intraosseous route is likely equivalent to intravenous.

‡Atropine might have some benefit via endotracheal tube or inhalation, as might aerosolized ipratropium. See also Table 723-4.

§Pralidoxime is reconstituted to 50 mg/mL (1 g in 20 mL water) for IV administration, and the total dose infused over 30 min, or may be given by continuous infusion (loading dose 25 mg/kg over 30 min, and then 10 mg/kg/hr). For IM use, it might be diluted to a concentration of 300 mg/mL (1 g added to 3 mL water—by analogy to the U.S. Army's Mark 1 autoinjector concentration), to effect a reasonable volume for injection. See also Table 723-4.

ABCs, airway, breathing, and circulatory support; max, maximum; min, minimum; prn, as needed.

Adapted from Henretig FH, Cieslak TJ, Eitzen EM: Biological and chemical terrorism, J Pediatr *141:311–326, 2002.*

intravenous administration. Many emergency management services stock military-style autoinjector kits consisting of atropine and 2-PAM for intramuscular injection. Pediatric atropine autoinjectors are licensed, although kits intended for adults (with 2 mg of atropine and 600 mg of pralidoxime) might be used in children >2-3 yr (Table 723-4). Animal studies support the routine prophylactic administration of anticonvulsant doses of benzodiazepines, even in the absence of observable convulsive activity.

Delayed neuromuscular symptoms in the setting of terrorism might be due to botulism. Supportive care, with meticulous attention

Table 723-4 Pediatric Autoinjector Recommendations for Mass Casualties or Prehospital Care*

ATROPINE AUTOINJECTOR THERAPY			
APPROXIMATE AGE	**APPROXIMATE WEIGHT (kg)**	**AUTOINJECTOR SIZE (mg)**	
<6 mo	<7.5	0.25	
6 mo-4 yr	7.5-18	0.5	
5-10 yr	18-30	1.0	
>10 yr	>30	2.0	
PRALIDOXIME AUTOINJECTOR THERAPY			
APPROXIMATE AGE (yr)	**APPROXIMATE WEIGHT (kg)**	**NUMBER OF AUTOINJECTORS**	**PRALIDOXIME DOSE (mg/kg)**
3-7	13-25	1	24-46
8-14	26-50	2	24-46
>14	>50	3	<35

*Consider adult pralidoxime autoinjector use for severely affected mass casualties when IV access or more precise mg/kg IM dosing is logistically impractical. The initial dose using atropine autoinjectors is 1 autoinjector of each recommended size. The initial dose using pralidoxime autoinjectors is the recommended number of (adult-intended, 600 mg) autoinjectors. These latter may also be injected into an empty sterile vile; the contents redrawn through a filter needle into a small syringe may then provide a ready source of concentrated (300 mg/mL) pralidoxime solution for IM injection to infants. Autoinjectors may become available that provide adult doses of both atropine and pralidoxime in one injector; these could be used in children ≥3 yr in lieu of two individual injectors and dosed as noted above for pralidoxime alone.

to ventilatory support, is the mainstay of botulism treatment. Such support may be necessary for several mo, making the management of a large-scale botulism outbreak especially problematic in terms of medical resources. A licensed heptavalent antitoxin (types A-G) is available through the Centers for Disease Control (1-800-232-4636). Administration of this antitoxin is unlikely to reverse disease in symptomatic patients but may prevent further progression. In addition, a pentavalent (containing antibody against toxin types A to E; but licensed only for treatment of type A or B intoxication) product, Botulism Immune Globulin Intravenous (Human), BabyBIG, is available through the California Department of Health Services (1-916-327-1400) specifically for the treatment of infant botulism.

The **rapid onset of respiratory symptoms** may signal an exposure to chlorine, phosgene, cyanide, or a number of other toxic industrial chemicals. Although the mainstay of therapy in virtually all of these exposures consists of removal to fresh air and intensive supportive care, cyanide intoxication often requires the administration of specific antidotes.

The classic cyanide antidote utilizes a nitrite along with sodium thiosulfate and is given in 2 stages. The methemoglobin-forming agent (e.g., sodium nitrite) is administered first, because methemoglobin has a high affinity for cyanide and causes it to dissociate from cytochrome oxidase. Nitrite dosing in children should be based on body weight to avoid excessive methemoglobin formation and nitrite-induced hypotension. For the same reasons, nitrites should be infused slowly over 5-10 min. A sulfur donor, such as sodium thiosulfate, is given next. This compound is used as a substrate by the hepatic enzyme rhodanese, which converts cyanide to thiocyanate, a less toxic compound excreted in the urine. Thiosulfate treatment itself is efficacious and relatively benign and may be used alone for mild to moderate cases. Sodium nitrite and sodium thiosulfate are packaged together in standard antidote kits, along with amyl nitrite, a sodium nitrite substitute that can be inhaled in prehospital settings in which intravenous access is not available.

Another antidote available in the United States is hydroxocobalamin, which exchanges its hydroxy group for cyanide, forming harmless cyanocobalamin (vitamin B_{12}), which is subsequently excreted by the kidneys. Hydroxycobalamin use is not complicated by the potential for nitrite-induced hypotension or methemoglobinemia, and it has low toxicity. The recommended dose is 5 g in adults or 70 mg/kg in children, administered IV over 15 min. A second dose (2.5-5 g in adults; 35-70 mg/kg in children) may be repeated in severely affected patients. Side effects include modest hypertension and reddening of skin, mucous membranes, and urine that may last several days. Although no human controlled trials are currently available to compare hydroxocobalamin with nitrite/thiosulfate-based therapies, many authorities believe that hydroxocobalamin's efficacy and safety profile favor it as the cyanide antidote of choice, especially for children in the mass casualty context.

Animal research suggests a modest benefit of steroid therapy in mitigating lung injury after chlorine inhalation, and thus steroids may be considered for patients with chlorine exposure, especially as an adjunct to bronchodilators in those manifesting bronchospasm and/or a history of asthma. Further, symptomatic relief has also been reported following chlorine exposure with nebulized 3.75% sodium bicarbonate therapy, though the impact of this regimen on pulmonary damage is unknown. Animal models have also suggested a benefit from antiinflammatory agents, including ibuprofen and *N*-acetylcysteine, which appear to ameliorate phosgene-induced pulmonary edema, as well as the utilization of low tidal volume ventilation (protective ventilation), although the results of such interventions have not yet been reported in clinical trials.

In cases in which the **delayed onset of respiratory symptoms** may be the result of a terrorist attack, consideration should be given to the empirical administration of an antibiotic effective against anthrax, plague, and tularemia. Ciprofloxacin (10-15 mg/kg IV q12h), levofloxacin (8 mg/kg IV q12h), or doxycycline (2.2 mg/kg IV q12h) is a reasonable choice. Although naturally occurring strains of *B. anthracis* usually are quite sensitive to penicillin G, these agents are chosen because penicillin-resistant strains of *B. anthracis* exist. Moreover, ciprofloxacin and doxycycline are effective against almost all known strains of *Y. pestis* and *F. tularensis*. Concerns about inducible β-lactamases in *B. anthracis* have led some experts to recommend 1 or 2 additional antibiotics in patients with inhalational anthrax. Rifampin, vancomycin, penicillin or ampicillin, clindamycin, imipenem, and clarithromycin are reasonable choices based on in vitro sensitivity data. Because *B. anthracis* relies on the production of 2 protein toxins, edema toxin, and lethal toxin, for its virulence, drugs that act at the ribosome to disrupt protein synthesis (e.g., clindamycin, the macrolides) provide a theoretical advantage. Frequent meningeal involvement among inhalational anthrax victims makes agents with superior central nervous system penetration desirable. A combination of ciprofloxacin plus clindamycin plus penicillin G is a good initial empiric therapy for presumed inhalational anthrax. Ciprofloxacin, levofloxacin, or doxycycline monotherapy is probably adequate in cases of cutaneous anthrax, although patients with cutaneous disease resulting from a terrorist attack initially should receive multidrug therapy, because of the possibility of concomitant inhalational exposure.

Raxibacumab, a monoclonal antibody that inhibits anthrax antigen binding to cell receptors, thus preventing toxins from entering cells, is

approved for the treatment of inhalation anthrax in combination with antibodies. The adult dose is 40 mg/kg given IV over 2 hr and 15 min. The dose for children is weight based; ≤15 kg: 80 mg/kg; >15-50 kg: 60 mg/kg; >50 kg: 40 mg/kg. Premedication with diphenhydramine IV or PO is recommended 1 hr before the infusion.

In patients in whom a diagnosis of plague or tularemia is established, streptomycin (15 mg/kg IM q12h) has historically been considered the drug of choice. Because this drug is generally unavailable, many experts consider gentamicin (2.5 mg/kg IV/IM q8h) the preferred choice for therapy. In addition to ciprofloxacin, levofloxacin, or doxycycline, chloramphenicol (25 mg/kg IV q6h) should be employed in the 6% of pneumonic plague cases with concomitant meningitis. To be effective, therapy for pneumonic plague must be initiated within 24 hr of the onset of symptoms. There is little clinical experience with ricin-induced pulmonary injury. The mainstay of therapy is expected to be supportive care.

The management of **vesicant-induced injury** is similar to that for burn victims and is largely symptomatic (see Chapter 75). Mustard victims will benefit from the application of soothing skin lotions such as calamine and the administration of analgesics. Early intubation of severely exposed patients is warranted to guard against edematous airway compromise. Oxygen and mechanical ventilation may be needed, and meticulous attention to hydration is of paramount importance. Ongoing research suggests a role for oral *N*-acetylcysteine in mitigating chronic pulmonary effects due to mustard injury. Lewisite victims can be managed in much the same manner as mustard victims. In addition, dimercaprol (British antilewisite) in oil, given intramuscularly, may help ameliorate the systemic effects of lewisite.

The management of symptomatic smallpox victims also is largely supportive, with attention to pain control, hydration status, and respiratory sufficiency again of primary importance. The parenteral antiviral compound cidofovir, licensed for the treatment of cytomegalovirus retinitis in HIV-infected patients, has in vitro efficacy against variola and other orthopoxviruses. Its utility in treating smallpox victims is untested. Moreover, in the face of a large outbreak of disease, wide parenteral use of this drug would be problematic. ST-246, mentioned previously, demonstrates excellent in vitro activity against orthopoxviruses, but its utility in treating patients with smallpox is likewise untested.

Chapter 724

Animal and Human Bites

Charles M. Ginsburg and David A. Hunstad

Many animals besides domestic and stray dogs and cats inflict bites on humans. The profile of such bites varies by country and region, based on living conditions, indigenous species, and opportunity for encounter.

EPIDEMIOLOGY

Worldwide there are tens of millions of **dog bites**, resulting in approximately 55,000 deaths from rabies (see Chapter 274). Dog bites represent approximately 80-90% of all bites in the United States; 5-15% are from cats, 2-5% from rodents, and the remainder from rabbits, ferrets, farm animals, monkeys, and reptiles. An estimated 4.5 million persons in the United States are bitten by dogs annually; approximately 885,000 of those bitten seek medical care. Bites from dogs are also most common in Bangladesh, India, Pakistan, and Myanmar, whereas in Nepal, cattle and buffalo account for more than half of bites, followed by dogs, pigs, and horses. Approximately 1% of dog bite wounds and 6% of cat bite wounds in the United States require hospitalization. During the past 3 decades, there have been approximately 20 deaths per year in the United States from dog-inflicted injuries; 65% of these occurred in children < age 11 yr. The breed of dog involved in attacks on children varies; Table 724-1 depicts the risk index of fatal dog bites by breed. Compared with other breeds, bites by pit bulls account for higher rates of hospital admission, higher Glasgow scores at admission, and an increased risk of death. Unaltered male dogs account for approximately 75% of attacks; nursing dams often inflict injury to humans when children attempt to handle their puppies.

The majority of dog attacks on children in the United States occur between the ages of 6 and 11 yr, with a slight predominance of males. Approximately 65% of the attacks occur around the home, 75% of the biting animals are known by the children, and almost 50% of the attacks are said to be unprovoked. Similar statistics apply in Canada, where 70% of all bites reported in 1 study were sustained by children between ages 2 and 14 yr; 65% of the dogs involved in the biting were part of the family or extended family, and the bite occurred in someone's home.

Of the approximately 450,000 reported **cat bites** per year occurring in the United States, nearly all are inflicted by known household animals. Because rodent bites (rat, mouse, gerbil) do not represent reportable conditions, little is known about the epidemiology of these injuries or the incidence of infection after rodent-inflicted bites or scratches.

Few data exist on the incidence and demographics of **human bite** injuries in pediatric patients; however, preschool and early school-age children appear to be at greatest risk of sustaining an injury from human bites, often in daycare or preschool settings. In some series, the proportion of human bites is highest among adolescents, an age group in which fist-to-tooth injuries (so-called fight bites) become more common.

CLINICAL MANIFESTATIONS

Dog bite–related injuries can be divided into 3 categories of almost equal incidence: abrasions, puncture wounds, and lacerations with or without an associated avulsion of tissue. Dog bites may also involve crush injury to tissues. In contrast, the most common type of injury from cat and rat bites is a puncture wound. Cat bites often penetrate to deep tissue. Human bite injuries are of 2 types: an occlusion injury that is incurred when the upper and lower teeth come together on a body part, or a clenched-fist injury that occurs when the injured fist, usually on the dominant hand, strikes the teeth of another individual.

DIAGNOSIS

Management of the bite victim should begin with a thorough history and physical examination. Careful attention should be paid to the circumstances surrounding the bite event (e.g., species and number of animals, type of animal [domestic or wild], whether the attack was provoked or unprovoked, location of the attack); a history of drug allergies; and the immunization status of the child (tetanus) and animal (rabies). During physical examination, meticulous attention should be paid to the type, size, and depth of the injury; the presence of any foreign material in the wound; the status of underlying structures; and, when the bite is on an extremity, the exact location of the injury, an assessment of possibly involved structures, and the range of motion of the affected area. A diagram of the injury should be recorded in the patient's medical record. Radiographs of the affected part should be considered if there is likelihood that a bone or joint was penetrated or fractured, or if foreign material is present. The possibility of a fracture or penetrating injury of the skull should particularly be considered in infants who have sustained dog bite injuries to the face or head.

COMPLICATIONS

Infection is the most common complication of bite injuries, regardless of the species of biting animal. The decision to obtain material for culture from a wound depends on the species of the biting animal, the

length of time that has elapsed since the injury, the depth of the wound, the presence of foreign material contaminating the wound, and whether there is clinical evidence of infection. Although potentially pathogenic bacteria have been isolated from up to 80% of dog bite wounds that are brought to medical attention within 8 hr after the bite, the infection rate for wounds receiving medical attention in <8 hr is relatively low (2.5-20%). If the dog bite(s) is(are) not deep and/or extensive, wounds that are <8 hr old do not require cultures unless there are early signs of infection or the patient is immunocompromised. *Capnocytophaga canimorsus* is isolated from approximately 5% of infected wounds in immunocompromised patients and can cause serious systemic infection in these individuals. The infection rate in **cat bite** wounds, even those that receive prompt medical attention, is >50%; therefore, it is prudent to obtain material for culture from all but the most trivial cat-bite wounds. Cultures should be taken from **all** other animal bite wounds that are not brought to medical attention within 8 hr, regardless of species.

The rate of infection after **rodent bite** injuries is not known. Most of the oral flora of rats is similar to that of other mammals; however, approximately 50% and 25% of rats harbor strains of *Streptobacillus moniliformis* and *Spirillum minus,* respectively, both of which cause **rat bite fever** (see Chapter 724.1).

All human bite wounds, regardless of the mechanism of injury, should be regarded as carrying a high risk for infection and should be cultured. Because of the high incidence of anaerobic infection after bite wounds, it is important to obtain material for anaerobic as well as aerobic cultures.

Table 724-2 lists common causes of soft tissue bacterial infections after dog, cat, or human bites. Bites of humans or cats, those in which treatment is delayed, those in immunocompromised patients, and those associated with deep puncture wounds or significant crush injury carry higher risk for infection. An elevated risk for infection is also present if the bite is to certain anatomic regions (e.g., hand, foot, or genitals) or there is penetration of bone or tendons.

TREATMENT

Table 724-3 describes the prophylactic management of human or animal bite wounds to prevent infection.

After appropriate material has been obtained for culture, the wound should be anesthetized, cleaned, and vigorously irrigated with copious amounts of sterile saline. Irrigation with antibiotic-containing solutions provides no advantage over irrigation with saline alone and may cause local irritation of the tissues. Puncture wounds should be thoroughly cleansed and gently irrigated with a catheter or blunt-tipped needle; high-pressure irrigation should not be employed. Avulsed or devitalized tissue should be debrided and any fluctuant areas incised and drained.

Insufficient data exist to settle questions of whether bite wounds should undergo primary closure, delayed primary closure (3-5 days), or healing by secondary intention. Factors to be considered are the type, size, and depth of the wound; the anatomic location; the presence of infection; the time since the injury; and the potential for cosmetic disfigurement. Appropriate surgical consultation (e.g., general pediatric surgery; plastic, hand, or orthopedic surgery) should be obtained for all patients with deep or extensive wounds; wounds involving the hands, face, or bones and joints; and infected wounds that require open drainage. Although there is general agreement that **visibly infected wounds and those that are more than 24 hr old should not be sutured**, there is variation in practice regarding the efficacy and safety of closing wounds <8 hr old with no evidence of infection. Because all **hand wounds** are at high risk for infection, particularly if there has been disruption of the tendons or penetration of the bones, surgical

consultation is almost always indicated, and delayed primary closure is recommended for many bite wounds of the hands. **Facial lacerations** are at smaller risk for secondary infection because of the more luxuriant blood supply to this region. Given this fact and cosmetic considerations, many plastic surgeons advocate primary closure of facial bite wounds that have been brought to medical attention within 6 hr and after thorough irrigation and debridement.

Similarly, there are few studies addressing the efficacy and selection of antimicrobial agents for **prophylaxis** of bite injuries. The bacteriology of bite wound infections is primarily a reflection of the oral flora of the biting animal more than the skin flora of the victim (see Table 724-2). Because many of the aerobic and anaerobic bacterial species colonizing the oral cavity of the biting animal have the potential to invade local tissue, multiply, and cause tissue destruction, most bite wound infections are polymicrobial.

Despite the large degree of homology in the bacterial flora of the oral cavity among humans, dogs, and cats, important differences exist between the biting species, and they are reflected in the type of wound infections that occur. The predominant bacterial species isolated from infected dog bite wounds are *Staphylococcus aureus* (20-30%), *Pasteurella multocida* (20-30%), *Staphylococcus intermedius* (25%), and *C. canimorsus;* approximately one half of dog bite wound infections also contain mixed anaerobes. Similar species are isolated from infected cat bite wounds; however, *P. multocida* is the predominant species in at least 50% of cat bite wound infections. At least 50% of rats harbor strains of *S. moniliformis* in the oropharynx, and approximately 25% harbor *Spirillum minor,* an aerobic Gram-negative organism. In human bite wounds, nontypable strains of *Haemophilus influenzae, Eikenella corrodens, S. aureus,* α-hemolytic streptococci, and β-lactamase–producing aerobes (~50%) are the predominant species. Clenched-fist injuries are particularly prone to infection by *Eikenella* spp. (25%) and anaerobic bacteria (50%).

The choice between oral and parenteral antimicrobial agents should be based on the severity of the wound, the presence and degree of overt infection, signs of systemic toxicity, and the patient's immune status. Amoxicillin–clavulanate is an excellent choice for empirical oral

Table 724-3 Prophylactic Management of Human or Animal Bite Wounds to Prevent Infection

CATEGORY OF MANAGEMENT	MANAGEMENT
Cleansing	Remove visible dirt. Cleanse the wound surface with soap and water, saline, 1% povidone–iodine, or 1% benzalkonium chloride. Irrigate with a copious volume of sterile saline solution by high-pressure syringe irrigation.* Do not irrigate puncture wounds; Standard Precautions should be used.
Wound culture	No, for fresh wounds, unless signs of infection exist. Yes for wounds that appear infected.†
Diagnostic Imaging	Indicated for penetrating injuries overlying bones or joints, for suspected fracture, or to assess foreign body inoculation.
Debridement	Remove superficial devitalized tissue.
Operative debridement and exploration	Yes if any of the following: • Extensive wounds (devitalized tissue) • Involvement of the metacarpophalangeal joint (clenched-fist injury) • Cranial bites by large animal
Wound closure	Yes for selected fresh, nonpuncture bite wounds.
Assess tetanus immunization status	Yes.
Assess risk of rabies from animal bites	Yes.
Assess risk of hepatitis B virus infection from human bites	Yes.
Assess risk of human immunodeficiency virus from human bites	Yes.
Initiate antimicrobial therapy	Yes for: • Moderate or severe bite wounds, especially if edema or crush injury is present • Puncture wounds, especially if penetration of bone, tendon sheath, or joint has occurred • Face, hand, foot, and genital bites • Wounds in immunocompromised and asplenic persons • Wounds with signs of infection
Follow-up	Inspect wound for signs of infection within 48 hr

*Use of an 18-gauge needle with a large-volume syringe is effective. Antimicrobial or antiinfective solutions offer no advantage and may increase tissue irritation.

†Both aerobic and anaerobic bacterial culture should be performed.

From American Academy of Pediatrics: Red Book: 2012 report of the Committee on Infectious Diseases, *ed 29, Elk Grove Village, IL, 2012, American Academy of Pediatrics, Table 2-18.*

therapy for human and animal bite wounds, because of its activity against most bacteria that have been isolated from infected bites. Similarly, ticarcillin–clavulanate or ampicillin–sulbactam is preferred for patients who require empirical parenteral therapy. Penicillin G remains the drug of choice for prophylaxis and treatment of rat-inflicted injuries, as this agent has excellent activity against *S. moniliformis* and *S. minor*. Because 1st-generation cephalosporins have limited activity against *P. multocida* and *E. corrodens*, they should not be used for prophylaxis or empirical initial therapy of bite wound infections. Therapeutic alternatives for penicillin-allergic patients are limited, because the traditional alternative agents are generally inactive against 1 or more of the multiple pathogens that cause bite wound infections. Clindamycin plus trimethoprim–sulfamethoxazole is the most commonly suggested regimen for these patients. Tetracycline is the drug of choice for penicillin-allergic patients who have sustained rat bite injuries.

Although **tetanus** occurs only rarely after human or animal bite injuries, it is important to obtain a careful immunization history and to provide tetanus toxoid to all patients who are incompletely immunized or in whom it has been longer than 5 yr since the last tetanus immunization. The need for postexposure **rabies** vaccination in victims of dog and cat bites depends on whether the biting animal is known to have been vaccinated and, most importantly, on local experience with rabid animals in the community. Bites from bats, foxes, skunks, and raccoons should be considered to carry a high risk of rabies, and postexposure prophylaxis is indicated. For dogs, cats, and other animals that are known or can be captured, observation for 7-10 days by the local animal control department is indicated. If a biting dog or cat has escaped, a decision about rabies prophylaxis can be based on the circumstances surrounding the bite and advice from local infectious diseases specialists and/or health department officials. Annually worldwide, animal bites and contacts result in more than 10 million postexposure courses. Postexposure prophylaxis for hepatitis B should be considered in the rare instance in which a susceptible individual has sustained a human bite from an individual who is at high risk for hepatitis B.

Table 724-4 Measures for Preventing Dog Bites

- Realistically evaluate environment and lifestyle and consult with a professional (e.g., veterinarian, animal behaviorist, or responsible breeder) to determine suitable breeds of dogs for consideration.
- Dogs with histories of aggression are inappropriate in households with children.
- Be sensitive to cues that a child is fearful or apprehensive about a dog and, if so, delay acquiring a dog.
- Spend time with a dog before buying or adopting it. Use caution when bringing a dog or puppy into the home of an infant or toddler.
- Spay/neuter virtually all dogs (this frequently reduces aggressive tendencies).
- Never leave infants or young children alone with any dog.
- Properly socialize and train any dog entering the household. Teach the dog submissive behaviors (e.g., rolling over to expose abdomen and relinquishing food without growling).
- Immediately seek professional advice (e.g., from veterinarians, animal behaviorists, or responsible breeders) if the dog develops aggressive or undesirable behaviors.
- Do not play aggressive games with your dog (e.g., wrestling).
- Teach children basic safety around dogs and review regularly:
  - Never approach an unfamiliar dog.
  - Never run from a dog and scream.
  - Remain motionless when approached by an unfamiliar dog (e.g., "be still like a tree").
  - If knocked over by a dog, roll into a ball and lie still (e.g., "be still like a log").
  - Never play with a dog unless supervised by an adult.
  - Immediately report stray dogs or dogs displaying unusual behavior to an adult.
  - Avoid direct eye contact with a dog.
  - Do not disturb a dog who is sleeping, eating, or caring for puppies.
  - Do not pet a dog without allowing it to see and sniff you first.
  - If bitten, immediately report the bite to an adult.

From Centers for Disease Control and Prevention: Dog bite-related fatalities—United States, 1995-1996, MMWR Morb Mortal Wkly Rep *46:463–467, 1997.*

PREVENTION

It is possible to reduce the risk of animal bite injury with anticipatory guidance (Table 724-4). Parents should be routinely counseled during prenatal visits and routine health maintenance examinations about the risks of having potentially biting pets in the household. All patients should be cautioned against harboring exotic animals for pets. Additionally, parents should be made aware of the proclivity of certain breeds of dogs to inflict serious injuries and the protective instincts of nursing dams. All young children should be closely supervised, particularly when in the presence of animals, and from a very early age should be taught to respect animals and to be aware of their potential to inflict injury. Reduction of the rate of human bite injuries, particularly in daycare centers and schools, can be achieved by good surveillance of the children and adequate teacher : child ratios.

Bibliography is available at Expert Consult.

724.1 Rat Bite Fever

Charles M. Ginsburg and David A. Hunstad

ETIOLOGY

Rat bite fever is a generic term that has been applied to at least 2 distinct clinical syndromes, each caused by a different microbial agent. Rat bite fever caused by *S. moniliformis* is most commonly reported in the United States, as well as in Brazil, Canada, Mexico, Paraguay, Great Britain, and France; it has been identified elsewhere in Europe and in Australia. *S. moniliformis* is a Gram-negative bacillus that is present in the nasopharyngeal flora of many laboratory and wild rats. Infection with *S. moniliformis* most commonly occurs following the bite of a rat; however, infection has also been reported in individuals who have been scratched by rats, in those who have handled dead rats, and in those who have ingested milk contaminated with the bacterium (termed **Haverhill fever**). Rat bite fever may also be transmitted by bites from wild mice. Rat bite fever caused by *S. minus,* called **sodoku,** is most commonly reported in Asia. *S. minus* is a small, spiral, aerobic Gram-negative organism. Reports of rat bite fever from Africa are rare, suggesting underrecognition rather than absence of the disease.

CLINICAL COURSE

The incubation period for the streptobacillary form of rat bite fever is variable, ranging from 3-10 days. The illness is characterized by an abrupt onset of fever up to 41°C (105.8°F) (fever occurring in more than 90% of reported cases), severe throbbing headache, intense myalgia, chills, and vomiting. In virtually all instances, the lesion at the cutaneous inoculation site has healed by the time the systemic systems first appear. Shortly after the onset of the fever, a polymorphous rash occurs in up to 75% of patients. In most patients, the rash consists of blotchy, red maculopapular lesions that often have a petechial component; the distribution of the rash is variable but is typically most dense on the extremities. Hemorrhagic vesicles may develop on the hands and feet and are very tender to palpation (Fig. 724-1).

Approximately 50% of patients have arthritis, which first manifests toward the end of the 1st wk of disease; early on, the arthritis may be migratory. If untreated, fever, rash, and arthritis last from 14-21 days, often with a biphasic pattern to the fever and arthritis. A wide range of complications are reported in patients with rat bite fever, the most common being pneumonia, persistent arthritis, brain and soft tissue abscesses, and, less commonly, myocarditis or endocarditis. The mortality rate of untreated rat bite fever is estimated to be approximately 13%.

The incubation period of sodoku is longer (14-21 days) than that of the streptobacillary form of disease. The hallmark of *Spirillum*-induced

Figure 724-1 Hemorrhagic vesicles on the 1st and 3rd toes of a patient with advanced rat bite fever. *(From Elliott SP: Rat bite fever and* Streptobacillus moniliformis. Clin Microbiol Rev *20:13–22, 2007, Fig. 3.)*

disease is fever associated with an indurated, often suppurative, nonhealing lesion at the bite site. Lymphadenitis and lymphadenopathy invariably are present in the regional nodes that drain the inoculation site, and many patients have a generalized macular rash most prominent when fever is present. In untreated patients, sodoku has a relapsing and remitting course; symptoms abate after 5-7 days of chills and fever but recur 7-10 days later. There may be multiple cycles if the disease is not recognized and treated.

DIAGNOSIS

Diagnosis of the streptobacillary form of rat bite fever is difficult, because the disease is uncommon and can be confused with Rocky Mountain spotted fever or (less commonly) meningococcemia. Furthermore, *S. moniliformis* is difficult both to isolate and to identify with classic bacteriologic techniques. The organism is fastidious, requires enriched media for growth, and is inhibited by sodium polyanethol sulfonate, an additive present in many commercial blood culture bottles. A definitive diagnosis is made when the organism is recovered from blood or joint fluid or is identified in human samples with molecular technology such as polymerase chain reaction analysis, which has been used successfully in humans and laboratory animals.

Diagnosis of sodoku is made on clinical grounds, because there are no diagnostic serologic tests and *S. minus* has not been cultured on artificial media. Rarely, the organism may be identified in Gram-stained smears of pus from the inoculation site.

TREATMENT

Penicillin is the drug of choice for both forms of rat bite fever. Intravenous penicillin G or intramuscular penicillin G procaine is recommended for 7-10 days; a regimen of IV penicillin G for 5-7 days followed by oral penicillin V for an additional 7 days has also been used. Doxycycline, gentamicin, or streptomycin represent effective alternatives for penicillin-allergic patients. Patients with endocarditis caused by *S. moniliformis* require high-dose penicillin G for 4 wk; the addition of streptomycin or gentamicin might be helpful.

724.2 Monkeypox

Charles M. Ginsburg and David A. Hunstad

ETIOLOGY

Monkeypox virus, causing the disease monkeypox, is the most important member for humans of the genus *Orthopoxvirus* since the eradication of smallpox (variola). Monkeys are the predominant host for the virus; however, it may be endemic in African rainforest squirrels and is present in African rats, mice, domestic pigs, hedgehogs, and opossums. It also has been identified in and transmitted by prairie dogs in the United States, and has affected elephants in zoos. Severity of infection varies by viral strain and by host; for example, disease is relatively mild in cynomolgus monkeys but severe in orangutans.

Monkeypox virus was first observed in humans from West and Central Africa in the 1970s at the time that smallpox had been eradicated from the area. In the 1970s, the secondary attack rate was around 3% (a stark comparison to the 80% seen in unvaccinated smallpox contacts). Few cases were observed over the next 2 decades; however, during a subsequent outbreak in the 1990s when immunity to smallpox was no longer prevalent in the population, the secondary attack rate exceeded 75%. Monkeypox outbreaks have also been reported in the Sudan. Monkeypox was inadvertently introduced into the United States in 2003, presumably through rodents from Ghana that infected prairie dogs who were distributed as pets; this outbreak affected more than 70 persons. Primary transmission of the disease from infected animal to human is by bite or by human contact with an infected animal's blood, wound discharge, or other body fluids. Human-to-human transmission of infection is uncommon but is believed to have been an important source for transmission of new cases during the United States outbreak.

CLINICAL COURSE

The clinical signs, symptoms, and course of monkeypox are similar to those of smallpox, although typically milder. After a 10-14 day incubation period during which the virus replicates in lymphoid tissues, humans experience an abrupt onset of malaise, fever, myalgia, headache, and severe backache. Nonproductive cough, nausea, vomiting, and abdominal pain may be present. Generalized lymphadenopathy, a finding unusual in smallpox, is invariably present during the acute stages of monkeypox illness. After a 2-4 day prodrome, an exanthem appears in cephalad-to-caudal progression. As the rash progresses, fevers begin to abate. The rash is initially macular, but transforms within hours to firm papules that rapidly vesiculate and become pustular over 2-3 days. Unlike smallpox lesions, but similar to chickenpox lesions, the lesions of monkeypox tend to occur in crops (Fig. 724-2). Late into the 2nd wk of illness, the lesions begin to desiccate, crust, scab, and fall off.

Monkeypox should be suspected in any child who has the characteristic prodrome associated with an atypical form of chickenpox and a history of contact with prairie dogs or exotic mammals such as Gambian rats and rope squirrels. Diagnosis is by isolation of monkeypox virus in culture, demonstration by polymerase chain reaction of viral DNA in a clinical specimen, or microscopic demonstration of an orthopoxvirus in a clinical specimen in the absence of other orthopoxvirus exposure.

TREATMENT

There is no proven effective therapy for monkeypox. Despite evidence that preexposure administration of smallpox vaccine is 85% effective in preventing or attenuating monkeypox disease, the rarity of monkeypox infection does not warrant universal vaccination. In instances of known exposure or in outbreak situations, there may be an indication

for administering smallpox vaccine. Consideration should be given to vaccinating close family contacts and health care workers who provide care to infected individuals. Vaccine is said to be preventive if given within 2 wk of exposure. Individuals with a compromised immune system and those with life-threatening allergies to latex or to smallpox vaccine or any of its components (polymyxin B, streptomycin, tetracycline, neomycin) also should not receive smallpox vaccine.

Although there are data indicating that cidofovir has in vitro activity against monkeypox virus and has been effective in preventing monkeypox infection in animals, there are no data to support its effectiveness in humans. Careful attention should be paid to skin hygiene, maintenance of adequate nutrition and hydration, and prompt implementation of local or systemic therapy of secondary bacterial infection that may occur. For prevention of human-to-human spread of disease, a combination of contact, droplet, and airborne infection control procedures should be implemented.

Chapter 725

Envenomations

Bill J. Schroeder and Robert L. Norris

Being bitten or stung by a venomous animal or insect is frightening for an adult, a child, or a child's parent or care provider. Although most bites and stings by spiders, snakes, scorpions, and other venomous animals cause little more than local pain and do not require medical attention, there are thousands of species of potentially harmful or deadly venomous creatures worldwide. Each country/region has its own array of medically important organisms.

The terms *venomous* and *poisonous* are not synonymous. *Venom* is produced in specialized glands of the host and is usually injected by means of a bite or sting. *Poisonous* refers to detrimental effects from consuming or touching a plant, animal, or insect. Poison is generally found throughout the animal and venom is isolated to the specialized glands.

Not every bite from a venomous creature is harmful. In many cases no venom is injected, so-called dry bites. A dry bite may occur for many reasons, including failure of the venom delivery mechanism and depletion of venom. Up to 20% of pit viper, 80% of coral snake, and approximately 50% of all venomous snake bites are dry.

In the 2011 report of the American Association of Poison Control Centers, more than 60,000 consultations were related to bites and stings of various creatures, with approximately one third involving victims < age 19 yr. There were 2 deaths, both from snake bites in adult males, 1 from the genera *Crotalus* (rattlesnake) and 1 from the genera *Agkistrodon* (copperhead or cottonmouth).

GENERAL APPROACH TO THE ENVENOMATED CHILD

Children may be bitten or stung as they play and explore their environment. The evaluation may be hampered by an unclear history of the circumstances and the possible offending organism, particularly with preverbal children. The overall effects of some venomous bites and stings may be relatively more severe in children than in adults, because children generally receive a similar venom load from the offending animal yet have less circulating blood volume to dilute its effects.

General Management

When faced with an envenomated child, the treating physician should anticipate a dynamic clinical syndrome that may progress with time, with important, potentially subtle, findings. Treatment of an envenomated child should start with assessing and managing as necessary the airway, breathing, and circulation (ABCs). Most envenomations require little more than local wound care, pain control, reassurance, and possibly observation. The severely envenomated child may need airway and respiratory protection and support (e.g., high-concentration oxygen administration and endotracheal intubation) and adequate IV access in an unaffected extremity if possible (see Chapters 70 and 71). Early hypotension tends to be related to vasodilation and should be treated with volume expansion using appropriate infusion of physiologic saline solutions (normal saline boluses of 20 mL/kg body weight; repeated as needed up to 3 times). Shock unresponsive to volume repletion may require addition of a vasoactive pharmacologic agent such as epinephrine or dopamine (in addition to antivenom administration as appropriate). If the presentation is suspicious for an anaphylactic reaction to venom, appropriate treatment (including epinephrine) should be initiated as soon as possible (see Chapter 149). Occasionally,

it is difficult to determine the precise etiology for sudden collapse after a venomous bite or sting–venom toxicity vs anaphylaxis. In such cases, treatment for both should be started.

The affected body part should be immobilized in a position of function and any areas of edema should be marked, measured, and monitored. If antivenom (AV) is available for the envenomation, efforts should be initiated to locate and secure an adequate amount to treat the patient (at least a starting dose). In the United States, regional poison control centers can facilitate this effort and are especially helpful if the offending species is exotic. Guidance in dosing the appropriate AV can generally be found in the package insert that accompanies the agent, although the advice in inserts for some products from developing countries may contain inaccurate and incorrect recommendations. Physicians who do not regularly treat venomous bites and stings should consult local or regional experts for assistance.

Antivenom Administration

Specific AVs are available for many venomous creatures of the world, particularly snakes, spiders, and scorpions. These products essentially impart passive immunity to the victim and should be given in cases of significant envenomation as early in the process as possible, because AV is capable of neutralizing only circulating, unbound venom components in the blood.

AVs may be either in liquid form or lyophilized (requiring reconstitution prior to administration). Most AVs are given intravenously. *There is no benefit to giving any AV locally at the bite site*. As soon as the need for AV is established, it should be placed into solution (generally diluted in a quantity of normal saline equivalent to 20 mL/kg body weight, up to 250-1,000 mL total).

As heterologous serum products, AVs carry some variable risk of inducing nonallergic or allergic anaphylactic reactions. Therefore, the patient should be closely monitored, and a physician should be present during the infusion, with access to all the appropriate equipment and medications needed to reverse such a reaction. Skin tests, often recommended by AV manufacturers, are unreliable and should be omitted.

Intravenous AV should be started slowly, and the rate gradually increased as tolerated by the patient, with a goal to administer the entire dose in approximately 1 hr.

If the victim experiences a reaction to the product, it should be temporarily stopped. Intramuscular epinephrine and intravenous antihistamines and steroids should be given. Then the AV should be restarted, possibly at a slower rate and in a more dilute solution. If the reaction is severe, the decision must be made as to whether the benefits of AV outweigh the risks of anaphylaxis on the basis of the patient's clinical condition. If AV is deemed critical for the patient's survival despite the occurrence of anaphylaxis, the patient should be placed in an intensive care setting with close, possibly invasive, monitoring, and should receive simultaneous administration of AV and an epinephrine infusion.

AV can also cause delayed immunoglobulin G and M–mediated serum sickness in some patients (see Chapter 150). Serum sickness occurs 1-2 wk after AV administration, manifesting as fever, myalgias, arthralgias, urticaria, and potential renal and neurologic involvement. It is easily treated with oral steroids, antihistamines, and acetaminophen.

General Wound Care

Bites and stings require basic wound care, including copious tap water or normal saline irrigation under pressure when possible. For small puncture wounds this is impractical, but the skin should still be cleaned with soap and water. Tetanus immunization should be updated as needed. Intact blisters should be left to act as natural bandages and help prevent infection, whereas broken blisters should be debrided. Exposed tissue should be covered with wet to dry dressings. Necrotic wounds, such as those that might follow some snake and spider bites, should be judiciously debrided, with removal of only clearly necrotic tissue. Reconstructive surgery with skin grafts or muscle/tendon grafts may be necessary. Prophylactic antibiotics are not necessary except, perhaps, in cases in which an ill-informed "rescuer" cut into the bite and applied mouth suction. Antibiotics should generally be reserved for signs of established secondary infection.

SNAKE BITES

Most snake bites are inflicted by nonvenomous species and are of no more consequence than a potentially contaminated puncture wound (Fig. 725-1). Venomous snakes, however, kill many tens of thousands of people in the world each year. The precise number is difficult to ascertain, because the toll in human suffering is far greatest in developing nations. Developed nations, with established medical care systems, have relatively few fatalities each year.

Most of the world's medically significant venomous snakes belong to 1 of 2 families—Viperidae and Elapidae (Table 725-1). In developing nations, most snake envenomations occur in agricultural workers who inadvertently contact snakes while in the fields. Many victims of snake envenomation in developed nations are adolescent or young adult males, frequently intoxicated, who are attempting to handle or catch the snake. Bites are located on an extremity in more than 95% of cases. In the United States, approximately 98% of venomous snake bites are inflicted by pit vipers (family Viperidae; subfamily *Crotalinae*). A small fraction of bites are caused by coral snakes (family Elapidae) in the South and Southwest, and by exotic snakes that have been imported.

Venoms and Effects

Snake venoms are complex mixtures of proteins including large enzymes that cause local tissue destruction and low-molecular-weight polypeptides that have the more lethal systemic effects. The symptoms and severity of an envenomation vary according to the type of snake, the amount of venom injected, and the location of the bite. The fear caused by a snake bite can result in nausea, vomiting, diarrhea, cold/clammy skin, and even syncope regardless of whether or not venom was injected. In general, viper venoms can have deleterious effects on almost any organ system. Most viper bites cause significant local pain, swelling, and ecchymosis and may result in variable necrosis of the bitten extremity (Fig. 725-2). The pain and swelling typically begin quickly after the bite and progress over hours to days. Serious envenomations may result in a consumptive coagulopathy, hypotension, and respiratory distress. In contrast, venoms from the **Elapidae** tend to be more neurotoxic with little or no local tissue damage. These bites cause variable local pain and the onset of systemic effects can be delayed for hours. Manifestations of neurotoxicity generally are caused by curare-like blockade at the neuromuscular junction. Symptoms usually begin with cranial nerve palsies such as ptosis, dysarthria, and dysphagia and may progress to respiratory failure and complete paralysis. There are exceptions; some members of the Elapidae family cause little or no neurotoxicity but rather severe tissue necrosis (e.g., African spitting cobras). Some vipers, including the southern Pacific rattlesnake *(Crotalus oreganus helleri)*, western diamondback rattlesnake *(Crotalus atrox)*, timber rattlesnake *(Crotalus horridus horridus)*, and some populations of the Mohave rattlesnake *(Crotalus scutulatus)*, cause significant neurotoxicity. Physicians should proactively learn the important species in their regions, including how the species can be identified, the expected effects of their venoms, and proper approaches to management.

Management

Prehospital care should focus on rapid transport to the emergency department while supporting the victim's vital signs as needed. Constrictive clothing, jewelry, and watches should be removed, and the injured body part should be immobilized in a position of function at the level of the heart. *All proposed field treatments for snake bites, such as tourniquets, ice, electric shock, incision, and suction, have proven problematic, with most being ineffective and deleterious.*

At the hospital, attention is directed to the ABCs and supportive care as needed. An effort should be made to identify the offending snake and then to secure the appropriate AV. Intravenous access should be established in an unaffected extremity, and standard laboratory specimens should be obtained, including those for a complete blood count, coagulation studies, fibrinogen concentration, and serum chemistry

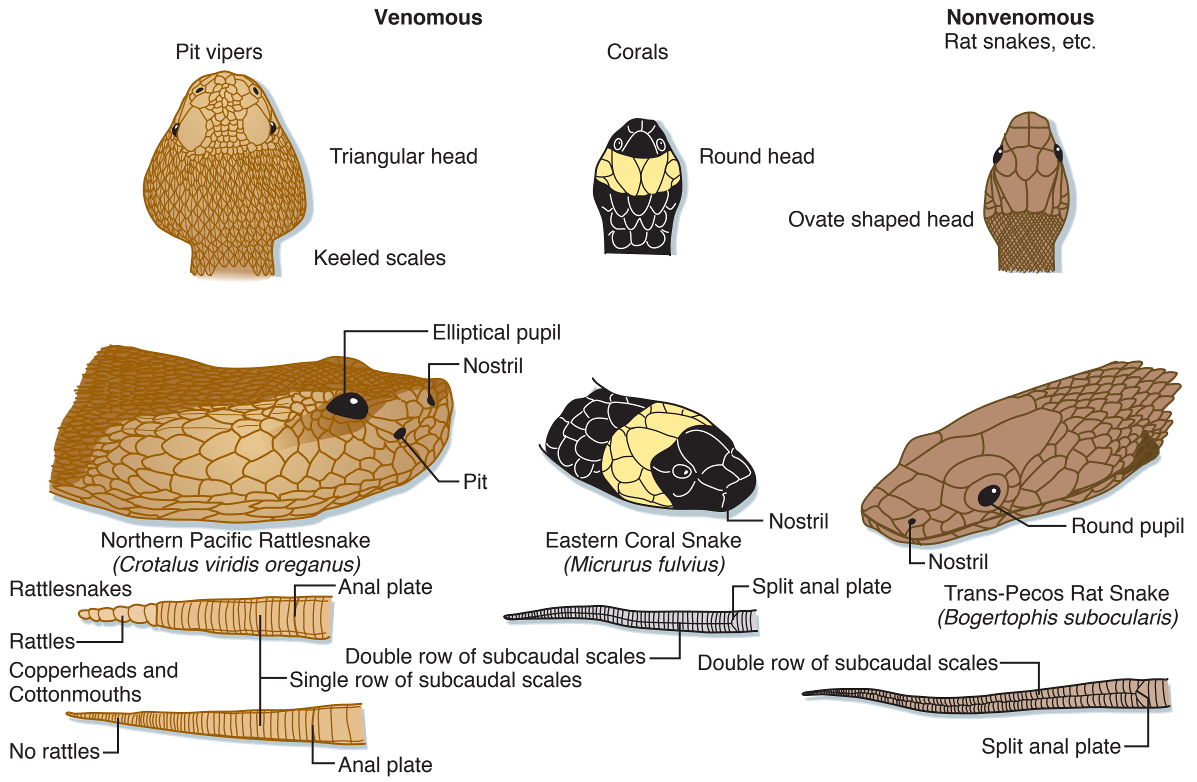

Figure 725-1 **Anatomic comparison of pit vipers, coral snakes, and nonvenomous snakes of the United States.** (Note: the northern Pacific rattlesnake is now classified as *Crotalus oreganus oreganus*.) *(Modified from Adams JG, et al, editors:* Emergency medicine, *Philadelphia, 2008, WB Saunders. Drawing by Marlin Sawyer.)*

Table 725-1 Medically Important Snake Families

FAMILY	VENOMOUS?	LOCATION	EXAMPLES	TOXIN EFFECTS/OTHER COMMENTS
Colubridae	Some species	Most parts of the world	Garter snakes (*Thamnophis* spp.), king snakes and milk snakes (*Lampropeltis* spp.)	Largest family of snakes; most are considered harmless to humans; a few species are dangerously toxic (e.g., African boomslang *[Dispholidus typus]*)
Boidae	None	Most parts of the world	*Boa* species, *Python* species	Constrictors; unsupervised children should not be allowed access to large constrictors
Viperidae				
Subfamily *Crotalinae* (pit vipers)	All	Americas, Asia	Rattlesnakes (*Crotalus* and *Sistrurus* spp.), cottonmouths and copperheads (*Agkistrodon* spp.), Lancehead pit vipers (*Bothrops* spp.)	Heat-sensing "pit" between each eye and nostril
Subfamily *Viperinae* (true vipers)	All	Europe, Africa, Middle East, Asia	Puff adder *(Bitis arietans)*, Gaboon viper *(Bitis gabonica)*	No heat-sensing pits
Elapidae	All	Americas, Africa, Middle East, Asia	Cobras (*Naja* spp.), mambas (*Dendroaspis* spp.), kraits (*Bungarus* spp.), coral snakes (*Micrurus* spp.), and the venomous snakes of Australia	Highly variable venom effects—some largely neurotoxic, others causing severe local tissue damage
Hydrophiidae	All	Warm waters of the Pacific Ocean, Indian Ocean, and Oceana (none in the Atlantic Ocean)	Sea snakes including the pelagic sea snake *(Pelamis platurus)*	Neurotoxins and myotoxins; rarely bite humans unless provoked

analysis including total creatine kinase. A blood sample should be sent for typing and screening, although blood products are rarely actually required in management of snake bite. Samples collected later in the clinical course may be hard to cross match because venom and AV can interfere with the testing. Tourniquets placed in the field by laypeople should be cautiously removed after venous access is obtained, to watch for and treat adverse effects that may follow a sudden bolus of acidotic, hyperkalemic blood mixed with venom into the systemic circulation. The bitten extremity should be marked at 2 or more sites proximal to the bite, and the circumferences at these locations should be assessed every 15 min to monitor for progressive edema—indicative of ongoing venom effects. Occasionally, the sharp, recurved teeth of snakes, including nonvenomous snakes, are left behind in wounds; they should be identified (using soft tissue radiographs or ultrasound as needed) and removed.

Assessing the severity of the envenomation in the field and at the hospital is essential (Table 725-2).

AVs are relatively specific for the snake species against which they are designed to protect. *There is no benefit to administering an AV for an unrelated species*, and doing so certainly involves unacceptable risk (e.g., anaphylaxis) and expense. If it is determined that the child requires AV, a search for the appropriate product should begin as soon as possible—checking the hospital pharmacy, regional poison control center, and perhaps local zoos and museums that keep captive snakes. Table 725-3 lists the indications for administering AV.

Figure 725-2 **Southern Pacific rattlesnake bite *(Crotalus oreganus helleri)* in a 2 yr old boy.** Note the fang marks, swelling, and bruising of the tissues (photograph taken 2 hr following the bite). *(Courtesy of Sean Bush, MD.)*

In October 2000, Crotalidae polyvalent immune Fab known as CroFab was approved by the FDA for use in crotaline envenomations. CroFab is derived from sheep (ovine) antibodies and replaces the previously used AV derived from horses (equine-derived AV). The most important advantage of this AV is fewer hypersensitivity reactions, including both immediate and delayed reactions. A metaanalysis showed only 8% immediate hypersensitivity reactions and 13% delayed or serum sickness reactions after administration of CroFab, compared to an estimated 23-56% from the previous equine-derived AV.

CroFab is derived from 4 snakes, 3 from the genera *Crotalus* (the eastern diamondback rattlesnake, the western diamondback rattlesnake, and the Mohave rattlesnake) and 1 from the genera *Agkistrodon* (the cottonmouth water moccasin). It is effective against the venoms of all pit vipers in the United States. There is controversy regarding the use of CroFab in bites from copperheads (*Agkistrodon contortrix*) because they tend to cause fewer systemic effects. Most copperhead envenomations cause only local tissue swelling, ecchymosis, and pain, and generally do well even without AV. Serious envenomations, including fatalities, have followed copperhead bites, and any child with evidence of systemic toxicity should receive CroFab.

The half-life of CroFab is considerably shorter than that of crotaline venom constituents, and redosing is frequently needed to prevent or treat recurrence of venom effects. Patients with significant envenomation should be followed for late hematologic abnormalities (coagulopathy) that can occur up to 2 weeks after the bite. Although these

Table 725-3 Indications for Snake Antivenom Administration

Evidence of systemic toxicity:	
Hemodynamic or respiratory instability	Hypotension, respiratory distress
Hemotoxicity	Clinically significant bleeding or abnormal coagulation studies
Neurotoxicity	Any evidence of toxicity: usually beginning with cranial nerve abnormalities and progressing to descending paralysis including the diaphragm
Evidence of worsening local toxicity	*Progressive* soft tissue swelling

Table 725-2 Crotaline Envenomation: Determining the Degree of Envenomation

DEGREE OF ENVENOMATION	CONTIGUOUS MANIFESTATIONS	SYSTEMIC MANIFESTATIONS	LABORATORY ABNORMALITIES
None or trivial ("dry bite")	Punctures or abrasions; pain and tenderness at bite	None	None
Mild or minimal	Punctures or abrasions; pain, tenderness, edema, and erythema at and adjacent to bite	None	None
Moderate	Punctures or abrasions; pain, tenderness, edema, and erythema beyond area adjacent to bite	Perioral paresthesias; peripheral paresthesias; gustatory changes; nausea; emesis; diarrhea; weakness; light-headedness; diaphoresis; chills	↑PT; ↑PTT; ↓platelets; ↓fibrinogen; ↑hemoglobin
Severe	Punctures or abrasions; pain, tenderness, edema, and erythema of entire extremity	Ventilatory insufficiency; hypotension; shock; bleeding; altered mental status; fasciculations; seizures	↑↑PT; ↑↑PTT; ↓↓platelets; ↓↓fibrinogen; ↑↓hemoglobin

↑, increased; ↑↑, very increased; ↑↓, increased or decreased; ↓, decreased; ↓↓, very decreased; PT, prothrombin time; PTT, partial thromboplastin time.

Table 725-4 Indications for Administration of Additional Antivenom in Patients with Recurrent Coagulopathy or Thrombocytopenia After Initial Control

- Evidence of clinically significant bleeding
- Platelet count below 25,000/cu mm
- International normalized ratio (INR) greater than 3
- Activated partial thromboplastin time (aPTT) greater than 50 sec
- Fibrinogen less than 50 mg/dL
- Presence of multicomponent coagulopathy
- Worsening trend in a patient with prior severe coagulopathy
- High-risk behavior for trauma
- Certain comorbid conditions (e.g., systemic vasculitis, seizure disorders, prior stroke)

From Norris RL, Bush SP, Smith J: Bites by venomous reptiles in Canada, the U.S. and Mexico. In Auerbach PS, editor: Wilderness medicine, *ed 6, Philadelphia, 2012, Elsevier.*

Figure 725-3 Female black widow spider (*Latrodectus mactans*). Note the red hourglass-shaped marking on the underside of her abdomen. *(From The Centers for Disease Control and Prevention Public Health Image Library, Image #5449.)*

tend to be mild laboratory coagulopathies without clinical bleeding, rare cases of intracranial bleeding have been reported. Further AV therapy should be considered for such delayed onset or recurrent coagulopathy as outlined in Table 725-4.

Disposition

Any child with a potential venomous snake bite should be admitted to a closely observed setting for at least 24 hr, regardless of whether evidence of envenomation exists or AV has been given. Children with evidence of systemic toxicity should initially be admitted to an intensive care setting until stabilized.

SPIDER BITES

More than 20,000 venomous spiders have been identified, but most lack either potent venom or fangs long enough to penetrate human skin, and are therefore of no medical significance. No spiders can be considered truly deadly, meaning that an untreated bite in a human would be expected to cause death. The spiders of medical significance can be broadly divided into 2 major groups: those that cause a neurotoxic syndrome and those that cause tissue necrosis. In the United States, the only significant morbidities are caused by 1 genus of spider from each group: *Latrodectus* (the widow spiders) and *Loxosceles* (the fiddleback or recluse spiders).

Neurotoxic Spiders

The major neurotoxic spiders are the widow spiders (*Latrodectus* spp.), the funnel web spiders (*Atrax* and *Hydronyche* spp.—found in Australia), and the banana spiders (*Phoneutria* spp.—indigenous to Latin America).

Venoms and Effects

Neurotoxic spiders all possess venoms that act at neural synapses, both at neuromuscular junctions and at autonomic nervous system junctions. All of the widow spiders (*Latrodectus* spp., including the well-studied black widow [*Latrodectus mactans;* Fig. 725-3)] and the Australian red-back spider [*Latrodectus hasselti*]) possess very similar venoms, with the most important neurotoxin being α-latrotoxin. The neurotoxin of the Sydney funnel web spider (*Atrax robustus*) is robustoxin.

Bites by the neurotoxic spiders tend to be very painful, and the offending spider is often seen. Systemic effects may include hypertension, tachycardia, bradycardia, hypersalivation, diaphoresis, and diffuse muscle spasms.

Management

Management of neurotoxic spider envenomation centers on sound supportive care. Several *Latrodectus* AVs are available, and each appears to be effective regardless of which species of widow spider was responsible for the bite. There is also an AV for the Sydney funnel web spider, the only species of funnel web that has caused human fatalities (none since the introduction of the AV), and a polyspecific AV for the banana spider in South America. These AVs should be used in significant bites with potentially serious systemic effects. The package insert for the appropriate product is used to guide therapy.

In the United States, *Latrodectus* AV is administered to reverse serious systemic effects of widow spider envenomation. One vial is given either intramuscularly (IM) or IV. Efficacy is usually noted within 1 hr of administration, reversal of systemic toxicity and relief of pain being noted. Occasionally, a second vial is necessary. There have been deaths related to acute nonallergic anaphylactic reactions to the U.S. AV, so its administration should be undertaken with due caution and close monitoring.

If AV is to be withheld or is not available, generous doses of opioid analgesics and benzodiazepines may be used to ease symptoms (although this may require up to 72 hr of therapy).

Disposition

Most neurotoxic spider bite victims, even those requiring AV, can be discharged from the emergency department if they have a satisfactory response to therapy. Parents should be warned to bring their child back for any reoccurrence of venom effects. Children with more-severe cases should be admitted for 24 hr of monitoring.

Necrotizing Spiders

Venoms and Effects

Although many spiders may cause a small amount of local tissue damage after their bites, the spiders most notorious for their dermonecrotic potential are the violin or recluse spiders of the genus *Loxosceles*. The best known member of this genus is the brown recluse (*Loxosceles reclusa*; Fig. 725-4), found in the midwestern and southern portions of the United States. The venom of *Loxosceles* spiders contains a phospholipase enzyme, sphingomyelinase D, which attacks cell membranes and can cause local tissue damage that can occasionally be severe. The bite of this spider, most common between April and October, is generally painless and initially goes unnoticed. A few hours after the bite, pain related to focal ischemia begins at the site. Within a day, the site may have a central clear or blood-filled vesicle with surrounding ecchymosis and a rim of pale ischemia. The lesion may gradually expand over a period of days to weeks until necrotic tissue sloughs and healing begins (Fig. 725-5).

Rare cases of systemic loxoscelism appear to be more common in young children than adults. Patients present with systemic toxicity, including fever, chills, nausea, malaise, diffuse macular rash, and petechiae, and may experience hemolysis, coagulopathy, and/or renal failure.

In cases of suspected necrotic arachnidism, when no spider was actually seen by the patient, a broad differential diagnosis must be considered to ensure appropriate management of the true etiology. The differential diagnosis includes skin infections (particularly methicillin-resistant *Staphylococcus aureus;* see Chapter 181), bites by other arthropods (e.g., fleas, ticks), pyoderma gangrenosum, or ecthyma gangrenosum.

Management

For necrotizing spider bites, management of the wound involves sound supportive care, including intermittent local ice therapy for the 1st 72 hr and administration of antibiotics if there is any question of secondary bacterial infection. Daily wound cleansings, combined with splinting of the bitten area, should be performed until the wound is healed.

Figure 725-4 Male recluse spider (*Loxosceles* spp.). Note the distinct violin-shaped marking on the dorsum of the cephalothorax. *(Courtesy of Michael Cardwell/Extreme Wildlife Photography.)*

Nothing has been definitively proven effective in limiting the extent of necrosis following a spider bite. There is no role for steroids in managing necrotic arachnidism. Dapsone, although used anecdotally in managing *Loxosceles* bites in adults, is not approved for use in children and should not be prescribed.

Children appearing systemically unwell should be admitted and undergo laboratory evaluation (complete blood count, coagulation studies, and urinalysis). Systemic loxoscelism is managed with intravenous hydration, management of renal failure as needed, and a brief course of systemic steroids to stabilize red blood cell membranes. Although there are documented fatalities following bites by the South American violin spider (*Loxosceles laeta*), there has never been a definitively proven fatality following a brown recluse bite in the United States. No AV is commercially available in the United States for management of necrotizing spider bites such as those from *Loxosceles* species.

Disposition

Victims with potentially necrotic bites should be monitored for a few days with daily wound checks. Local, intermittent cooling therapy should be continued for approximately 72 hr. Any child with a probable necrotizing spider bite and evidence of systemic involvement should be admitted to be watched for hemolysis and coagulopathy.

SCORPION STINGS

Of the more than 1,200 species of scorpions worldwide, only a few cause more than a painful sting. In the United States, there is 1 medically significant scorpion, the bark scorpion (*Centruroides sculpturatus* [formerly *Centruroides exilicauda*]). Although this scorpion has caused death in children in the past, such an outcome is exceedingly rare. It is found only in Arizona and small areas of immediately surrounding states. In other regions of the world, especially Latin America, Africa, the Middle East, and Asia, a number of scorpions regularly cause fatalities, particularly in small children.

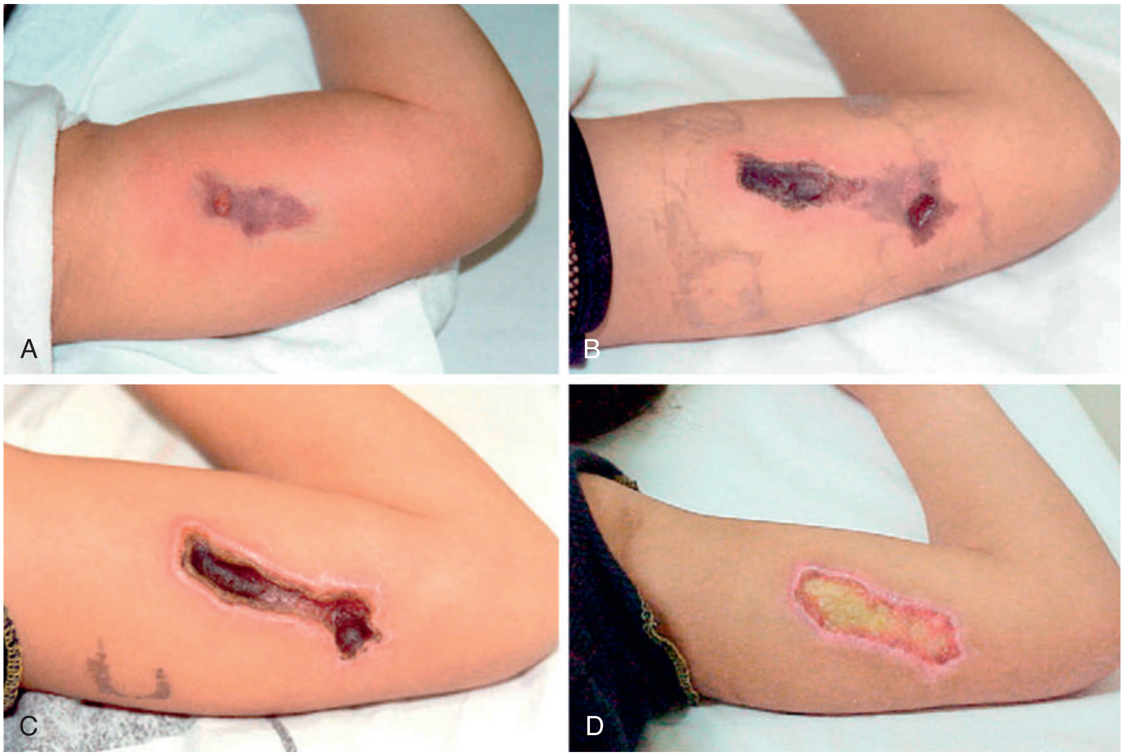

Figure 725-5 Progression of cutaneous loxoscelism in a Brazilian patient who was bitten inside a house while putting on a shirt. Ulceration and necrosis at day 1 **(A),** day 9 **(B),** day 16 **(C),** and day 25 **(D).** *(From Isbister G, Fan HW: Spider bite.* Lancet *378:2039–2046, 2011, Fig. 3. Photographs by Ceila MS Malaque.)*

Venoms and Effects

The major components of important scorpion venoms are neurotoxins that alter neural membrane ionic channels, causing autonomic and cardiovascular dysfunction through the release of acetylcholine and catecholamines. Manifestations of scorpion stings in children vary from mild to severe and may include pain, paresthesias, roving eye movements, cranial nerve dysfunction, opisthotonos/emprosthotonos, seizures, hypertensive crisis, cardiovascular collapse, and respiratory failure. Two important ingestions that can be confused with a bark scorpion envenomation are organophosphate poisoning (see Chapter 63) and methamphetamine intoxication (see Chapter 114). The opsoclonus-like roving eye movements seen in bark scorpion envenomations are not seen in the above ingestions and may help differentiate these conditions.

Management

Most stings require only pain control and respond well to ice, immobilization, and analgesics. Management of severe stings should begin with the ABCs. Opioid analgesics may have some synergy with scorpion neurotoxins and should be used with caution. Benzodiazepines may be more useful, especially for severe muscle spasms or sedation of the agitated child. Approximately 20 different scorpion AVs are available worldwide, but their use is controversial because of variable efficacy and the risk of potential nonallergic anaphylaxis. Practitioners should be familiar with the local standard of care for treating the stings of their indigenous scorpions and should consult a local or regional expert for assistance as necessary. In August 2011, the FDA approved a bark scorpion–specific AV, Anascorp, for use in the United States. It is manufactured in Mexico and marketed there under the name Alacramyn. The AV is generally given to any patient with cranial nerve or somatic skeletal neuromuscular dysfunction. The starting dose is 3 vials given IV, followed by another vial if symptoms still persist 30-60 min later and up to 5 vials were used in the initial study. Anascorp is currently only approved for IV administration; however, there are case reports of it being given IM and IO in children without IV access. *For more specific information about the administration of Anascorp, the practitioner should contact the Arizona Poison and Drug Information Center for details and assistance (800-222-1222).* In some regions of the world, prazosin is used in severe scorpion stings to ameliorate acute cardiovascular effects.

Disposition

The child with evidence of systemic toxicity following a scorpion sting should be admitted for at least 24 hr of monitoring (including cardiac monitoring) and, if envenomation is severe, should be monitored in a pediatric intensive care unit. In the absence of systemic toxicity and with adequate pain control, children >1 yr can be discharged to go home with a responsible adult.

HYMENOPTERA STINGS

The insect order Hymenoptera includes the stinging ants, bees, and wasps, which are characterized by the presence of a modified ovipositor (the "sting" or "stinger") at the end of the abdomen through which venom is injected. Various members of the order can be found throughout the world.

Venoms and Effects

Hymenoptera venoms, mixtures of proteins and vasoactive substances, are not very potent. Most stings result in only local pain, redness, and swelling, followed by itching and resolution. Some patients experience a large local reaction in which swelling progresses beyond the sting site, possibly involving the entire extremity. Approximately 0.4-0.8% of children are at risk for acute, life-threatening allergic reactions as a result of hymenoptera venom sensitivity. Each year, an estimated 50-150 people in the United States die of allergic anaphylaxis caused by hymenoptera stings (see Chapter 70). Rare cases of delayed serum sickness can follow hymenoptera stings (see Chapter 150). Finally, with the spread of Africanized honey bees *(Apis mellifera scutellata),* massive stinging episodes resulting in systemic venom toxicity (hypotension, respiratory failure, shock, hemolysis, and renal failure) appear to be increasing in Latin America and the southwestern U.S. states.

Management

Children with typical local reactions can be treated with application of cold compresses and with analgesics and antihistamines as needed. Children with large local reactions should also receive a 5 day course of oral corticosteroids and a prescription for an epinephrine autoinjection kit (and instructions in its use) prior to discharge. Patients presenting with urticaria, angioedema, wheezing, or hypotension should be treated aggressively for an immediate hypersensitivity reaction with intramuscular epinephrine (0.01 mg/kg, up to 0.3-0.5 mg of 1 : 1,000 formulation), airway management as needed, oxygen, intravenous fluids, antihistamines, and corticosteroids. Children suffering massive stinging episodes should undergo treatment similar to that for allergic anaphylaxis.

Disposition

Children with local reactions (limited or large local) can be discharged with continued care as outlined previously and instructions for wound precautions. More difficult disposition decisions are involved for children with systemic manifestations. Children with only diffuse urticaria, who are stable after a period of observation, can be discharged in the care of a responsible adult to continue antihistamines and steroids and to carry an epinephrine self-administration kit. These children seem to be at little risk for progressing to systemic anaphylaxis with future stings. Children suffering more than simple hives (e.g., wheezing, evidence of laryngeal edema or cardiovascular instability) should be admitted for 24 hr of observation and should receive a referral to an allergist for testing for hymenoptera venom sensitivity and possible immunotherapy. Immunotherapy reduces the risk of systemic anaphylaxis from future stings in high-risk patients from somewhere between 30% and 60% to less than 5%.

MARINE ENVENOMATION

The most commonly encountered venomous marine creatures are the jellyfish (Cnidaria), stingrays (Chondrichthyes), and members of the family Scorpaenidae—the lionfish, scorpionfish, and stonefish. Although most injuries occur when a child ventures into the animal's natural environment, lionfish (*Pterois* spp.) are commonly kept in private aquariums and children may be stung if they attempt to handle these beautiful fish.

Venoms and Effects

All jellyfish have unique stinging cells called **nematocysts**. These cells contain a highly folded tubule that everts on contact and injects venom. The venom is antigenic and can be dermonecrotic, hemolytic, cardiotoxic, or neuropathic, depending on the species. The nematocysts can sting even after the tentacle is severed from the body and after the jellyfish is dead. The Pacific box jellyfish *(Chironex fleckeri)* of Australia, with its cardiotoxic venom, is known to cause rapidly fatal stings. Although fatal anaphylaxis to jellyfish stings has been reported in coastal waters of the United States, these events are rare. For clinicians in the Americas, the primary concern with jellyfish stings is localized pain that may be associated with paresthesias or pruritus. Rarely, jellyfish victims may have systemic symptoms such as nausea, vomiting, headache, and chills.

Stingrays have a sharp, retroserrated spine and associated venom gland at the base of the tail. Stings tend to occur when the victim steps on the animal hidden in the surf. Injuries involve jagged lacerations from the spine, often with retained debris (spine fragments, glandular tissue, sand, etc.), and the venom has vasoconstrictive properties that can result in tissue necrosis and poor wound healing. Stingray envenomations are noteworthy for immediate and intense pain at the site of injury that lasts 24-48 hr. Some patients experience nausea, vomiting, and muscle cramps, and, rarely, hypotension or seizures.

The Scorpaenidae have venomous dorsal, pelvic, and anal spines that become erect when threatened. The glands associated with these spines contain venoms that result in direct myotoxicity leading to

paralysis of cardiac, involuntary, and skeletal muscles. Envenomation causes immediate pain that may persist for hours or days. Victims may experience intense local tissue destruction in which superinfections are common. Systemic symptoms include vomiting, abdominal pain, headache, delirium, seizures, and respiratory failure.

Management

Treatment of jellyfish stings begins in the ocean. The involved skin should be quickly rinsed *in seawater (fresh water may stimulate further nematocyst firing)*. Dousing the sting site with vinegar or rubbing alcohol can inhibit nematocyst discharge. Visible tentacle fragments should be removed with a gloved hand or forceps, and microscopic fragments may be removed by gently shaving the affected area. Folk remedies such as rubbing the sting with sand and applying urine are not helpful and cause more irritation. Meat tenderizer is not effective. Antihistamines and corticosteroids are indicated for swelling and urticaria. An apparent, acute allergic reaction should be treated with intramuscular epinephrine. Antibiotics are not needed.

Treatment of stingray and Scorpaenidae stings is similar. These toxins are heat labile, and immersion in hot water (approximately 42°C [107.6°F]) for 30-60 min denatures the protein constituents and decreases pain significantly. The wounds should be thoroughly cleaned and explored with use of local or regional anesthesia to rule out retention of spine or integument fragments. Stingray spines are radiopaque and may be seen on plain films of the wounded area or identified by ultrasonography. Lacerations should be treated with delayed primary closure or allowed to heal by secondary intention. Systemic analgesia should be provided as needed. Because of the risk of secondary bacterial infection, there should be a low threshold for administering prophylactic antibiotics to cover *Staphylococcus*, *Streptococcus,* and *Vibrio* species, and wounds should be rechecked daily for a few days.

Disposition

After wound care, most victims can be discharged home with responsible adults. If there are significant systemic effects after pain control is achieved, the child should be admitted for monitoring and further care as needed.

Bites and stings by venomous creatures are common occurrences in children, but they uncommonly cause major morbidity or mortality. The majority of such injuries do very well with sound supportive care. In serious cases, aggressive management of the ABCs combined with specific interventions (such as AVs when available) maximize the potential for an optimal outcome. A low threshold should be maintained for consulting specialists in envenomation medicine, available through regional poison control centers.

Laboratory Medicine

PART XXXV

Chapter 726 Laboratory Testing in Infants and Children

Stanley F. Lo

"Normal values" (reference intervals) are difficult to establish within the pediatric population. Differences in genetic composition, physiologic development, environmental influences, and subclinical disease are variables that need to be considered when developing reference intervals. Other considerations for further defining reference intervals include partitioning based on sex and age. The most commonly used reference range is generally given as the mean of the reference population ±2 standard deviations (SD). This is acceptable when the distribution of results for the tested population is essentially gaussian. The serum sodium concentration in children, which is tightly controlled physiologically, has a distribution that is essentially gaussian; the mean value ±2 SD gives a range very close to that actually observed in 95% of children (Table 726-1). However, not all analytes have a gaussian distribution. The serum creatine kinase level, which is subject to diverse influences and is not actively controlled, does not show a gaussian distribution, as evidenced by the lack of agreement between the range actually observed and that predicted by the mean value ±2 SD. In these cases, a reference interval defining the 2.5-97.5 percentiles is typically used.

Reference cutoffs are typically established from large studies with a large reference population. Examples of these cutoffs are illustrated by reference cutoffs established for cholesterol, lipoproteins, and neonatal bilirubin. Patient results exceeding these cutoffs have a future risk of acquiring disease. A final modification needed for reporting reference intervals is referencing the Tanner stage of sexual maturation, which is most useful in assessing pituitary and gonadal function.

The establishment of common reference intervals remains an elusive target. Although some patient results are directly comparable between laboratories and methods, most are not. Careful interpretation of patient results must consider when testing was performed and what method was used. Higher-order methods, methods that are more accurate and precise, continue to be slowly developed. These will be critical to the standardization of tests and the establishment of common reference intervals.

ACCURACY AND PRECISION OF LABORATORY TESTS

Technical accuracy, or trueness, is an important consideration in interpreting the results of a laboratory test. Because of improvements in methods of analysis and elimination of analytic interference, the accuracy of most tests is limited primarily by their precision. **Accuracy** is a measure of the nearness of a test result to the actual value, whereas **precision** is a measure of the reproducibility of a result. No test can be more accurate than it is precise. Analysis of precision by repetitive measurements of a single sample gives rise to a gaussian distribution with a mean and an SD. The estimate of precision is the coefficient of variation (CV):

$$CV = \frac{SD}{Mean} \times 100$$

The CV is not likely to be constant over the full range of values obtained in clinical testing, but it is approximately 5% in the normal range. The CV is generally not reported, but is always known by the laboratory. It is particularly important in assessing the significance of changes in laboratory results. For example, a common situation is the need to assess hepatotoxicity incurred as a result of the administration of a therapeutic drug and reflected in the serum alanine aminotransferase (ALT) value. If serum ALT increases from 25 units/L to 40 units/L, is the change significant? The CV for ALT is 7%. Using the value obtained ±2 × CV to express the extremes of imprecision, it can be seen that a value of 25 units/L is unlikely to reflect an actual concentration of >29 units/L, and a value of 40 units/L is unlikely to reflect an actual concentration of <34 units/L. Therefore, the change in the value as obtained by testing is likely to reflect a real change in circulating ALT levels. Continued monitoring of serum ALT is indicated, even though both values for ALT are within normal limits. *Likely* in this case is only a probability. Inherent biologic variability is such that the results of 2 successive tests may suggest a trend that will disappear on further testing.

The precision of a test may also be indicated by providing confidence limits for a given result. Ordinarily, 95% confidence limits are used, indicating that it is 95% certain that the value obtained lies between the 2 limits reported. Confidence limits are calculated using the mean and SD of replicate determinations:

$$95\% \text{ confidence limits} = Mean \pm t \times SD$$

where t is a constant derived from the number of replications. In most cases, $t = 2$.

Accuracy is expressed by determining the difference, or bias, between results from a comparative method and a definitive or reference method. A definitive or reference method provides results with increased precision and accuracy compared to the clinical laboratory. When these methods are used, along with highly purified materials (i.e., Standard Reference Materials from the National Institute of Standards and Technology) to establish values for assay calibrators used in the clinical laboratory, the accuracy of patient results is improved. Creatinine, hemoglobin A_{1c}, and neonatal bilirubin are examples in which the accuracy of these tests has been improved.

SENSITIVITY, ACCURACY, AND ANALYTIC TESTING

In some circumstances, the sensitivity and accuracy of an analysis are reduced or increased as functions of clinical purpose. For example, ion exchange chromatography of plasma amino acids for the diagnosis of inborn errors of metabolism is usually performed at an analytic sensitivity that allows measurement of all of the amino acids with a single set of standards. The range of values is approximately 20-800 µmol/L, and accuracy is poor at values ≤20 µmol/L. The detection of homocysteine in this type of analysis suggests an inborn error of methionine metabolism. If the analysis is adjusted to achieve greater analytic sensitivity, it is possible to measure homocysteine accurately in normal plasma (3-12 µmol/L). This more sensitive test is used to assess cobalamin status and analyze risk factors for atherosclerotic cardiovascular disease.

PREDICTIVE VALUE OF LABORATORY TESTS

Predictive value (PV) theory deals with the usefulness of tests as defined by their clinical sensitivity (ability to detect a disease) and specificity (ability to define the absence of a disease).

$$Sensitivity = \frac{\text{Number positive by test}}{\text{Total number positive}} \times 100$$

Table 726-1 Gaussian and Nongaussian Laboratory Values in 458 Normal School Children 7-14 Yr of Age

	SERUM SODIUM (mmol/L)	SERUM CREATINE KINASE (units/L)
Mean	141	68
SD	1.7	34
Mean ±2 SD	138-144	0-136
Actual 95% range	137-144	24-162

$$\text{Specificity} = \frac{\text{Number negative by test}}{\text{Total number without disease}} \times 100$$

$$\text{PV of a positive test result} = \frac{\text{True-positive results}}{\text{Total positive results}} \times 100$$

$$\text{PV of a negative test result} = \frac{\text{True-negative results}}{\text{Total negative results}} \times 100$$

The problems addressed by PV theory are false-negative and false-positive test results. Both are major considerations in interpreting the results of screening tests in general and neonatal screening tests in particular.

Testing for HIV seroreactivity illustrates some of these considerations. If it is assumed that approximately 1,100,000 of 284,000,000 residents of the United States are infected with HIV (prevalence = 0.39%) and that 90% of those infected demonstrate antibodies to HIV, then we can consider the usefulness of a simple test with 99% sensitivity and 99.5% specificity (see Chapter 276). If the entire population of the United States were screened, it would be possible to identify most of those infected with HIV.

$$1{,}100{,}000 \times 0.9 \times 0.99 = 980{,}100\ (89.1\%)$$

However, there will be 119,900 false-negative test results. Even with 99.5% specificity, the number of false-positive test results would be larger than the number of true-positive results:

$$284{,}000{,}000 \times 0.0005 = 1{,}420{,}000$$

In addition, there will be 281,480,000 true-negative results:

$$\text{PV of positive test result} = \frac{980{,}100}{(980{,}100 + 1{,}420{,}000)} \times 100 = 41\%$$

$$\text{PV of negative test result} = \frac{281{,}480{,}000}{(281{,}480{,}000 + 119{,}900)} \times 100 = 99.96\%$$

Given the high cost associated with follow-up and the anguish produced by a false-positive result, it is easy to see why universal screening for HIV seropositivity received a low priority immediately after the introduction of testing for HIV infection.

By contrast, we can consider the screening of 100,000 individuals from groups at increased risk for HIV in whom the overall prevalence of disease is 10%, with all other considerations being unchanged.

$$\text{True-positive results} = 0.9 \times 0.99 \times 10{,}000 = 8{,}910$$

$$\text{False-positive results} = 0.005 \times 90{,}000 = 450$$

$$\text{False-negative results} = 10{,}000 - 8{,}910 = 1{,}090$$

$$\text{PV of positive test result} = \frac{8{,}910}{8{,}910 + 450} \times 100 = 95\%$$

$$\text{PV of negative test result} = \frac{89{,}500}{89{,}550 + 1{,}090} \times 100 = 99\%$$

These 2 hypothetical testing strategies show that the diagnostic efficiency of testing depends heavily on the prevalence of the disease being tested for, even with a superior test, such as the test for HIV antibodies. Because the treatment of pregnant women infected with HIV is effective in preventing vertical transmission of the infection, screening has now been expanded to all pregnant women. The proven effectiveness of current therapy in preventing neonatal infection has intensified screening for HIV early in pregnancy.

However, because of the long time needed to test for HIV antibodies, it was difficult to screen women during labor and provide the necessary therapy. Recently, rapid HIV antibody testing procedures using a fingerstick or venipuncture to obtain whole blood, plasma, or serum, and tests using oral fluid were approved (Table 726-2). The HIV test results are usually obtained in <20 min. The collection of oral fluid samples provides an alternative for individuals who avoid HIV testing because of their dislike of needlesticks. HIV testing using whole blood or oral fluid is classified as a waived test under the **Clinical Laboratory Improvement Amendments of 1988,** and these tests are allowed in a point-of-care setting. Waived tests are simple laboratory procedures that use methodologies that are so simple and accurate as to render the likelihood of an erroneous result by the user negligible. A positive rapid HIV test result is then confirmed by Western blot analysis or immunofluorescence assay.

According to the U.S. Centers for Disease Control and Prevention, 162 infants were born with HIV in 2010 in the United States. Rapid HIV testing during labor allows for implementation of antiretroviral therapy for HIV-infected women who have not been tested or are unaware of their HIV status. The initiation of therapy at the time of labor or within the 1st 12 hr of an infant's birth significantly reduces the risk of mother-to-child transmission. In the mother–infant rapid intervention at delivery study, it was shown that the sensitivity and specificity of a rapid whole blood test for HIV during labor were 100% and 99.9%, respectively, with a positive PV of 90%. The median turnaround time for obtaining results from blood collection to patient notification was only 66 min. The performance of the rapid blood test was better than that of the standard HIV enzyme immunoassay, which had sensitivity and specificity of 100% and 99.8%, respectively, with a positive PV of 76%. In addition, the median turnaround time from blood collection to patient notification was 28 hr. As a result, rapid whole blood HIV testing is now the standard of care for women in labor with undocumented HIV status.

Rapid HIV testing can also be used in developing countries. In resource-poor settings, because of the lack of properly equipped laboratories, skilled technologists, and basic resources, such as electricity and water, these self-contained, point-of-care HIV tests are very attractive. In areas of Asia and Africa in which HIV is epidemic, screening pregnant women with rapid HIV tests and offering antiretroviral therapy can significantly reduce the transmission of HIV to hundreds of thousands of infants.

NEONATAL SCREENING TESTS

Almost all of the diseases detected in neonatal screening programs have a very low prevalence, and for the most part, the tests are quantitative rather than qualitative. In general, the strategy is to use the initial screening test to separate a highly suspect group of patients from normal infants (i.e., to increase the prevalence) and then to follow this suspect group aggressively. There are 2 common strategies used to detect congenital hypothyroidism (see Chapter 568.2): 1 uses thyroid-stimulating hormone for the initial screen and the other uses thyroxine. In the thyroxine strategy for congenital hypothyroidism, which has a prevalence of 25 in 100,000 liveborn infants, the initial test performed is for thyroxine in whole blood. Infants with the lowest 10% of test results are considered suspect. If all infants with hypothyroidism were included in the suspect group, the prevalence of disease in this group would be 250 in 100,000 infants. The original samples obtained from the suspect group are retested for thyroxine and are tested for thyroid-stimulating hormone. This second round of testing results in an even more highly suspect group composed of 0.1% of the infants screened and having a prevalence of hypothyroidism of 25,000

Table 726-2 Rapid HIV Antibody Tests and Status Under the Clinical Laboratory Improvement Amendments of 1988 (CLIA)

in 100,000 subjects. This final group is aggressively pursued for further testing and treatment. Even with a 1,000-fold increase in prevalence, 75% of the aggressively tested population is euthyroid. The justifications advanced for the program are that treatment is easy and effective and that the alternative, if congenital hypothyroidism is undetected and untreated—long-term custodial care—is both unsatisfactory and expensive.

At its inception, newborn screening was driven by the selection of genetic diseases whose clinical manifestations developed postnatally, such as phenylketonuria, galactosemia, and hypothyroidism. Diseases selected for screening typically had to meet certain criteria. The prevalence of disease had to meet a minimum, typically 1 in 100,000. Disease selection required demonstrated reduction in morbidity and mortality in the neonatal period. Effective therapies needed to be available, and the cost of screening and the feasibility of laboratory testing were also considerations in this selection process.

More common diseases have also become targets for neonatal screening programs. Sickle cell disease (see Chapter 462.1), easily detected using liquid chromatography or isoelectric focusing, can be treated more effectively if it is diagnosed before clinical signs appear. In addition, the results of neonatal screening for cystic fibrosis (CF; see Chapter 403) show that there are clear benefits associated with preclinical diagnosis, but also that there are some inherent difficulties associated with genetic screening for complex autosomal recessive diseases that are common and are caused by a rather large number of mutations (>1,500) of a single gene. The definitive diagnostic test for CF is the measurement of concentrations of chloride in sweat, a test that is not practical during the 1st wk of life. Neonates with CF generally have elevations in whole blood trypsinogen. This test allows the identification of a group of neonates at risk for CF. Unfortunately, trypsinogen as an initial screening test has a high false-positive rate, an unfavorable characteristic that creates unnecessary anxiety among newborn parents and families, and is costly because of the time and expense for medical follow-up. Performing DNA analysis for common mutations that cause CF reduces the size of the suspect group and identifies neonates with a higher likelihood of disease. This 2-tiered strategy identifies a manageable number of infants on whom to perform sweat tests. Problems include the following: (1) Uncommon mutations are not included in the screening panel (thus, cases of CF caused by these mutations can be missed); (2) common mutations that cause clinically innocent elevations of whole blood trypsinogen in heterozygous neonates cause potentially alarming false-positive findings; and (3) CF in patients with normal sweat test results is rare but is likely to be missed.

Tandem mass spectrometry (MS/MS) is a technically advanced method in which many compounds are initially fragmented and separated by molecular weight. Each compound is then fragmented again. Identification of compounds is based upon characteristic fragments. The process requires roughly 2 min per sample and can detect 20 or more inborn errors of metabolism. The effects of prematurity, neonatal illness, and intensive neonatal management on metabolites in blood complicate the interpretation of results. The PV of a positive screening result is likely to be <10%; that is, 90% of positive results are not indicative of a genetic disorder of metabolism. Nonetheless, MS/MS permits a diagnosis to be made before clinical illness develops and has revolutionized the purpose and ability of newborn screening. MS/MS is not directed toward diseases defined as treatable, but it is directed toward all of the diseases, each of which is rare, that the technique can identify.

Electrospray MS/MS permits the detection of rare inborn errors of metabolism and has been introduced as a newborn screening tool all around the world. Since 1998, when mass spectrometry was implemented in Australia, the rate of detection per 100,000 births has been 15.7, significantly higher than the rate of 8.6-9.5 in the 6 preceding 4 yr periods. Disorders of fatty acid oxidation, particularly medium-chain acyl coenzyme A dehydrogenase deficiency (see Chapter 86), accounted for the majority of increased diagnoses.

Table 726-3	American College of Medical Genetics Core Panel
Isovalericacidemia	
Glutaric aciduria type 1	
3-Hydroxy-3-methylglutaricaciduria	
Multiple coenzyme A (CoA) carboxylase deficiency	
Methylmalonic acidemia (mutase deficiency)	
3-Methylcrotonyl CoA carboxylase deficiency	
Methylmalonic acidemia (cobalamin [Cbl] A, B)	
Propionicacidemia	
β-Ketothiolase deficiency	
Medium-chain acyl-CoA dehydrogenase deficiency	
Very-long-chain acyl-CoA dehydrogenase deficiency	
Long-chain L-3-hydroxy acyl-CoA dehydrogenase deficiency	
Trifunctional protein deficiency	
Carnitine uptake deficiency	
Phenylketonuria	
Maple syrup urine disease	
Homocystinuria (because of cystathionine β-synthase deficiency)	
Citrullinemia	
Argininosuccinic acidemia	
Tyrosinemia type 1	
Sickle cell anemia (Hb SS disease)	
Hemoglobin (Hb) S/β-thalassemia	
Hb S/C disease	
Congenital hypothyroidism	
Biotinidase deficiency	
Congenital adrenal hyperplasia (21-hydroxylase deficiency)	
Classical galactosemia	
Hearing loss	
Cystic fibrosis	

Expanded newborn screening programs using MS/MS increase the detection of inherited metabolic disorders. All states in the United States use MS/MS in their neonatal screening programs. The metabolic conditions screened for by states using MS/MS vary, ranging from 31 to >50.

In an attempt to standardize newborn screening programs, the American College of Medical Genetics recommends that every baby born in the United States be screened for a core panel of 29 disorders (Table 726-3). An additional 25 conditions were recommended as secondary targets because they may be identified while screening for the core panel disorders. The March of Dimes and the American Academy of Pediatrics also endorse the recommendation by the American College of Medical Genetics. However, expansion of the screening test menu raises several issues. The cost of implementation can be significant because many states will need multiple MS/MS systems. Staffing the laboratory with qualified technical personnel to run the MS/MS system and qualified clinical scientists to interpret the profiles can be a challenge. A number of false-positive results will also be obtained with these newborn screening programs. Many of these findings are the result of parenteral nutrition, biologic variation, or treatment, and are not the result of an inborn error of metabolism. Consequently, qualified staff will be needed to ensure that patients with abnormal results are contacted and receive follow-up testing and counseling, if needed. Even with these concerns, the American College of Medical Genetics report is a step in the right direction toward standardizing guidelines for state newborn screening programs.

TESTING IN REFINING A DIFFERENTIAL DIAGNOSIS

The use of laboratory tests in refining a differential diagnosis satisfies PV theory because a correct differential diagnosis should result in a relatively high prevalence of the disease under consideration. An example of testing in refining a differential diagnosis is the measurement of urinary vanillylmandelic acid (VMA) for the diagnosis of neuroblastoma (see Chapter 498). A simple spot test for VMA is not useful in general screening programs because of the low prevalence of neuroblastoma (3 cases/100,000) and the low sensitivity of the test (69%). Even though the specificity of urinary VMA is 99.6%, testing of 100,000 children would produce 2 true-positive test results, 400 false-positive results, and 1 false-negative result. The PV of a positive result in this setting is 0.5%, and the PV of a negative result is 99.99%, not much different from the assumption that neuroblastoma is not present. Testing for urinary VMA in a 3 yr old child with an abdominal mass, however, gives a useful result because the prevalence of neuroblastoma is at least 50% in 3 yr old children with abdominal masses. If 100 such children are tested and the prevalence of neuroblastoma in the group is assumed to be 50%, then a satisfactory PV is obtained.

$$\text{PV of positive test result} = \frac{0.69 \times 50}{0.69 \times 50 + (0.004 \times 50)} \times 100 = 99\%$$

$$\text{PV of negative test result} = \frac{0.996 \times 50}{0.996 \times 50 + (0.31 \times 50)} \times 100 = 76\%$$

Thus, in this situation, a test with low sensitivity is powerful in refining the differential diagnosis because the PV of a positive result is almost 100% in the setting of high prevalence.

Serologic Testing

Using laboratory testing to refine a differential diagnosis poses problems, as exemplified by serologic testing for Lyme disease, which is a tick-borne infection by *Borrelia burgdorferi* that has various manifestations in both early and late stages of infection (see Chapter 222). Direct demonstration of the organism is difficult, and serologic test results for Lyme disease are not reliably positive in young patients presenting early with erythema chronicum migrans. These results become positive after a few weeks of infection and remain positive for a number of years. In an older population being evaluated for late-stage Lyme disease, some individuals will have recovered from either clinical or subclinical Lyme disease and some will have active Lyme disease, with both groups having true-positive serologic test results. Of individuals without Lyme disease, some will have true-negative serologic test results, but a significant percentage will have antibodies to other organisms that cross react with *B. burgdorferi* antigens.

This set of circumstances gives rise to a number of problems. First, the protean nature of Lyme disease makes it difficult to ensure a high prevalence of disease in subjects to be tested. Second, the most appropriate antibodies to be detected are imperfectly defined, leading to a wide variety of tests with varying false-positive and false-negative rates. Third, the natural history of the antibody response to infection and the difficulty of showing the causative organism directly combine to make laboratory diagnosis of early Lyme disease difficult. Fourth, in the diagnosis of late-stage Lyme disease in older subjects, the laboratory diagnosis is plagued by misleading positive (either false-positive or true-positive, but not clinically relevant) results, typically an enzyme-linked immunosorbent assay that uses whole *B. burgdorferi* organisms. In a review of 788 patients referred to a specialty clinic with the diagnosis of Lyme disease, the diagnosis was correct in 180 patients, 156 patients had true seropositivity without active Lyme disease, and 452 had never had Lyme disease, even though 45% of them were found to be seropositive by at least 1 test before referral.

A 2-step approach, similar to that used in HIV testing, is commonly used: a screening test that has high sensitivity (e.g., enzyme-linked immunosorbent assay) and excellent negative PV, followed by a very specific confirmatory test for verification of positive screening test results (e.g., Western blot to detect antibodies to selected bacterial antigens). Negative screening test results and negative verification test results are reported as negative. Positive verification test results are reported as positive. However, standardization of the testing procedures is difficult in North America, where only 1 pathogenic strain of *B. burgdorferi* is found, and is more difficult elsewhere in the Northern hemisphere, where as many as 3 pathogenic strains are present. Identification of microbial DNA in body fluids by polymerase chain reaction is definitive but invasive.

Table 726-4 Laboratory Profile as a Review of Systems

LABORATORY TEST	ASSESSMENT FACILITATED BY TESTS
Complete blood cell count and platelets	Nutrition, status of formed elements
Complete urinalysis	Renal function/genitourinary tract inflammation
Albumin and cholesterol	Nutrition
ALT, bilirubin, GGT	Liver function
BUN, creatinine	Renal function, nutrition
Sodium, potassium, chloride, bicarbonate	Electrolyte homeostasis
Calcium and phosphorus	Calcium homeostasis

ALT, alanine aminotransferase; BUN, blood urea nitrogen; GGT, γ-glutamyltransferase.

Laboratory Screening

Screening profiles (Table 726-4) are used as part of a complete review of systems, to establish a baseline value, or to facilitate patient care in specific circumstances, such as (1) when a patient clearly has an illness, but a specific diagnosis remains elusive; (2) when a patient requires intensive care; (3) for postmarketing surveillance and evaluation of a new drug; and (4) when a drug is used that is known to have systemic adverse effects. Laboratory screening tests should be used in a targeted manner to supplement, not supplant, a complete history and physical examination.

Chapter **727**

Reference Intervals for Laboratory Tests and Procedures

Stanley F. Lo

In Tables 727-1 through 727-5, the reference intervals apply to infants, children, and adolescents when possible. For many analyses, separate reference intervals for children and adolescents are not well delineated. When interpreting a test result, the reference interval supplied by the laboratory performing the test should always be used as these intervals are instrument and/or method dependent. Figures 727-1 and 727-2 provide estimations related to dosages. Figure 727-3 is a nomogram for risk assessment of hyperbilirubinemia.

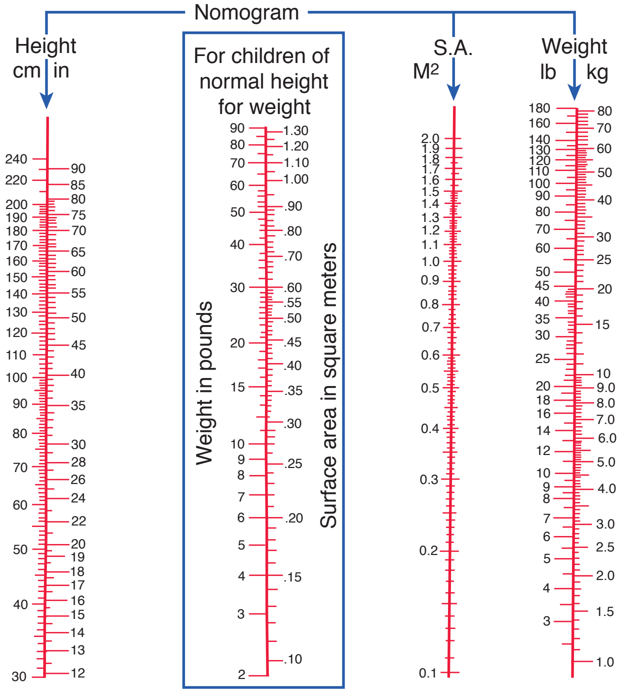
		3-30 days	5.0-15.0		64-193	
		31-365 days	6.0-14.0		77-180	
		1-5 yr	4.5-11.0		58-142	
		6-18 yr	4.5-10.0		58-129	
Thyroxine, free	S		ng/dL		pmol/L	
		0-3 days	2.00-5.00	×12.9	25.7-64.3	g (Dugaw, Jack, Rutledge, 2001)
		3-30 days	0.90-2.20		11.6-28.3	
		31 days-18 yr	0.7-2.00		9.0-25.7	
Thyroxine, total	W	Newborn screen (filter paper) 6.2-22.0 μg/dL		×12.9	80-283 nmol/L	
Triiodothyronine, free	S		pg/dL		pmol/L	
		Cord blood	20-240	×0.01536	0.3-3.7	
		1-3 days	200-610		3.1-9.4	
		6 wk	240-560		3.7-8.6	
		Adult (20-50 yr)	230-660		3.5-10.0	
Triiodothyronine resin uptake test (T3RU)	S				Fractional uptake	
		Newborn 26-36%		×0.01	0.26-0.36	
		Thereafter 26-35%			0.26-0.35	
Triiodothyronine, total	S		ng/dL		nmol/L	
		0-3 days	60-300	×0.0154	0.9-4.7	g (Dugaw, Jack, Rutledge, 2001)
		4-365 days	90-260		1.4-4.0	
		1-6 yr	90-240		1.4-3.7	
		7-11 yr	90-230		1.4-3.6	
		12-18 yr	100-210		1.5-3.3	
Urea nitrogen	S,P		mg/dL		mmol/L	
		Cord blood	21-40	×0.357	7.5-14.3	
		Premature (1 wk)	3-25		1.1-9.0	
		Newborn	3-12		1.1-4.3	
		infant or child	5-18		1.8-6.4	
		Thereafter	7-18		2.5-6.4	
Uric acid	S		mg/dL		μmol/L	
		1-3 yr	1.8-5.0	×59.48	100-300	(Lockitch, Halstead, Albersheim, et al, 1988)
		4-6 yr	2.2-4.7		130-280	
		7-9 yr	2.0-5.0		120-295	
		10-11 yr M	2.3-5.4		135-320	
		10-11 yr F	3.0-4.7		180-280	
		12-13 yr M	2.7-6.7		160-400	
		14-15 yr M	2.4-7.8		140-465	
		12-15 yr F	3.0-5.8		180-345	
		16-19 yr M	4.0-8.6		235-510	
		16-19 yr F	3.0-5.9		180-350	

*In preparing the reference range listings, a number of abbreviations, symbols, and codes were used (see Table 727-2).
†Reference values are shown in SI units (International System of Units) and US units (Traditional Units).]



Alternative (Mosteller's formula):

$$\text{Surface area (m}^2\text{)} = \sqrt{\frac{\text{Height (cm)} \times \text{Weight (kg)}}{3600}}$$

Figure 727-1 **Nomogram for the estimation of surface area.** The surface area is indicated where a straight line that connects the height and weight levels intersects the surface area column, or if the patient is roughly of average size, from the weight alone *(enclosed area). (Nomogram modified from the data of E. Boyd by C.D. West. See also Briars GL, Bailey BJ: Surface area estimation: pocket calculator v nomogram,* Arch Dis Child *70:246–247, 1994.)*

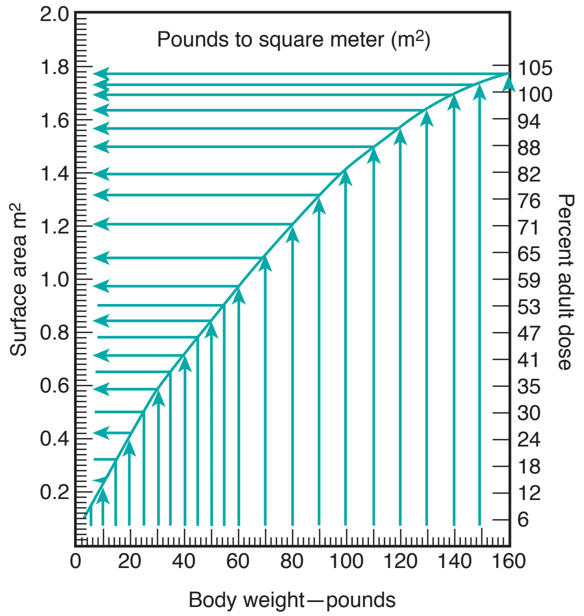


Figure 727-2 **Relationships among body weight (lb), body surface area, and adult dosage.** The surface area values correspond with those set forth by Crawford JD, Terry ME, Rourke GM: Simplification of drug dosage calculation by application of the surface area principle, *Pediatrics* 5:783–790, 1950. Note that the 100% adult dose is for a patient weighing approximately 140 lb and having a surface area of approximately 1.7 m^2. *(From Talbot NB, Richie RH, Crawford JH:* Metabolic homeostasis: a syllabus for those concerned with the care of patients, *Cambridge, MA, 1959, Harvard University Press.)*

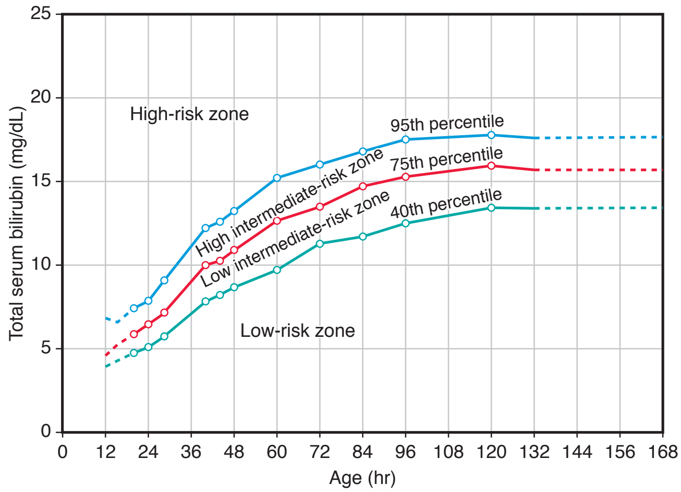

Figure 727-3 Nomogram for risk assessment of hyperbilirubinemia. *(From Bhutani VK, Johnson L, Sivieri EM: Predictive ability of a predischarge hour-specific serum bilirubin for subsequent significant hyperbilirubinemia in healthy term and near-term newborns,* Pediatrics *103:6–14, 1999, Fig. 2, p. 9.)*
